Effect of Delta Current and Delta Current Frequency on tensile properties and microstructure of Gas Tungsten Constricted Arc (GTCA) welded Inconel 718 sheets

https://doi.org/10.1515/jmbm-2019-0020
Received Nov 01, 2019; accepted Dec 07, 2019

Abstract: Inconel 718 is a nickel-based superalloy which finds major applications in lightweight welded frames and other parts in gas turbine engines. This alloy is frequently joined by gas tungsten arc welding (GTAW) process for clean and precise welds. However, the weldability of Inconel 718 alloy is limited by the high heat input and slower cooling rate in GTAW process. It leads to the segregation of alloying elements and detrimental laves phase formation in weld metal which significantly reduces the tensile properties of the welded joints. To overcome this problem, a newly developed gas tungsten constricted arc welding (GTCAW) process is used for joining Inconel 718 alloy. The main effect of Delta Current (DC) and Delta Current Frequency (DCF) on the tensile properties and microstructure of GTCA welded 2 mm thick Inconel 718 alloy sheets was investigated. Superior tensile properties were exhibited at Delta Current of 50 A and Delta Current Frequency of 4 kHz due to the refinement in fusion zone. Delta Current and Delta Current Frequency showed deleterious effect at higher levels due to the high heat input.

Keywords: Gas Tungsten Constricted Arcwelding, Delta Current, Delta Current Frequency, Inconel 718 alloy, tensile properties, microstructure

1 Introduction

Inconel 718 is a Ni-Cr-Fe based alloy containing Nb, Mo, Ti and Al as principal strengthening elements [1]. It is strengthened by gamma prime \( \gamma' \) \([\text{Ni}_3(\text{Al}, \text{Ti})]\) and gamma double prime precipitates \( \gamma'' \) \(\text{(Ni}_3\text{Nb})\) [2]. It possesses high strength, excellent creep and stress rupture properties, good corrosion and oxidation resistance [3]. It possesses excellent resistance to strain age cracking due to its sluggish precipitation behavior of gamma double prime precipitates [4]. It is used in rocket combustor, gas turbine engines for casing, discs and blades, in high temperature system of cryogenic rocket engines etc [5, 6]. It finds major applications in critically stressed components at a high temperature up to 650°C [7].

Gas tungsten arc welding (GTAW) process is widely used for joining Inconel 718 alloy for the fabrication and service repair of the components as it is economical, shop friendly and give clean and precise welds. The main constraint in joining of Inconel 718 alloy by GTAW process is the segregation of alloying elements and laves phase formation in weld metal region due to the high heat input as the arc is wider and heat intensity of the arc is less. The formation of laves phase has deleterious effects on the weld mechanical properties. Radhakrishna et al. [8] found that faster cooling rate in EBW reduces the segregation and laves phase formation in Inconel 718 welds significantly. Hence the joining techniques which increase the cooling rate and refine the dendrite structure of fusion zone, can control the problem of segregation and improve the weld mechanical properties. Ram et al. [9] employed current pulsing technique in GTAW process and achieved improved tensile properties due to the refinement in fusion zone microstructure. Sivaprasad et al. [10] observed finer and discrete laves phase formation in Inconel 718 welds due to the refinement in fusion zone by magnetic arc oscillation technique in GTAW process; thereby achieved im-
Effect of Delta Current and Delta Current Frequency on Gas Tungsten Constricted Arc (GTCA)

proved tensile properties in welded joints. Manikandan et al. [11] used liquid nitrogen cooling in GTA welding of Inconel 718 alloy to enhance the cooling rate and reduce the segregation of Nb. In this investigation, a newly developed gas tungsten constricted arc (GTCA) welding process is used to join Inconel 718 alloy to refine the dendritic structure of fusion zone. GTCAW is the advanced variant of GTAW process which involves the use of magnetic arc constriction produced by Delta Current pulsing at a very high frequency up to 20 kHz.

The research on welding of Inconel 718 alloy, so far, is mainly focussed on the gas tungsten arc welding (GTAW) [12–14], electron beam welding (EBW) [15, 16] and laser beam welding (LBW) [17, 18]. Researchers reported the use of current pulsing [19–21] and magnetic arc oscillation technique [22–24] to reduce the heat input and refine the fusion zone microstructure of Inconel 718 welds. However, the published literature on the use of gas tungsten constricted arc (GTCA) welding of Inconel 718 alloy is deficient. Delta Current and Delta Current Frequency are the main controlling parameters for the magnetic arc constriction in GTCAW. So, the main objective of this research work is to investigate the effect of Delta Current (DC) and Delta Current Frequency (DCF) on the tensile properties and microstructure of Inconel 718 alloy joints.

