Abstract

In subfamily Salsoloideae (family Chenopodiaceae) most species are C₄ plants having terete leaves with Salsoloid Kranz anatomy characterized by a continuous dual chlorenchyma layer of Kranz cells (KCs) and mesophyll (M) cells, surrounding water storage and vascular tissue. From section Cocosalsola sensu Botschantzev, leaf structural and photosynthetic features were analysed on selected species of Salsola which are not performing C₄ based on leaf carbon isotope composition. The results infer the following progression in distinct functional and structural forms from C₃ to intermediate to C₄ photosynthesis with increased leaf succulence without changes in vein density: From species performing C₃ photosynthesis with Sympegmoid anatomy with two equivalent layers of elongated M cells, with few organelles in a discontinuous layer of bundle sheath (BS) cells (S. genistoides, S. masenderanica, S. webbii) > development of proto-Kranz BS cells having mitochondria in a centripetal position and increased chloroplast number (S. montana) > functional C₃–C₄ intermediates having intermediate CO₂ compensation points with refixation of photorespired CO₂, development of Kranz-like anatomy with reduction in the outer M cell layer to hypodermal-like cells, and increased specialization (but not size) of a Kranz-like inner layer of cells with increased cell wall thickness, organelle number, and selective expression of mitochondrial glycine decarboxylase (Kranz-like Sympegmoid, S. arbusculiformis; and Kranz-like Salsoloid, S. divaricata) > selective expression of enzymes between the two cell types for performing C₄ with Salsoloid-type anatomy. Phylogenetic analysis of tribe Salsoleae shows the occurrence of C₃ and intermediates in several clades, and lineages of interest for studying different forms of anatomy.

Key words: C₃ plants, C₃–C₄ intermediate, C₄ plants, Chenopodiaceae, immunolocalization, leaf anatomy, photosynthetic enzymes, Salsola divaricata, Salsola genistoides, Salsola masenderanica, Salsola montana, Salsola webbii.

Introduction

Among eudicot families, it is well established that family Chenopodiaceae has the largest number of C₄ species (Akhani et al., 1997; Kadereit and Freitag, 2011; Sage et al., 2012), and also the greatest diversity in C₄-type leaf anatomy, with eight main structural types (Carolin et al., 1975; Edwards and Voznesenskaya, 2011), and up to 16 forms considering all
differences (Kadereit et al., 2003). This includes the occurrence of Kranz anatomy around individual veins as well as Kranz anatomy with a concentric dual layer of cells surrounding all the veins in the leaf, and two structural forms of C_4 occurring in individual cells without Kranz anatomy. Currently, 10 C_4 lineages have been recognized in Chenopodiaceae (Kadereit and Freitag, 2011; Sage et al., 2012).

C_3–C_4 intermediates are important in studying the evolution of C_4 photosynthesis. They have been identified in 14 families: Amaranthaceae, Asteraceae, Boraginaceae, Brassicaceae, Chenopodiaceae, Cleomaceae, Euphorbiaceae, Molluginaceae, Nyctaginaceae, Portulacaceae, Cyperaceae, Hydrocharitaceae, Scrophulariaceae, and Poaceae (Sage et al., 2011; Khoshravesh et al., 2012). However, despite the diversity of C_3 in family Chenopodiaceae, to date only one species, *Salsola arbusculiformis* in subfamily Salsoloideae, has been structurally and functionally characterized to be a C_3–C_4 intermediate (Voznesenskaya et al., 2001). Another species, *Sedobassia sedoides* in subfamily Camphorosmoideae, was recently suggested to be an intermediate based on anatomical features (Kadereit and Freitag, 2011); and shown to function as an intermediate based on gas exchange analysis and immunolocalization of glycine decarboxylase (GDC) (NKK, EVV, and GEE, unpublished data).

In Chenopodiaceae, most species which have been analysed in subfamily Salsoloideae have C_4-type photosynthesis and Kranz anatomy (Zalenskii and Glagoleva, 1981; Pyankov and Vakhruhseva, 1989; Pyankov et al., 1999, 2000, 2001a, 2002). Most representatives of the genus *Salsola* sensu lato (s.l.) are C_4 plants with the so-called Salsolid (Carolin et al., 1975) or ‘crown-centric’ (Voznesenskaya and Gamaley, 1986; Edwards and Voznesenskaya, 2011) type of Kranz leaf anatomy with two layers of chlorophylla on the leaf periphery. The outer layer of chlorophylla is represented by elongated palisade mesophyll (M) cells and the inner layer consists of roundish specialized Kranz cells (KCs). The main vascular bundle is in the centre of the leaf surrounded by the water storage (WS) tissue, and only small, peripheral bundles have contact with chlorophylla. In this anatomical type, peripheral bundles have their xylem part facing towards the outer chlorophylla layers (see Edwards and Voznesenskaya, 2011). Also, there are two groups of species in tribe Salsoleae and within the genus *Salsola* s.l., one group lacking and the other group having hypodermal tissue (a subepidermal layer of roundish parenchyma cells which participates in water storage and has a lower number of organelles compared with M cells). C_3 species from sections *Caroxylon* and *Coccosalsola* have a hypoderm, but the hypoderm is absent in species from sections *Malpighipila*, *Cardiumbra*, *Belanthera*, and *Salsola* (Pyankov et al., 2001a). Molecular phylogenetic analyses suggest that the traditionally recognized sections of *Salsala* are not monophyletic; a revised, clade-based classification has recently reorganized sectional and generic boundaries (Akhani et al., 2007).

Studies on C_4 photosynthesis have been largely focused on species which form Kranz anatomy with two chlorophylla layers surrounding each vein (called a multiple simple Kranz unit by Peter and Katinas, 2003), as occurs in C_4 monocots and numerous C_4 eudicot species. However, among C_4 eudicots, there are nine types of Kranz anatomy with two concentric chlorophylla layers surrounding all veins (single compound Kranz unit according to Peter and Katinas, 2003); see Edwards and Voznesenskaya (2011). Among these is the Salsolid type of anatomy which is characteristic for C_4 species in subfamily Salsoloideae. Current, commonly used structural descriptions of the dual layer of cells forming Kranz anatomy refer to the outer layer as M cells (usually consisting of palisade parenchyma) and the inner layer as specialized bundle sheath (BS) cells (referring to a layer of cells in leaves of plants which surrounds the vascular tissue). However, in C_4 species such as the Salsolid type, the inner chlorophylla layer does not form a real sheath around individual peripheral veins, but rather a sheath which encloses the veins and WS tissue. Thus, here the inner layer of chlorophylla cells which are specialized for C_4 photosynthesis is referred to as the KC layer (Edwards and Voznesenskaya, 2011). All structural forms of Kranz have in common a double concentric layer of chlorophylla cells with the outer layer of palisade M capturing atmospheric CO_2 in the C_4 cycle, and the inner layer (BS cells or KCS) donating CO_2 from C_4 acids to Rubisco in the C_4 cycle.

It is also known that some species in genus *Salsola* s.l. have a different type of leaf anatomy, with multiple layers of chlorophylla and, adjacent to veins, indistinctive BS cells with few chloroplasts. This type, described by Carolin et al. (1975) in *Salsola webbii* and in the genus *Sympegma*, was designated ‘Sympegmoid’, and defined as having non-Kranz-type anatomy. Analysis of the carbon isotope composition (δ^{13}C) of plant biomass showed that *S. webbii* has C_3-type values (Akhani et al., 1997; Winter, 1981). To date, several species in the genus *Salsola* have been identified as having this C_3-like leaf anatomy and/or C_3-type δ^{13}C: namely, *A. abrotanoides* (Pyankov et al., 2001b), *S. sotschantzevii* (Pyankov et al., 2001b), *S. divaricata* (Pyankov et al., 2001b), *S. genistoides* (Voznesenskaya, 1976; Akhani et al., 1997; Pyankov et al., 2001b), *S. drobovii* (Butnik, 1984; Pyankov et al., 2001b), *S. loricifolia* (Wen and Zhang, 2011), *S. masanderica* (Pyankov et al., 2001a), *S. montana* (Akhani et al., 1997; Akhani and Ghasemkhani, 2007), *S. oreophila* (Pyankov et al., 1997), *S. pachyphylla* (Butnik, 1984), *S. tianshanica* (Pyankov et al., 2001b), and *S. webbii* (Carolin et al., 1975; Winter, 1981; Akhani et al., 1997; Pyankov et al., 2001b).

*Salsola arbusculiformis* has C_4-type carbon isotope composition (Akhani et al., 1997; Akhani and Ghasemkhani, 2007) and intermediate anatomy with Kranz-like BS cells around the veins (Pyankov et al., 1997; Voznesenskaya et al., 2001). According to Botschantzev (1969, 1976, 1985, 1989), all of them belong to section *Coccosalsola* in genus *Salsola* and were classified in the following subsections: *Genistoides* (Akhani et al., 2007) showed that section *Coccosalsola* is polyphyletic and rearranged the species of this group in the clade-based genera.

