Food insecurity — the unreliable access to sufficient quantities of affordable, nutritious food — is a serious public health concern in Canada. PROOF (Food Insecurity Policy Research) reported that 12% of Canadian households faced some level of food insecurity in 2014. In adults, food insecurity has been associated with poor physical and mental health, including chronic health conditions like diabetes and depression, and an increased rate of hospital admissions. Households with children have a greater risk for food insecurity; one in six Canadian children faced household food insecurity in 2014. Inadequate quality and quantity of food is associated with adverse outcomes in children. Children living in families that report food insecurity have reduced healthy food intake and lower academic outcomes, as well as higher rates of asthma, obesity, depression and anxiety.

In a linked study, Orr and colleagues report on the association of household food insecurity and breastfeeding initiation, the duration of exclusive breastfeeding and vitamin D supplementation of women who participated in the Canadian Community Health Survey (2005–2014).

Interestingly, the authors did not identify an association between food insecurity and the initiation of breastfeeding and the supplementation of vitamin D. A strength of the study is that the authors adjusted their analysis for important sociodemographic factors associated with breastfeeding, including education, partnership status, immigrant status, household income, Aboriginal identity and maternal health factors related to breastfeeding (mood disorders and diabetes). However, they did not include general ethnocultural identity in their analysis. Rates of breastfeeding initiation are strongly influenced by social and ethnocultural factors. In Canada, according to the 2009–2010 Community Health Survey, significantly more mothers who were of self-identified Asian (93.5%) or black (93.9%) background began breastfeeding than mothers who self-identified as white (86.7%). To explore the association between breastfeeding initiation and food insecurity in more detail, future studies should explore ethnocultural factors.

The linked study did show an association between food insecurity and the duration of exclusive breastfeeding. Almost half of women in food-insecure households had ceased exclusive breastfeeding after two months, whereas half of the women in food-secure households breastfed exclusively for at least four months. Exclusive breastfeeding rates are low in Canada. In 2009–2010, only 25.9% of mothers breastfed exclusively for the recommended six months. This rate was even lower in women in food-insecure households (20.7% in the marginally food-insecure group, 16.7% in the moderately insecure group and 15.7% in the severely food-insecure group). Surprisingly, only the women in the moderately food-insecure group had a significant risk of early cessation of exclusive breastfeeding (before six months) compared with mothers in food-secure households in the adjusted analysis. This may be explained by the relatively small number of women in the severely food-insecure group in the study, as acknowledged by the authors.

Another important confounder for both food insecurity and duration of breastfeeding is maternal employment. In the United States, early cessation of breastfeeding is associated with non-managerial employment and a lack of job flexibility. In the 2009–2010 Canadian Health Survey, 9% of women identified the need to return to employment as a reason to stop breastfeeding. Therefore, an alternative explanation for the nonsignificant association between women in the marginally and severely food-insecure groups and the duration of breastfeeding could also be explained by a difference in employment status. Other unmeasured sociobiological factors — such as comorbid medical or mental health problems, use of medications or maternal weight status — could also explain the association.

Despite these limitations, and those raised by the authors, the current study provides an important contribution to the literature on food insecurity and key maternal and child health outcomes. It is alarming that “women who can least afford to buy...
infant formula and whose babies can benefit most from the health-promoting qualities of breast milk are the least likely to breastfeed.11,12 Many social, emotional and cultural barriers undermine breastfeeding, and for many women, exclusive breastfeeding is not feasible.11 However, the literature does not provide us with an answer about why women in food-insecure households in Canada stop exclusive breastfeeding early. A better understanding about the biopsychosocial determinants of breastfeeding in this vulnerable population is necessary to develop effective interventions.

Canada’s policy relating to infant food security focuses mainly on promoting breastfeeding as the pathway to infant food security. Relying on promoting breastfeeding alone to address nutrition in vulnerable children is inadequate.11 In contrast to the US, where the Women, Infants and Children program provides food supplementation to infants and children, there is no national feeding program for infants and children in Canada. When Canadian mothers who report food insecurity require nutritional supplementation for their infants, they are left to rely on local food banks to obtain formula. The local policies of these food banks vary with respect to formula provisioning, likely resulting in differing access to appropriate nutrition for infants.31 Other options for nutritional supplementation to breastfeeding may include access to donor breast milk; however, this is limited in Canada. Intensifying public policy to ensure optimal nutrition during sensitive periods of early child development is essential to improve child health outcomes.12

Measures to increase household income comprise a promising strategy to promote food security. A recent randomized clinical trial showed that in the United Kingdom, financial incentives improved breastfeeding rates in areas with low breastfeeding prevalence.13 In Canada, the recent introduction of the nationwide Canada Child Benefit might have an important impact on household food insecurity. However, a rigorous evaluation of this income support program is needed, with specific focus on maternal and child health outcomes, to answer key questions; for example, “Will mothers who report food insecurity have equitable access to these benefits?” To improve outcomes for food-insecure families, policy-makers must evaluate the Canada Child Benefit program by examining child and family health outcomes, and providers of child health, researchers and tax-payers must ensure that policy-makers do so.