2 Experimental methodology

The rolled 2 mm thick sheets of Inconel 718 alloy in 980°C solution treated condition was used for the present investigation. Table 1 shows the chemical composition of base metal. The mechanical properties of base metal are presented in Table 2. The sheets were cut into required size for the preparation of square butt joint as shown in Figure 1. Gas tungsten constricted arc (GTCA) welding machine (Make & Model: VBC, UK; InterPulse IE175i) was used to fabricate the weld joints to produce single pass autogenous welds. Figure 2 shows the setup of GTCA welding machine used in the present investigation. The delta straight arc mode was selected for deeper penetration in welding. One factor at a time approach was selected to design the experiment. The welding parameters used for the

Figure 3: Photograph of welded joints

(a) Joints fabricated at various levels of Delta Current
(b) Joints fabricated at various levels of Delta Current Frequency

fabrication of the joints are listed in Table 3. The photograph of the welded joints is shown in Figure 3.

Figure 4 shows the dimensions of the tensile specimens extracted from the welded joints. The tensile testing was carried out as per ASTM E8M-05 standard using a 50 kN servo-controlled tensile testing machine (Make & Model: Tinius Olsen, Horsham, Pennsylvania; H50KL). The tensile specimens were subjected to a tensile loading at a cross head speed of 2 mm/min. The 0.2 % offset method was used to calculate the yield strength from the engineering stress-strain curve of the tested specimen. The tensile elongation was measured at a gauge length of 50
mm. Three tensile specimens were tested and the average of three was reported as final property value. The tensile fracture surface was analysed by SEM.

Vickers microhardness was measured as per ASTM E384-17 standard on the mirror polished cross-sectional surface of the metallographic samples. The microhardness survey was carried out across the mid thickness region from the weld centre at an interval of 0.1 mm. The microhardness was measured in the weld centre using a Vickers Microhardness testing machine (Make & Model: SHIMADZU HMV-2T) at a testing load of 0.5 kg and 15 s dwell time. The average microhardness of FZ and HAZ was also recorded.

The microstructural analysis was performed at the cross section of the mirror polished metallographic samples etched by Kalling’s reagent. The stereozoom microscope was used to record the macrostructure of the welded joints. Image J analyzer software was used to measure the weld bead geometry. The etched metallographic samples were then observed under an optical microscope (Make & Model: MEJI, Japan; MIL-7100) and the microstructure was recorded at different magnifications.

Calculation of heat input

The heat input (J/mm) was calculated using the general formula

\[ H_i = \frac{I_{\text{avg}} \times V \times \eta}{S} \]

where \( I_{\text{avg}} \) is the average of main current and Delta Current in amps, \( V \) is the arc voltage in volts, \( S \) is the welding speed in mm/min and \( \eta \) is the efficiency of the process in %.

3 Results

3.1 Macrostructure

Tables 4 and 5 show the effect of DC and DCF on the macrostructure of the welded joints. All the joints were observed to be defect free. Complete penetration was obtained in all the joints. As DC increases, the weld bead geometry decreases from a lower level of 40 A to 50 A. It is due to the increase in magnetic arc constriction which reduces the heat input and causes localized melting of the metal at the joint. Further increase in DC to a higher level of 60 A results in increase in weld bead geometry. It is due to the increase in heat input during welding owing to the constant welding speed resulting in more melting of metal at the joint. The joints welded above the DC of 50 A showed increase in concavity on the top surface. The increase in arc force and more melting of metal at the joint due to the higher heat input is responsible for the deeper concavity on the weld pool surface at a higher level of 60 A.

The increase in DCF results in an increase in the weld bead geometry. But there are no significant changes in the weld bead size up to 12 kHz. However, it increases significantly at a higher level of DCF (20 kHz) as compared to the lower level (4 kHz). The Fusion zone area is increased significantly by 13.38% at a higher level as compared to the lower level. The width of the weld bead and HAZ increases with an increase in DCF. It is attributed to the increase in average heat input during welding with increase in DCF. The joints welded at a 50 A DC and 4 kHz DCF showed better weld bead geometry. It shows that the weld bead geometry is sensitive to the change in the level of DC and DCF and necessitates the optimum selection to control the weld bead.