Further examination of the inter-relationships between structure and biochemistry in *Salsola* species having Sympegmoid leaf structure showed that *S. oreophila*, a close
relative of S. montana, has C₃-type δ¹³C values and low activity of C₄ enzymes (Pyankov et al., 1997). It also has 2–3 layers of M and thin-walled BS cells with sparse chloroplasts distributed usually in the centrifugal position; thus, all structural features in this species are C₃ like. In contrast, S. arbusculiformis was suggested to be a C₃–C₄ intermediate. Although it usually has two layers of M cells, its BS was found to be Kranz like, containing rather numerous chloroplasts in the centripetal position, and the walls of these cells were thinner than in the M (Pyankov et al., 1997). A detailed study of the anatomy, biochemistry, and physiology of this species showed that it is a C₃–C₄ intermediate (Voznesenskaya et al., 2001). It has an intermediate-type photosynthetic CO₂ response curve with a CO₂ compensation point (Γ) midway between characteristic of C₃ and C₄ species. Photorespiration was shown to be reduced by exclusive localization of GDC to BS mitochondria (a diagnostic feature of all intermediates and C₄ plants) which allows the photorespired CO₂ to be partially refixed. It is classified as a type I intermediate as it lacks a partially functional C₄ cycle (see Edwards and Ku, 1987).

In the present study, the carbon isotope composition was analysed for all species of polyphylectic section Coccosalsola (recorded by Botschantzev, 1976, 1989), including S. botschantzevii (Botschantzev et al., 1983) and S. drummondii (Freitag and Rilke, 1997), of which a large number have C₄-type values (approximately half of the 36 species). A comprehensive anatomical and physiological characterization was performed for five Salsola species in the section having C₄-type δ¹³C values: S. divaricata, S. genistoides, S. masenderanica, S. montana, and S. webbii, and the results were analysed relative to two C₄ species, Caroxylon orientale (= Salsola orientalis) and Xylosalsola richteri (= S. richteri). The results show that section Coccosalsola, which does not form a monophyletic group relative to other sections of Salsola and other genera of the Salsoleae (Akhani et al., 2007), has large diversity in forms of photosynthesis. Species in tribe Salsoleae are of interest for studying the evolution of a form of C₄ anatomy where a single, continuous layer of Kranz tissue surrounds the veins and WS cells, as opposed to the occurrence of Kranz anatomy around individual veins. Differences in structural and functional traits were identified which suggest how Salsoloid-type C₄ photosynthesis evolved from C₃ ancestors.

Materials and methods

Plant material

Seeds of S. divaricata Masson ex Link were collected in the Canary Islands (Canaria, western coasts, near Agaete, 23.9.2002, H. Akhani 16469), while seeds of S. masenderanica Botsch. were collected from N Iran (Mazandaran, 169 km to Tehran, 5 km after Veresk towards Amol, 1201 m, 16.10.2003, H. Akhani 17403) and seeds of S. montana Litv. were collected from NE Iran (Golestan, southern parts of Golestan National Park, near Sharlegh, 15.10.2003, H. Akhani 17391). Voucher specimens are available in the Halophytes and C₄ Plants Research Laboratory, School of Biology, University of Tehran (Hb. Akhani). Seeds of S. webbii Moq. and S. genistoides Juss. ex Poir. were provided via Jeromi Galmes from the Germplasm Collection of the University of Almeria (GERMUAL), research group RNM-344, and Forestaria SL (see Supplementary Appendix S1 available at JXB online for GenBank accession numbers for new sequence information on these two species and voucher numbers of specimens in the WSU Herbarium). Seeds of Xylosalsola richteri (Moq.) Akhani & E. H. Roalson (=Salsola richteri Moq.) and Caroxylon orientale (S.G. Gmel.) Tzvelev (=Salsola orientalis S.G. Gmel.) were collected in deserts of Central Asia in Uzbekistan. Seeds were stored at –18 °C before germination. They were germinated on moist paper at room temperature and then transplanted to soil. For studies on light and electron microscopy, polysaccharide content, enzyme content, and gas exchange, all plants were grown under the same conditions (in Enconair Ecological chambers, model GC-16) under a photosynthetic photon flux density (PPFD) of ~400 μmol quanta m⁻² s⁻¹ with a 14h/10h light/dark photoperiod and 25/18 °C day/night temperature regime. Figure 1 shows the appearance of the plants during growth in the WSU chambers (Fig. 1A, D, G, J, M) and their branches (Fig. 1B, E, H, K, N), and the fruiting branches of the plants grown in nature (Fig. 1C, F, I, L, O). All species have terete succulent leaves. In S. masenderanica, S. montana, S. webbii, and S. divaricata, young plants and vegetative branches have rather long leaves (up to 2–2.5 cm) (Fig. 1E, H, N) compared with shorter leaves (up to 1 cm) in growth chamber-grown plants of S. genistoides beginning from the early stages of seedling growth (Fig. 1A, B). Leaves were sampled from plants of different ages, from 6 week up to 2 years old. Samples of fully expanded leaves were taken from recently developed vegetative branches at the same time for determination of enzyme content and for light and electron microscopy. For most species, samples were taken from at least two or three individual plants. For comparison, two C₄ Salsola s.l. species, which represent two biochemical subtypes in Salsolidaeae, were analysed, X. richteri, an NADP-malic enzyme (NADP-ME) species, and C. orientale, an NAD–ME species.

Light and electron microscopy

Samples for ultrastructural characterization were fixed overnight at 4 °C in 2% (v/v) paraformaldehyde and 2 % (v/v) glutaraldehyde in 0.1 M phosphate buffer (pH 7.2), post-fixed in 2% (w/v) OsO₄, and then, after a standard acetone dehydration procedure, embedded in Spurr’s resin. Cross-sections were made on a Reichert Ultracut R ultramicrotome (Reichert-Jung GmbH, Heidelberg, Germany). For light microscopy, semi-thin sections were stained with 1% (w/v) Toluidine blue O in 1% (w/v) Na₂B₄O₇, and studied with 2% (w/v) uranyl acetate followed by 2% (w/v) lead citrate. Hitachi H-600 (Hitachi Scientific Instruments, Tokyo, Japan), JEOL JEM-1200 EX (JEOL USA, Inc., MA, USA) with MegaView III Camera and Soft Imaging System Corp. (Lakewood, CO, USA) and FEI Tecnai G2 (Field Emission Instruments Company, Hillsboro, OR, USA) equipped with Eagle FP 5271/82 4K HR200KV digital camera transmission electron microscopes were used for observation and photography. For quantitative characterization of leaf tissues, cells, and organelles, the image analysis program ImageJ 1.37v (Wayne Rasband, National Institutes of Health, USA) was used. The sizes of the cells and areas of the tissues in the leaves were measured on light microscopy images of leaf cross-sections. The volume density of each tissue of interest was estimated from the ratio of the area of the tissue to the total leaf area (expressed as a percentage). The thickness of cell walls (CWs) and the size of mitochondria were measured on electron microscopy images from leaf cross-sections. The small diameters of mitochondria were measured on profiles from cross-sections. As was previously noted in quantitative studies, only the small diameter reflects the difference in size between different tissues or species since measurements of elongation are more variable as very elongated mitochondria are occasionally observed in microscopy sections (see Voznesenskaya et al., 2007). For all measurements, 15–25 micrographs were used for analysis from at least 2–3 different leaves.
To observe the pattern of leaf venation, leaves were cleared in 70% ethanol (v/v) until chlorophyll was removed, bleached with 5% (w/v) NaOH overnight, and then rinsed three times in water. At least three leaves from two different plants were used. The pattern and density (per mm² of the leaf surface area) of the peripheral venation were determined using hand-made paradermal sections. The leaf samples were mounted in water and examined under UV light [with a 4′,6-diamidino-2-phenylindole (DAPI) filter] on a Leica DMFSA fluorescence microscope (Leica Microsystems Wetzlar GmbH, Germany).

In situ immunolocalization
Leaf samples were fixed at 4 °C in 2% (v/v) paraformaldehyde and 1.25% (v/v) glutaraldehyde in 0.05 M PIPES buffer, pH 7.2 early in the morning. The samples were dehydrated with a graded ethanol series and embedded in London Resin White (LR White, Electron Microscopy Sciences, Fort Washington, PA, USA) acrylic resin. The antibody used (raised in rabbit) was against the P subunit of GDC from *Pisum sativum* L. (courtesy of D. Oliver). Pre-immune serum was used for controls.

For transmission electron microscopy (TEM) immunolabelling, thin sections on formvar-coated nickel grids were incubated for 1 h in TRIS-buffered saline–Tween (TBST)+bovine serum albumin (BSA) to block non-specific protein binding on the sections. They were then incubated for 3 h with either the pre-immune serum diluted in TBST+BSA (1:50) or anti-P protein of GDC (1:10) antibody. After washing with TBST+BSA, the sections were incubated for 1 h with protein A–gold (15 nm) diluted 1:100 with TBST+BSA. The sections were washed sequentially with TBST+BSA, TBST, and distilled water, and then post-stained with a 1:4 dilution of 1% (w/v) potassium permanganate and 2% (w/v) uranyl acetate. Images were collected using JEOL JEM-1200 EX and FEI Tecnai G2 transmission electron microscopes. The density of labelling was determined by counting the gold particles on electron micrographs and calculating the number per unit area (μm²) with an image analysis program (ImageJ 1.37v). For each cell type, replicate measurements were made on parts of cell sections (n=10–15). Immunolabelling procedures were performed separately for different species; the difference in the labelling intensity reflects the difference between cell types but not between species. The level of background labelling was low in all cases.

Staining for polysaccharides
To reveal the localization of starch, the leaf samples were fixed in the same way as for immunolocalization, but after 15:00h. The periodic acid–Schiff’s procedure was used for staining starch in sectioned materials. Sections, 0.8–1 μm thick, were dried onto gelatin-coated slides, incubated in 1% (w/v) periodic acid for 30 min, washed, dried, and then incubated with Schiff’s reagent (Sigma, St Louis, MO,
USA) for 1 h. After rinsing, the sections were ready for analysis by light microscopy. Cell walls and starch stained bright red but pink, while other elements of the cells (cytoplasm) remained unstained. Controls lacking the periodic acid treatment (required for oxidation of the polysaccharides giving rise to Schiff’s-reactive groups) showed little or no background staining (not shown).

Western blot analysis
Total soluble proteins were extracted from leaves by homogenizing 0.2 g of tissue in 0.2 ml of extraction buffer (100 mM TRIS-HCl, pH 7.5, 10 mM (w/v) MgCl₂, 1 mM (w/v) EDTA, 15 mM (v/v) β-mercaptoethanol, 20% (v/v) glycerol, and 1 mM phenylmethylsulfonyl fluoride). Insoluble material was removed by centrifugation (5 min, 14,000 g). The supernatant fraction was diluted 1:1 in 60 mM TRIS-HCl, pH 7.5, 4% (w/v) SDS, 20% (v/v) glycerol, 1% (v/v) β-mercaptoethanol, and 0.1% (w/v) bromophenol blue, and boiled for 5 min for SDS-PAGE. Protein concentration was determined with an RCDC protein quantitation kit (Bio-Rad), which tolerates detergents and reducing agents. Protein samples (20 μg) were separated by 12% SDS-PAGE, blotted onto nitrocellulose, and probed overnight at 4 °C with anti-Z. mays 62 kDa NADP-ME IgG, courtesy of C. Andreo (Maurino et al., 2006) (1:5000), anti-Z. mays pyruvate,PDH kinase IgG, courtesy of T. Sugiyama (1:5000), and anti-Spinacia oleracea (PEPC) IgG (1:100 000), anti-Z. mays α-amylase, courtesy of J. Berry (Long and Berry, 1996) (1:5000), anti-Z. mays phosphoenolpyruvate carboxylase (PEPC) IgG, courtesy of T. Sugiyama (1:10 000). Goat anti-rabbit IgG–alkaline phosphatase conjugate antibody (Sigma Chemical Co.) was used at a dilution of 1:5 000 for detection. Bound antibodies were localized by developing the blots with 20 mM nitroblue tetrazolium and 75 mM 5-bromo-4-chloro-3-indolyl phosphate in detection buffer (100 mM TRIS-HCl, pH 9.5, 100 mM NaCl, and 5 mM MgCl₂). 

CO₂ compensation point (Γ) and photosynthetic CO₂ response
For measurement of the response of photosynthesis to varying light and CO₂, and for determining the CO₂ compensation point (Γ), gas exchange was measured with a portable CO₂ analyser ADC LCPro+ (ADC BioScientific Ltd., Hoddesdon, UK). For each experiment, part of a branch of an intact plant was enclosed in the confiler chamber designed for terete or semi-terete leaves. The branch was illuminated with a PPFD of 920 μmol quanta m⁻² s⁻¹ under 370 μbar CO₂ until a steady-state rate of CO₂ fixation was obtained (generally 45–60 min). The air temperature was 25 ± 0.5 °C, the leaf temperature 27.2 ± 0.2 °C, the minimum percentage humidity in the chamber was 38 ± 1.5%, and the flow rate was 200 μmol s⁻¹. For varying light experiments at 370 μbar CO₂, measurements were made beginning at a PPFD of 1380, with decreasing levels at 4 min intervals. For varying CO₂ experiments at a PPFD of 920, the CO₂ level was first decreased, and then increased up to 1000 μmol mol⁻¹ at 7 min intervals. Γ was determined at a PPFD of 920 and 25°C by extrapolation of the initial slope of rates of CO₂ fixation (A) versus the intercellular CO₂ concentration in the leaf (C) through the x-axis where the net rate of CO₂ assimilation equals zero.

The leaf area exposed to incident light was calculated by taking a digital image of the part of the branch that was enclosed in the chamber, and then determining the exposed leaf area using an image analysis program (ImageJ 1.37v).

δ¹³C values
Measurements of the carbon isotope composition were determined at Washington State University on plant samples using a standard procedure relative to PDB (Pee Dee Belemnite) limestone as the carbon isotope standard (Bender et al., 1973). Leaf samples (from plants growing in the WSU School of Biological Sciences growth chamber) were dried at 60 °C for 24 h, milled to a fine powder, and then 1–2 mg were placed in a tin capsule and combusted in a Eurovector elemental analyser. The resulting N₂ and CO₂ gases were separated by gas chromatography and admitted into the inlet of a Micromass Isoprime isotope ratio mass spectrometer (IRMS) for determination of ¹³C/¹²C ratios (R). δ¹³C values were determined where δ=1000×(Rsample/Rstandard)−1.

Phylogenetic analysis
Samples of S. webbii and S. genistoides were added to previously published data sets (Akhani et al., 2007; Wen et al., 2010) for the nuclear ribosomal DNA internal transcribed spacer region (ITS); samples utilized in the analysis are listed in Supplementary Appendix S1 at JXB online. The sequences were aligned using MUSCLE (Edgar, 2004). The aligned matrix of 110 samples and 724 aligned bases was analysed using RAxML (Stamatakis et al., 2008) with the GTR gamma model. Nine species of tribe Caroxyloneae were used as the outgroup based on previous studies (Akhani et al., 2007).

Results
General leaf anatomy and starch content
Leaf anatomy was studied in five Salsola species, formerly classified under section Cocosalsola, but representing different clades of Salsoleae and which were previously identified as having C₃-type carbon isotope composition: S. divaricata, S. genistoides, S. masenderanica, S. montana, and S. webbii. Figure 2 shows the leaf structure and the distribution of chlorophyll in four species (S. genistoides not shown; its general features are very similar to those of S. webbii). Under the fluorescent microscope (Fig. 2A–D), there is red fluorescence from the chloroplast-containing tissues and blue fluorescence from all CWs, especially from the WS tissue (the blue fluorescence is typical of species of family Chenopodiaceae due to the presence of ferulic acid in the CWs; Voznesenskaya et al., 2008). There are usually two (or 2–3) layers of palisade-like chlorophyll (which will subsequently be referred to as M) cells directly beneath the epidermis: the outer subepidermal layer (M1) and the inner layer (M2) (Fig. 2E–H). There is an often indistinct layer of relatively small BS cells around the peripheral vascular bundles in S. masenderanica, S. montana, and S. webbii (Fig. 2F–G), and S. genistoides (not shown); however, there is a continuous layer of Kranz-like cells (KLCs), internal to the M cells around the whole leaf in S. divaricata (Fig. 2H). There is WS tissue in the centre of the leaves of all species which consists of 2–4 layers of cells with some differences in size and shape (Fig. 2A–G). The peripheral vascular bundles are situated under the chlorophyll cells with their xylem side facing towards the outside of the leaf. The main vein is located more or less in the centre of the leaf and surrounded by the WS tissue. A quantitative study of leaf chlorophyll showed that in four of the Salsola species (S. genistoides, S. masenderanica, S. montana, and S. webbii) the cells of the outer (M1) and inner (M2) layers of the palisade M have nearly equal length (mean values of 104 μm for M1 and 118 μm for M2, see Supplementary Table S1 at JXB online). In S. masenderanica, sometimes there are a few extremely elongated palisade parenchyma cells extending through both layers of M cells (not shown). In contrast to the above species, in S. divaricata...
the layer of M1 cells is much thinner than the layer of M2 cells, with a ratio of M1/M2 cell length of 0.5 similar to the hypoderm/M ratio of the two C4 species (Supplementary Table S1). Compared with the M2 layer, the cells of the outer M1 layer of \textit{S. divaricata} have few chloroplasts and appear more like hypodermal cells (Fig. 2H, L) which occur in some C4 \textit{Salsola} species. The arrangement of chlorenchyma cells in the leaf also differs between the species studied. The BS cells surrounding the peripheral vascular bundles in \textit{S. genistoides} and \textit{S. webbii} are not specialized and sometimes they resemble the cells of the inner layer of M or the outer layer of WS tissue, which explains why there is high variability in the size of the BS cells. In \textit{S. masenderanica} and \textit{S. montana}, BS cells around the peripheral vascular bundles are more diverse and, in this case, the BS cells facing outwards are more specialized. They are smaller (area between 300 $\mu$m$^2$ and 400 $\mu$m$^2$) and contain more organelles compared with the laterally arranged BS cells, which are elongated along the vein towards the phloem part (on transverse section) and thus have a larger area. This difference accounts for the high values for BS cell area in these two species (Supplementary Table S1).

In \textit{S. divaricata}, parenchyma BS cells adjacent to peripheral veins have even more advanced diversification, with the outermost cells becoming Kranz-like; and the KLCs which form a contiguous inner chlorenchyma layer on the leaf periphery are more or less similar in shape and appearance. They form clear arcs above the veins (next to the xylem) consisting of square specialized cells of nearly similar size, while between veins these KLCs are obviously larger. In the two C4 species, \textit{C. orientale} and \textit{X. richteri}, the size of KLCs is less variable, and they have a uniform curvilinear pattern (nevertheless, there is an ~2-fold difference in the size of the KLCs between the two C4 species studied; Supplementary Table S1).

Among the five \textit{Salsola} species, the percentage volume densities of chlorenchyma (M and BS cells, or KLCs) and WS tissue and the portion of M versus BS or KLC tissue in the leaf were compared with the two C4 species (from analysis of leaf cross-sections in mature leaves). In four species, \textit{S. genistoides}, \textit{S. masenderanica}, \textit{S. montana}, and \textit{S. webbii}, the chlorenchyma occupies ~60–70\% (mean 64\%) of leaf volume, with the main contribution from M cells, while the BS generally comprises only 4.5–6.8\% of leaf volume (mean 5.5\%). However, in \textit{S. divaricata}, the chlorenchyma occupies only ~37\% of leaf volume and, in comparison with the above species, invests only about half as much in the M cells, with a similar volume density of the layer of KLCs (6\%). In the C4 species studied, the chlorenchyma occupies ~30–35\% of leaf volume. The ratios of volume densities of M/BS cells was high in four \textit{Salsola} species (from 9 to 15, mean=12), compared with 5.2 for the M/KLCs in \textit{S. divaricata}, and the lowest ratios of M/KCs in the C4 species (2.1–4.5) (Supplementary Table S2 at JXB online).

The leaf volume invested in WS tissue in the four species \textit{S. genistoides}, \textit{S. masenderanica}, \textit{S. montana}, and \textit{S. webbii} is low (mean 23\%, lowest in \textit{S. webbii} and \textit{S. genistoides}), versus 55\% in \textit{S. divaricata} versus a mean of 38\% for the C4 species (Supplementary Table S2).

The specific periodic acid–Schiff’s staining for polysaccharides shows a similar density of starch staining in chloroplasts...
of M and BS cells of \textit{S. masenderanica} and \textit{S. montana}, indicating equivalent starch storage in all chloroplasts (Fig. 2I, J). In \textit{S. webbii} (Fig. 2K) and \textit{S. genistoides} (not shown), there is little labelling for starch in BS cells (which is due to few chloroplasts in BS cells as shown subsequently by electron microscopy). In contrast, in \textit{S. divaricata}, there is a gradient in starch distribution from little to no starch in the hypodermal layer (M1), with substantial starch in the inner palisade layer (M2), and with the largest starch grains in KLCs (Fig. 2L). In \textit{S. genistoides}, with substantial starch in the inner palisade layer (M2), distribution from little to no starch in the hypodermal layer (M1), with substantial starch in the inner palisade layer (M2), and with the largest starch grains in KLCs (Fig. 2L).

Results on the pattern and density of peripheral veins in the five \textit{Salsola} species compared with the two \textit{C4} representatives are shown in \Fig{3} and Table 1. All studied species, except for \textit{S. genistoides}, have small peripheral veins distributed more or less evenly around the leaf under the chlorenchyma, especially in the middle part of the leaf, often with gaps on the adaxial and/or abaxial side below or above the main vein in cross-sections (Fig. 2A–D). In \textit{S. genistoides}, peripheral veins occur in the lateral plane of the leaf and are represented by closely arranged thicker vascular bundles (not shown). Except for \textit{S. montana}, all species have a similar pattern with a vein network consisting of a reticulate venation with rare terminal ends in minor veins; the network is elongated along the axis of the leaf. In \textit{S. montana}, the venation consists of an elaborated reticulate network with rather numerous terminal ends (Fig. 3). The vein densities in the \textit{Salsola} species range from \(\sim 10 \text{mm/mm}^2\) to 15 \text{mm/mm}^2 while the \textit{C4} species \textit{C. orientale} and \textit{X. richteri} have vein densities of 9.2 \text{mm/mm}^2 and 15 \text{mm/mm}^2, respectively. The lower densities of peripheral veins in \textit{S. masenderanica} and \textit{S. divaricata} are similar to that of the \textit{C4} \textit{C. orientale}, while the high vein density in \textit{S. genistoides}, \textit{S. montana} and \textit{S. webbii} is close to that in \textit{C4} \textit{X. richteri} (Table 1).

Transmission electron microscopy

\Fig{4} shows electron microscopy of leaf chlorenchyma for four of the \textit{‘Cocosalsola’} \textit{Salsola} species (\textit{S. masenderanica}, \textit{S. montana}, \textit{S. webbii}, and \textit{S. divaricata}). There are differences between these in the quantity and level of development of organelles in BS cells; \textit{S. genistoides} (not shown) has features which are very close to those of \textit{S. webbii}. \textit{Salsola masenderanica} (Fig. 4A, B) and \textit{S. webbii} (Fig. 4I, J) have the lowest occurrence of chloroplasts and mitochondria in BS cells; \textit{S. montana} have a thicker cytoplasmic layer with more organelles in BS cells (Fig. 4E, F), while the KLCs in \textit{S. divaricata} contain numerous chloroplasts and mitochondria (Fig. 4M, N).

In \textit{S. masenderanica} (Fig. 4A), \textit{S. webbii} (Fig. 4I), and \textit{S. genistoides} (not shown) chloroplasts and mitochondria are distributed more or less evenly around the CWs, with some mitochondria also located in a centrifugal position. However, in the BS cells of \textit{S. montana} and KLCs of \textit{S. divaricata}, while the chloroplasts are distributed around the CWs, most of the mitochondria are located close to the inner periclinal or radial CWs (Fig. 4E, F, M–O).

Bundle sheath (Fig. 4C, G, K, O) and M (Fig. 4D, H, L, P) chloroplasts in all five species have a similar structure with a well-developed system of medium sized grana. The mitochondria in BS and M cells in \textit{S. genistoides}, \textit{S. masenderanica}, \textit{S. montana}, and \textit{S. webbii} have a similar size and structure (0.3–0.5 \text{μm}; Table 2, Fig. 4B, F, J for BS mitochondria); but, in \textit{S. divaricata} the KLC mitochondria are larger (average 0.6 \text{μm}; Table 2) and they have a more elaborated system of cristae (Fig. 4N, O). The KC mitochondria of \textit{C. orientale} (an NAD-ME-type \textit{C4} species), which are 2.3 times larger than in M cells, are about the same size as the KLC mitochondria in \textit{S. divaricata} (Table 2), and they are distributed

in a centripetal position, close to the vascular bundles (not shown). The KC mitochondria of *X. richteri*, an NADP-ME-type C₄ species, which are also distributed in a centripetal position, are small (not shown) and similar in size to BS mitochondria of *S. genistoides*, *S. masenderanica*, *S. montana*, and *S. webbii* (Table 2).

Table 3 shows results on the thickness of CWs of chlorenchyma cells where they are exposed to the intercellular air space (IS), the M and BS cells of *S. genistoides*, *S. masenderanica*, *S. montana*, and *S. webbii*, the M cells and KLCs of *S. divaricata*, and the M cells versus KCs of the C₄ species *X. richteri*. Among the *Salsola* species, for thickness of BS...
Diverse forms of photosynthesis in Salsoleae

Western blot analysis

Immunoblots for Rubisco, and for key C₄ cycle enzymes PEPC, PPDK, NAD-ME, and NADP-ME from total soluble proteins extracted from leaves of the studied species are presented in Fig. 5. The carboxylase of the C₃ pathway, Rubisco, analysed by western blots with the large subunit antibody, is abundant in all species. The C₄ species X. richteri and C. orientale have very high labelling of the C₄ pathway enzymes, PEPC and PPDK, with difference in abundance of the two malic enzymes. Xylosalsola richteri has clear labelling for NADP-ME and lower labelling for NAD-ME, while C. orientale has strong labelling for NAD-ME, and no detectable labelling for NADP-ME. Compared with the two C₄ species, the five Salsola species, S. genistoides, S. masenderanica, S. montana, S. webbii, and S. divaricata, have no labelling for the C₄ cycle enzymes PPDK and NADP-ME, very low labelling for PEPC, and to varying degrees less labelling for NAD-ME (lowest in S. webbii, highest in S. divaricata).

Carbon isotope composition

The focus of this study is on five species of the tribe Salsoleae (formerly classified under section Coccosalsola) where C₃-type carbon isotope composition, and/or lack of Kranz-type anatomy has been recognized (see the Introduction). Leaves of plants of S. genistoides, S. masenderanica, S. montana, S. webbii, and S. divaricata grown in the current study have C₃-type isotope composition with mean δ¹³C values between –22.6‰ and –29.7‰ (Table 4; see also Table 5 for values for these species from previous reports). Comparative values for the C₄ species C. orientale and X. richteri were –13.5‰

Table 2. Mitochondrial size (small diameter) in representative Salsola s.l. species

| Species               | Mitochondrial size (μm) |
|-----------------------|--------------------------|
|                       | BS, KLC, or KC | M                        |
| S. genistoides        | 0.45 ± 0.02    | 0.40 ± 0.02               |
| S. masenderanica      | 0.42 ± 0.03    | 0.36 ± 0.02               |
| S. montana            | 0.44 ± 0.01    | 0.43 ± 0.03               |
| S. webbii             | 0.38 ± 0.02    | 0.51 ± 0.02               |
| S. divaricata         | 0.62 ± 0.02    | 0.38 ± 0.03               |
| C. orientale, C₄      | 0.65 ± 0.04    | 0.32 ± 0.02               |
| X. richteri           | 0.39 ± 0.04    | 0.47 ± 0.01               |

BS, bundle sheath cells along veins; KCL/KC, inner layer of Kranz-like or Kranz cells, M, mesophyll cells.

cell/KLC/KC CWs exposed to the IS, S. divaricata had the highest value (0.31 μm), which was 1.5- to 3-fold higher than that of the other species; while this value for the C₄ X. richteri was much higher (2.9 μm).

The thickness of CWs exposed to the IS is shown for the subepidermal M1 versus the inner M2 cells. In the M1 cells (which are specialized hypodermal cells in X. richteri), the thickness of the CWs exposed to the IS ranged between 0.11 μm and 0.20 μm, with the highest values in S. divaricata and the C₄ X. richteri. In three species, S. genistoides, S. divaricata, and C₄ X. richteri, the subepidermal M1 cells have thicker CWs than the M2 cells, being slightly thicker in S. genistoides, ~1.5 times thicker in X. richteri, and up to ~3 times thicker in S. divaricata. The thickness of M2 CWs exposed to the IS was similar and low among the species, ranging from 0.07 μm to 0.12 μm.

Among the five Salsola species, the combined thickness of the BS or KLC CWs in contact with other cells (M or BS/KLCs) ranged from 0.20 to 0.29, while in C₄ X. richteri these values for KCs in contact with M cells or other KCs were much higher (2.42 in contact with M cells and 0.97 μm).

Table 3. Thickness of cell walls in leaf cross-sections of representative Salsola s.l. species

| Species               | A. Thickness of individual cell walls towards the IS (μm) | B. Combined thickness of adjacent cell walls (μm) |
|-----------------------|---------------------------------------------------------|-------------------------------------------------|
|                       | BS, KLC, KC | M1 | M2 | BS, KLC or KC in contact with other cells |
|                       | Towards M IS | Towards IS | Towards IS | BS, M | BS, KLC, KC | WS |
| S. genistoides        | 0.20 ± 0.005 | 0.16 ± 0.003 | 0.12 ± 0.004 | 0.21 ± 0.011 | 0.26 ± 0.008 | 0.36 ± 0.017 |
| S. masenderanica      | 0.19 ± 0.007 | 0.13 ± 0.003 | 0.11 ± 0.003 | 0.22 ± 0.002 | 0.20 ± 0.002 | 0.13 ± 0.003 |
| S. montana            | 0.11 ± 0.01  | 0.11 ± 0.005 | 0.11 ± 0.003 | 0.24 ± 0.011 | 0.25 ± 0.001 | 0.19 ± 0.002 |
| S. webbii             | 0.17 ± 0.004 | 0.12 ± 0.004 | 0.10 ± 0.002 | 0.29 ± 0.008 | 0.29 ± 0.012 | 0.14 ± 0.004 |
| S. divaricata         | 0.31 ± 0.01  | 0.20 ± 0.01  | 0.07 ± 0.002 | 0.29 ± 0.013 | 0.24 ± 0.002 | 0.73 ± 0.002 |
| X. richteri, C₄       | 2.9 ± 0.22   | 0.18 ± 0.01  | 0.11 ± 0.004 | 2.42 ± 0.12  | 0.97 ± 0.003 | 1.52 ± 0.12 |

BS, bundle sheath cells along veins; KLC, KLC, internal layer of Kranz or Kranz-like cells; IS, intercellular air space; M, mesophyll cell; WS, water storage cell. In each case n=15–30 measurements. Values are shown with standard errors.

Table A. Thickness of individual cell walls towards the IS (μm) | Table B. Combined thickness of adjacent cell walls (μm)

a For X. richteri, this layer represents specialized hypoderm.

b For X. richteri, this layer could be also referred as M.

(A) Thickness of individual cell walls of BS, KLC, or KC, M1 (or hypodermal cells in Xylosalsola richteri and hypodermal-like in S. divaricata), or M2 cells when in contact with intercellular air space. (B) Combined thickness of cell walls where BS cells, KLCs, or KCs are in contact with other cells (M, WS, or an adjacent BS, KLC or KC).
Table 4. Carbon isotope composition of leaf biomass (δ¹³C) and CO₂ compensation point (f) at 25 °C and 920 PPFD in representative Salsola s.l. species

| Species            | Carbon isotope composition (δ¹³C) | CO₂ compensation point (f, ppm) |
|--------------------|----------------------------------|---------------------------------|
| S. genistoides     | $-29.7 \pm 1.00$                 | $46.3 \pm 0.2 \,(n=2)$          |
| S. mazenderanica   | $-23.6 \pm 0.06$                 | $74.9 \pm 1.8 \,(n=6)$          |
| S. montana         | $-22.6 \pm 0.03$                 | $52.8 \pm 6.1 \,(n=4)$          |
| S. webbi           | $-24.5 \pm 0.10$                 | $49.7 \pm 0.1 \,(n=4)$          |
| S. divaricata      | $-29.2 \pm 0.17$                 | $32.3 \pm 2.9 \,(n=6)$          |
| C. orientale       | $-13.5 \pm 0.46$                 | $5.5 \pm 1.5 \,(n=5)$           |
| X. richteri        | $-12.1 \pm 0.04$                 | $5.8 \pm 0.9 \,(n=4)$           |

Immunolabelling for GDC

In situ immunolabelling for GDC using the antibody to the P protein was examined by electron microscopy, and quantitative analysis made based on the density of gold particles, in four of the Salsola species (S. genistoides, S. montana, S. webbi, and S. divaricata), and compared with that in the C₄ species C. orientale. Analysis of the immunolabelling distribution shows that there is no significant difference in density of the gold particles between the mitochondria of M and BS cells in S. mazenderanica, S. montana, and S. webbi (Fig. 7). In contrast, in S. divaricata, the number of gold particles is 7.5 times higher in the KLC compared with M mitochondria. In the C₂ species C. orientale, gold particles are also selectively localized in the KC mitochondria, with low labelling in M mitochondria (Fig. 7).

Phylogenetic analysis

The tree depicted in Fig. 8 shows the maximum likelihood phylogenetic analysis of tribe Salsoleae based on ITS sequence data. The colour coding shows species studied herein, belonging formerly to section ‘Coccosalsola’, including the five Salsola species of interest (S. genistoides, S. mazenderanica, S. montana, S. webbi, and S. divaricata), S. arbusculiformis, S. larifoliot, and the C₄ species X. richteri, X. arbuscula, and X. chivensis, S. foliosa and S. zygophylla; and, in addition, three other species (Salsola ‘touranica’, Sympegma regelli, and Raphidophytum regelli). All of these, other than the C₄ species, are known to be species with C₃-type isotope composition and/or non-Kranz anatomy. The positions of the two known C₂ – C₄ intermediates are highlighted (blue). The results found here closely reflect the results of previous studies (Akhanl et al., 2007; Wen et al., 2010). This is the first study to find strong support for S. webbi and S. genistoides forming a grade with Sympegma leading to the rest of the tribe.
Table 5. Data on carbon isotope composition and leaf anatomy of species formerly classified under Salsola section Coccosalsola

Some species are placed in the informal clade 'Oreosalsola' based on morphological features (HA, unpublished); additional analysis by molecular phylogeny is needed.

*Salsola euryphylla* Botsch. and *S. transhyrcanica* are presumed to belong to the *Xylosalsola* clade, but have not been included in any phylogenetic analyses and do not have a combination as of yet in *Xylosalsola*. 
Currently most known *Salsola* species having C\textsubscript{3}-like values of carbon isotope composition occur in what was originally described as section *Coccosalsola* (Botschantzev, 1976, 1985, 1989). Among the five *Salsola* species in this study, *S. masenderanica* and *S. montana* (together with previously studied *S. arbusculiformis*) belong to subsection *Arbusculae*, *S. genistoides* and *S. webbii* belong to subsection *Genistoides*, and *S. divaricata* belongs to subsection *Coccosalsola* (Botschantzev, 1976, 1985). However, according to nuclear and chloroplast sequence data, these species do not form a monophyletic group and the following informal clade names were applied to the distinct lineages: ‘*Collinosalsola*’ for *S. arbusculiformis*, ‘*Oreosalalsa*’ for *S. masenderanica* and *S. montana*, and ‘*Canarosalalsa*’ for *S. divaricata* (Akhani et al., 2007) (Table 6). The position of *S. genistoides* and *S. webbii* in the phylogenetic tree clearly suggests that they also do not belong to *Salsola* sensu stricto (s.s.); geographically, they are from the Mediterranean area. *Salsola genistoides* prefers arid south hill slopes; this species is an endemic of Spanish provinces Almería, Murcia, and Alicante along the Iberian Peninsula. *Salsola webbii* is distributed on the alkaline soils of sunny arid slopes of coastal mountains in Morocco and Spain (Castroviejo and Luceño, 1990). *Salsola masenderanica* and *S. montana* are distributed through the Irano-Turanian area, but *S. montana* also occurs in the lower montane zone of the Central Asian area. *Salsola montana* often grows in gypsum, marl, calcareous, and slightly salty soils (Akhani and Ghasemkhani, 2007), and *S. masenderanica* occurs in similar habitats in Alborz Mount. *Salsola divaricata* is an endemic species from the Canary Islands, which grows in semi-arid rocky zones near coastal areas (Fritsch and Brandes, 1999; Delgado et al., 2006; and observation by...
Diverse forms of photosynthesis in Salsoleae

Fig. 7. Graphs showing quantitative data obtained from electron microscopy of in situ immunolocalization of glycine decarboxylase (GDC) in mesophyll (M) versus bundle sheath (BS) of Salsola species s.l., S. masenderanica, S. montana, and S. webbii, M versus Kranz-like cells (KLCs) of S. divaricata in section Coccosalsola, and M versus Kranz cells (KCs) in the C₄ Salsoloid-type species Caroxylon orientale. The density of labelling (number of gold particles per μm² of mitochondrial area) for GDC in mitochondria in the chlorenchyma cell types is shown. For each cell type, 10–15 cell fragments were used for counting.

Most other species having C₃-type carbon isotope composition in Salsoleae, together with the previously identified C₃–C₄ intermediate species S. arbusculiformis, are distributed throughout the Irano-Turanian and Central Asian areas, often on slopes of hills. In formerly section Coccosalsola, the C₄ species which have been previously studied are NADP-ME type with Salsoloid-type Kranz anatomy (see the scheme in Pyankov et al., 1997). They occur almost continuously in arid and semi-arid zones of the Mediterranean, N African, SW and Central Asian areas.

Determination of type of photosynthesis

Gas exchange analyses of the five Salsola species shows that S. genistoides, S. masenderanica, S. montana, S. webbii, and S. divaricata are not functioning as C₄ plants since photosynthesis is saturated at lower light levels, and higher levels of CO₂ are required for saturation compared with the two representative C₃ Salsoloideae species. An important functional test for whether a species may be functioning as a C₃–C₄ intermediate is the CO₂ compensation point, since C₃ values lower than that of C₄ plants are indicative of a reduction in photorespiration (Edwards and Ku, 1987). Previously, S. arbusculiformis was identified as the first C₃–C₄ intermediate in family Chenopodiaceae; at 25 °C it has a Γ value of 36.7 μbar compared with 5 μbar for the C₄ species X. richteri (Voznesenskaya et al., 2001). C₃ plants have minimum Γ values of ~45 ppm at 25 °C and 21% O₂, which is similar to that predicted from kinetic properties of spinach Rubisco (Woodrow and Berry, 1988). In the present study, S. divaricata has a lower than expected Γ value (32 μbar) suggestive of a C₃–C₄ intermediate. Values of S. genistoides, S. montana, and S. webbii were within the range expected of C₃ plants (46–53 μbar); while the value was higher in S. masenderanica (74.9 μbar). At a given temperature, higher than predicted Γ can occur depending on the rate of dark-type respiration relative to the rate of CO₂ assimilation (Furbank et al., 2009).

In C₃–C₄ intermediates, the proof of compartmentation to support refixation of photorespired CO₂, and intermediate-type Γ values comes from analysis by immunolocalization of GDC levels in BS/KLC versus M mitochondria (Rawsthorne et al., 1988; Voznesenskaya et al., 2001). Salsola divaricata, like the C₄ species C. orientale, has selective compartmentation of GDC in KLC mitochondria, as shown by quantifying the number of gold particles from immunolocalization, while in S. masenderanica, S. montana, and S. webbii the labelling is nearly equal in both BS and M mitochondria. Thus, S. divaricata, together with S. arbusculiformis, is the second intermediate to be identified in family Chenopodiaceae, a family that has been found to contain the most C₄ species among the dicots.

The carbon isotope composition of biomass is a means of analysing whether species are directly fixing atmospheric CO₂ via Rubisco or via PEPC in C₃ photosynthesis. In C₃ plants, Rubisco discriminates against fixing atmospheric ¹³CO₂ (resulting in more negative δ¹³C isotope values), which is prevented or minimized in C₄ plants where atmospheric CO₂ is delivered to Rubisco in BS cells via the C₄ cycle. Previous studies showed that δ¹³C values for C₃ plants are between ~10‰ and −15‰. Typical δ¹³C values for C₄ species are ~24‰ to −30‰, but values in C₃ plants can become a few‰ more positive (e.g. −21‰ to −22‰) in plants growing in arid conditions, where water stress can cause photosynthesis to be more limiting due to increased diffusive resistance (Cerling, 1999).

Analyses of the carbon isotope composition of the Salsola species in this study show that they have C₃-type values (average ranging from −22.6‰ in S. montana to −29.7‰ in S. genistoides) compared with the C₄-type values of X. richteri and C. orientale (−12.1‰ and −13.5‰, respectively). Analyses from gas exchange (including Γ), compartmentation of GDC between M and BS cells, and carbon isotope composition of biomass indicate that S. masenderanica, S. montana, S. webbii, and S. genistoides are functioning like C₃ species.

Salsola divaricata is a C₃–C₄ intermediate based on its reduced Γ, the selective localization of GDC in mitochondria of the KLCs, and other structural features. If intermediates fix atmospheric CO₂ via Rubisco with discrimination against fixation of ¹³CO₂ in M cells, and reduce Γ by refixing photorespired CO₂ in KLCs (Type I), their carbon isotope composition will be like that of C₃ plants; whereas, if they reduce photorespiration via a partially functioning C₄ cycle which does not discriminate against ¹³CO₂ (Type II), the isotope composition is expected to have an intermediate value (Edwards and Ku, 1987). The C₃-type isotope value of S. divaricata (δ¹³C = −29.2‰) indicates that it is functioning as a type I intermediate. The low expression of C₄ cycle enzymes in this species is similar to that of the four C₃ species...
Fig. 8. Maximum likelihood phylogram of relationships in tribes Salsoleae and Caroxyloneae. Numbers at nodes reflect bootstrap percentages >50%. Genera are abbreviated as: A., Anabasis; C., Climacoptera; Ca., Caroxylon; Co., Comulula; Cy., Cyatobotas; G., Girgensohnia; H., Halothamnus; Halo., Halogeton; Halox., Haloxylon; Ham., Hammada; Ho., Horaninowia; I., Iljinia; K., Kaviria; N., Noaea; O., Ofaiston; Pe., Petrosimonia; R., Raphidophyton; S., Salsola; Sy., Sympegma; T., Turania; Tr., Traganum; X., Xylosalsola. The colour coding shows species from section ‘Coccosalsola’ plus S. touranica, Sy. regelii, and R. regelii. The species boxed in blue are known C₃-C₄ intermediates in tribe Salsoleae. The species boxed in yellow have non-Kranz-type leaf anatomy and/or C₃-type carbon isotope composition (including S. webbi, S. genistoides, S. montana, and S. masenderanica in the present study; S. laricifolia putative intermediate based on structure but not functionally tested). The species boxed in pink are C₄ species from concept section Coccosalsola. The remaining species are C₄.
In subfamily Salsoloideae, most species are C₄ plants with Salsoloid-type Kranz anatomy, including the NAD-ME-type C. orientale and the NADP-ME-type X. richteri in this study (see the Introduction). In tribe Salsoleae, species lacking Kranz anatomy have previously been defined as having Sympegmoid-type leaf structure, with two well-developed layers of photosynthetic M cells and indistinctive BS cells having few chloroplasts. However, among the five Salsola species in the current study, along with the C₃-C₄ intermediate S. arbusculiformis, all of which have C₃-type carbon isotope composition, there are significant differences.

Three of these species (S. genistoides, S. masenderanica, and S. webbii), which functionally are C₃, have classical Sympegmoid-type anatomy with equally developed M1 and M2 photosynthetic cells, and indistinct BS cells. The BS cells have very few organelles, with chloroplasts and mitochondria distributed around the cells without any special positioning. Salsola montana also has Sympegmoid-type anatomy with quantitative features of M and BS cells similar to the above species. This includes M1 and M2 cells having equal lengths and widths (Fig. 2B, F; Supplementary Table S1 at JXB online; see also light micrograph in Akhani and Ghasemkhani, 2007). However, S. montana has greater development of organelles in BS cells, and the mitochondria are arranged along the inner or radial CW. This structural feature of BS cells occurs in all C₃-C₄ intermediates which have been studied. Thus, S. montana is classified as a proto-Kranz species, which is defined as a species exhibiting early development of a C₄ trait in BS cells, while functionally exhibiting C₃-type photosynthetic features. Proto-Kranz species have been found in a few genera in other families and they have been recognized as C₃ relatives in lineages having C₃–C₄ intermediate species (Muhaiedat et al., 2011; Khoshravesh et al., 2012; Sage et al., 2012). In the BS cells of S. montana, some of the photorespired CO₂ from GDC, as a consequence of RuBP oxygenase activity in the BS chloroplasts, may be refixed (see discussion of proto-Kranz, Muhaiedat et al., 2011). However, the effect on Γ would probably be small and very difficult to detect from gas exchange analysis, since the dual layers of M cells in S. montana account for most of the photosynthetic tissue (Fig. 2B, F; Supplementary Table S2), and dark-type respiration is also a component of Γ.

The C₃-C₄ intermediates S. divaricata (current study) and S. arbusculiformis (Voznesenskaya et al., 2001) have some features of Kranz-like anatomy. The cells of the outer M1 layer are much shorter and appear more like the hypodermal cells (if present) in C₄ Salsoloideae species. A similar
trend can be seen in leaf cross-sections of *S. laricifolia* (Wen and Zhang, 2011). Also, *S. drobovii* which has C₃ carbon isotope composition, represents another structural variant with a complete elimination of the outer M layer; it has only two layers of chlorenchyma characteristic of species with C₄ photosynthesis, M and KC (or KLC in this case; NKK and EVV, unpublished data). In *S. divaricata*, the layer of KLCs contains chloroplasts and numerous large mitochondria which are characteristic for other species with C₃–C₄ intermediate features (Edwards and Ku, 1987; Rawsthorne and Bauwe, 1998; Voznesenskaya et al., 2007, 2010; Muhaidat et al., 2011), including *S. arbusculiformis* (Voznesenskaya et al., 2001). The positioning of mitochondria in *S. divaricata* towards the inner CW is characteristic of all C₃–C₄ intermediates. Also, compared with the other four *Salsola* species in the current study, *S. divaricata* has some thickening of the CW of KLCs especially facing the intercellular space and adjacent to the WS tissue, a feature observed in Salsoloid anatomy, and a characteristic of many C₄ species which is considered to provide resistance to leakage of CO₂ from the KCs (von Caemmerer and Furbank, 2003).

In *S. divaricata*, the layer of KLCs is continuous around the leaf as in C₄ *Salsola* species. A similar arrangement of KLCs containing a visible layer of cytoplasm with organelles can also be seen in *S. laricifolia* (see fig. 13 in Wen and Zhang, 2011) and *S. drobovii* (EVV and NKK, unpublished), suggesting that they may functionally be a C₃–C₄ intermediate. In the other *Salsola* species in the current study (*S. genistoides*, *S. masenderanica*, and *S. webbii*), the BS cells adjacent to the small peripheral veins are represented by non-specialized parenchyma cells. In *S. masenderanica* and *S. montana*, they are similar to that observed previously for the C₃ species *S. oreophila* (Pyankov et al., 1997) and the C₃–C₄ intermediate *S. arbusculiformis* (Voznesenskaya et al., 2001), except for the difference in the number of organelles, with a higher number in *S. arbusculiformis* and *S. montana*, especially in the outermost BS cells occurring exactly above the vascular bundle.

From quantitative analysis, differences in the size and volume densities of tissues were identified between the M and BS cells of C₃ species (*S. genistoides*, *S. masenderanica*, *S. montana*, and *S. webbii*), the M cells and KLCs of the C₃–C₄ intermediates *S. arbusculiformis* and *S. divaricata*, and the M cells and KCs of representative C₄ species (*Supplementary Table S1* at *JXB* online). The results show that the anatomy of the C₃–C₄ intermediate *S. arbusculiformis* is similar to that of the four C₃ *Salsola* species, with the exception that the intermediate has much smaller M1 cells, and more distinctive BS cells due to more numerous organelles. Both *S. arbusculiformis* and *S. divaricata* have smaller M1 cells and a larger investment in WS tissue than the C₃ species. The intermediate *S. divaricata* is unlike the C₃ species and the intermediate *S. arbusculiformis*, and rather like the C₄ species in having a lower volume density of M cells, a lower M/KLC ratio indicating an increased investment in KLCs, along with the Salsoloid-like anatomy.

Proposed sequence of evolution of Salsoloid-type C₄

C₄ species are considered to have evolved from C₃ ancestors. Based on the structural and functional differences between the *Salsola* species in this study, the previously identified C₃–C₄ intermediate *S. arbusculiformis*, and the C₄ species with Salsoloid-type anatomy, the following sequential structural and functional progression in evolution from C₃ to C₄ (or backward regression of C₃) is proposed (Fig. 9).

Pre-conditioning for evolution of Salsoloid-type anatomy is increased succulence in C₃ species having Sympegmoid-type anatomy by adaptation to hot/dry climates and development of specialized WS tissue (Fig. 9A). In this study, the fraction of leaf tissue invested in WS tissue was lower in the C₃ species, with the lowest values in *S. genistoides* and *S. webbii*, which are proposed to represent the ancestral condition for the other *Salsola* species.

C₃-type photosynthesis was shown by functional analyses for three *Salsola* species (*S. genistoides*, *S. masenderanica*, and *S. webbii*) which have Sympegmoid-type anatomy with two layers of photosynthetic tissue, M1 and M2, and with BS cells adjacent to veins having few organelles. For these three species, and especially for *S. genistoides* and *S. webbii*, the non-specialized BS cells, having only a few chloroplasts, contribute to the WS tissue rather than as chlorenchyma. The first proposed step towards development of Kranz anatomy is represented by the development of proto-Kranz features in *S. montana* (Fig. 9B). It has Sympegmoid-type anatomy; but, compared with the above species, it has an increase in the organelle number in BS cells and positioning of the mitochondria towards the inner CW. As in C₃ species, GDC is expressed equally in M and BS mitochondria, there is no thickening of the BS cell walls, and functionally it has C₃ traits. Also, the quantitative features of M and BS cells, and volume density of tissues in *S. montana* are similar to those of the other C₃ species.

The next steps in evolution involve establishment of the C₃–C₄ intermediate characters with Kranz-like anatomy (i.e. *S. arbusculiformis* and *S. divaricata*). This includes reduction of photosynthetic investment in M1 and an increased investment of development of KLCs. In the intermediates, the M1 cells appear more like the WS hypodermal layer found in some C₄ Salsoloid species, which suggests an evolutionary progression from M1 to hypoderm by reducing the cell length and organelle number. This could occur either by transforming the M1 cells to hypodermal cells, or by loss of the M1 layer (Salsoloid anatomy with and without a hypoderm, respectively). There is selective compartmentation of GDC to KLC mitochondria together with their enlargement, and the thickening of the KLC CWs which could decrease the loss of CO₂ from the KLC, and reduce Γ by refixing photorespired CO₂ in KLC.

The C₃–C₄ intermediate *S. arbusculiformis* has Kranz-like Sympegmoid anatomy with a discontinuous layer of KLCs which surround the separate vascular bundles. The anatomy is similar to that of the proto-Kranz species *S. montana* which has a large number of organelles in the BS cells. The main difference is that *S. arbusculiformis* has smaller M1 cells, and
Diverse forms of photosynthesis in Salsoleae

the KLCs are specialized for selective decarboxylation of glycine in photosynthesis (Fig. 9C). An important further step is development of a continuous layer of KLCs under the layer of M, as seen in the intermediate S. divaricata with Kranz-like Salsoloid anatomy (Fig. 9D). Having the structural development of Kranz anatomy with one layer of M chlorenchyma around the leaf periphery, with an underlying layer of small rounded KLCs, the final development of functional C₄ photosynthesis occurs by conversion of M to WS hypoderm and expression of the C₄ cycle between M and KCs, and selective expression of the C₃ cycle in the KC chlorenchyma (Fig. 9E).

This proposed development of Salsoloid-type C₄ based on physiological and structural features of the species studied has in common some of the previously proposed biochemical modifications and steps in the progression from C₃ to C₄ photosynthesis (Edwards and Ku, 1987; Christin et al., 2011; Sage et al., 2012). In the model by Sage et al. (2012), which involves five phases, an important initial step is structural preconditioning of C₃ plants for closer positioning of organelles and decreased numbers of M cells between veins as an adaptation to dry climates. Also, an important event is the enlargement of BS cells around the vascular tissue and reduction of the M/BS ratio. However, in this model, the structural changes were described for species having flat leaves and anatomy with so-called multiple simple Kranz units around individual veins according to the classification of Peter and Katinas (2003). C₄ Salsoloideae species have a single compound Kranz unit with all veins located inside the continuous double chlorenchyma layers. Analysis of patterns of venation in different types of Salsola species indicates that the type of photosynthesis and evolution to C₄ is not dependent on peripheral vein density; rather vein density is a species-specific character. Differences in vein density may reflect species-specific adaptations which depend on the environment and availability of water. Crucial events in the evolution of Salsoloid-type anatomy is a decrease in the layers of M cells and a significant increase in the number, but not the size of the KLCs or KCs. It is important to recognize that the current phylogenetic hypothesis (Fig. 8) does not suggest that the different stages described here represent a direct progression, in a phylogenetic sense, among the species described. Instead, it is suggested that the species described here represent different stages of progression in this model in parallel. One of the difficulties in the current study is that there is insufficient clarity in phylogenetic relationships, particularly in contrast to the patterns found in Mollugo (Christin et al., 2011), to test the number and precise direction of changes in the Salsoleae. While recognizing the basal position of C₃, Sympegna, Salsola genistoides, and S. webbii, species with intermediate features may represent either a progression in evolution of C₄ traits from C₃ ancestors or reversions from C₄.

Fig. 9. A model illustrating five conceptual phases of evolution of C₄ Salsoloid-type anatomy, having a single compound Kranz unit, from C₃ Sympegmoid-type anatomy. Similar events might take place during reversions from C₄. Additional abbreviations: F, functional type; cp, centripetal, indicating positioning of organelles toward the inner BS, KLC, KC wall; mito, mitochondria. Colours: chloroplasts (green, dark green in KC in C₄), mitochondria (orange with GDC; dark brown without GDC).
In a treatment of representative *Salsola* species by Pyankov et al. (2001b), species lacking Kranz anatomy were distributed between two large branches within the tribe Salsoleae; one branch included mostly *C*₄ species with NAD-ME-type biochemistry and Salsoloid anatomy (together with several species having Sympegmoid-type anatomy, e.g. *S. oregophila*, *S. botschantzevii*, and *S. droboviit*), and another branch including NADP-ME-type species with Salsoloid anatomy (together with species lacking Kranz anatomy, e.g. *S. arbusculiformis* and *S. montana*). In a more detailed phylogeny, it was shown that the *C*₃ species with NAD-ME biochemistry belong to the tribe Caroxyloneae and the NADP-ME species belong to Salsoleae s.s. (Akhani et al., 2007). Furthermore, the results of that study show that section Cocosalsola is not monophyletic; *C*₃ species fall into two clades, the *C*₄ species of subsection Cocosalsola belong to the clade representing *Salsola* s.s. while the *C*₃ species of subsection Arbusculae were renamed to the genus *Xylosalsola* in tribe Salsoleae (sensu Akhani et al., 2007). Based on the analysis of one nuclear and one chloroplastic gene region (ITS and chloroplast *psbB-psbH*), sequences in phylogenetic schemes show that *S. masenderanica* and *S. montana* are very closely related species forming a clade with *S. arbusculiformis*, *Rhaphydophyton*, and *Noaea*, while *S. divaricata* forms an independent clade which is related to other *C*₃ species (Akhani et al., 2007). A close relationship between *C*₁ *S. montana* and *S. masenderanica*, the known *C*₁–*C*₄ intermediate *S. arbusculiformis*, and *S. laricifolia* is further supported by the maximum likelihood tree derived from ITS, *psbB-psbH*, and *rbcL* sequences (Wen et al., 2010). Similarly, a clade of *S. montana* and *S. masenderanica* is shown grouping with *S. arbusculiformis* (*C*₁–*C*₄ intermediate) and *S. laricifolia*, along with *C*₃ species of *Noaea* and *S. roacea*. *Salsola laricifolia*, has a *C*₃-type isotope value (Table 5); Wen and Zhang (2011) suggested that this may be a *C*₁–*C*₄ intermediate based on it having a well-developed layer of KLCs. The *C*₁–*C*₄ species *S. divaricata* continues to be a lineage isolated from any of the other *C*₃ or *C*₁–*C*₄ intermediate species; however, better resolution and support will be necessary to clarify this.

Botschantzev (1976, 1985) considered *S. montana* Litv., *S. masenderanica* Botsch., *S. oregophila* Botsch., and *S. botschantzevii* Kurbanov to be separate species; later, Freitag and Rilke (1997) suggested that they all are synonyms for *S. montana* Litw. s.l.). However, ITS sequence data and anatomical differences given herein demonstrate at least the distinctness of *S. montana* and *S. masenderanica*. The distinctness of the other possible segregates of *S. montana* will require further study.

The evolutionary relationships of the Sympegmoid- and Salsoloid-type anatomies and gradations in between in tribe Salsoleae are still unclear. While a model for evolution from *C*₃ to *C*₄ developed from structural and physiological analysis has been proposed here, the model needs to be evaluated with a more robust phylogenetic hypothesis, which will require additional sequence data and species sampling. Earlier, Carolin et al. (1975) proposed that Sympegmoid anatomy evolved from Salsoloid, which is consistent with the suggestion of Pyankov et al. (1997, 2001a) that some *C*₃ Sympegmoid-type *Salsola* species, for example those occurring at higher elevations, may be reversions from *C*₄ species. However, Akhani et al. (1997) supported the idea that Salsoloid-type *C*₄ evolved from species having Sympegmoid-type anatomy; interestingly, *S. webbi* *, S. genistoides*, and *Sympegma regelii* form a grade leading to the rest of the Salsoleae (Fig. 8), which is consistent with this hypothesis. Similar positioning of *S. webbi* and *S. genistoides* has been previously suggested by Kaderet et al. (2003) and Kadereit and Freitag (2011), but with many fewer Salsoleae species sampled and with some variation in their precise position depending on the analysis. Here strong support is found for these species forming a grade at the base of the Salsoleae s.s. The phylogenetic patterns suggest that the ancestral species in Salsoleae are *C*₂ taxa such as *Sympegma regelii* (a Central Asian plant) and *Salsola genistoides* and *S. webbi* (two Iberian species). However, the *C*₁–*C*₄ intermediates and other *C*₃ species are all interwoven with *C*₄ clades (Fig. 8). It is therefore not clear whether there have been many origins of *C*₃ in this clade, or if in some cases these have been reversions from *C*₄. In the latter case, reversions from *C*₄ to intermediate to *C*₁ might occur by a gain of function of M cell chloroplasts to carry out *C*₃ photosynthesis by Rubisco, followed by a loss of this function in the KCs, accompanied by reversal of the structural features illustrated in Fig. 9. Further analysis will be necessary to determine the directions of change in photosynthetic pathways in this lineage. In the future, more detailed physiological and anatomical evaluations of all *Salsola* s.l. species with *C*₃ carbon isotope values are needed to determine whether they are *C*₃ or intermediates, along with phylogenetic analysis to consider how *C*₄ photosynthesis evolved in tribe Salsoleae.

### Supplementary data

Supplementary data are available at *JXB* online.

#### Appendix S1. Sampling table for phylogenetic analysis.

**Table S1.** Mesophyll cell (M1, M2), hypodermal cell (H), bundle sheath cell (BS), Kranz-like cell (KLC), and Kranz cell (KC) sizes of *Salsola* s.l. species.

**Table S2.** Volume density of tissues (%) and ratios of M/BS in *C*₃, M/KL in *C*₃–*C*₄, and M/KC in *C*₄ species of representative *Salsola* s.l.