3.2 Tensile properties

The transverse tensile properties of the welded joints at different levels of DC and DCF are presented in Table 6 and 7 respectively. The tensile properties of all the joints are lower than the base metal. It is due to the difference in the microstructural characteristics of base metal and fusion zone. Figure 5 shows the photograph of tensile specimens after testing. All the joints welded at different levels of DC and DCF failed in the fusion zone only. It is attributed to the segregation of alloying elements resulting in the formation of hard and brittle laves phase in fusion zone which does not assist in plastic deformation [25–27]. Figure 6 represents the effect of DC on the tensile properties of welded joints. Increase in DC results in an increase in tensile and yield strength from a lower level of 40 A to mid-level of 50 A. It is due to the increase in magnetic arc constriction which reduces the average heat input during welding. Further increase above 50 A results in a considerable decrease in the strength of the welded joints. Similar results were obtained for the tensile elongation of the welded joints. DC at a higher level of 60 A results in a 30%

- (a) Delta Current (A) vs strength (MPa)
- (b) Delta Current (A) vs elongation (%)

reduction in ductility of the welded joints as compared to the lower level of 40 A. The joints welded at DC of 50 A exhibited superior tensile properties. It showed 854 MPa tensile strength, 532 MPa yield strength and 29.64% ductility. The effect of DCF on the tensile properties of welded joints is shown in Figure 7. The tensile strength decreases with an increase in DCF. The decrease in tensile strength up to 12 kHz is not significant. The higher tensile strength of 863 MPa, yield strength of 548 MPa, and elongation of 27.93% was achieved at 4 kHz DCF. The tensile strength decreases from 863 MPa to 834 MPa at a higher level of 20 kHz. The tensile elongation increases slightly with an increase in DCF up to 12 kHz. Further increase results in a slight reduction in tensile elongation. The tensile elongation is higher about 29.64% at 12 kHz DCF. The decrease in tensile properties with an increase in DCF is attributed to the accumulation of heat input during welding with increase in each distinct level.

Figure 8 and 9 show the fractographs of the tensile specimens at different levels of DC and DCF. The fracture surface of the base material showed no favorable fracture path and exhibited completely dimpled region. The frac-

The microhardness of various regions of the welded joints under incremental levels of DC and DCF are compiled in Tables 8 and 9. It shows that the fusion zone hardness is lower than the base material. It is attributed to the depletion of strengthening alloying elements from the dendrite core into the interdendritic regions which leads to the formation of intermetallic laves phase. The hardness of the fusion zone is dependent on the Nb content in the dendrite core regions. Higher the depletion of Nb from the dendrite core regions, lower the hardness of the fusion zone. Figure 10 a) and b) shows the microhardness distribution of welded joints across the mid-thickness region at different levels of DC and DCF. It showed microhardness gradient i.e. variation in microhardness of the fusion zone from the weld centre. The microhardness gradient shows the uniformity of the elemental composition in the weld microstruc-
Figure 9: SEM fractograph of tensile specimens at different levels of DCF

Figure 10: Microhardness variation across the welded joint along the mid-thickness region at different levels of a) DC and b) DCF

The joints welded at 50 A DC and up to 12 kHz DCF showed a comparatively reduced microhardness gradient as compared to the higher levels of DC and DCF. However, lower microhardness values were observed in the fusion zone. These are the regions which are mainly responsible for the failure of the welded joints in the fusion zone. The microhardness gradient in the fusion zone is higher at incremental levels of DC and DCF. It is attributed to the higher heat input. Figure 11a) and b) shows the effect of DC and DCF on average microhardness of the fusion zone (FZ) and heat affected zone (HAZ). It follows the trend of tensile strength at incremental levels of DC and DCF.
3.4 Microstructure

The base material microstructure of Inconel 718 alloy in 980°C solution treated condition is shown in Figure 12. It shows an equiaxed grain structure in nickel austenitic matrix with the presence of carbides at the grain boundaries and across the grains. The annealing twinning is clearly observed in grains. Figure 13 shows the effect of DC on the microstructure of fusion zone (FZ). The dendritic structure of the fusion zone gets coarsen with the increase in DC compared to lower level and higher level of DC. The increase in DC from a lower level of 40 A to mid-level of 50 A, showed refinement in the dendritic structure of the fusion zone. However, further increase in DC results in the coarsening of dendrites. The dendritic structure is much coarser at a higher level of 60 A. It shows larger interdendritic spacings which are preferential sites for segregation of alloying elements.

Figure 14 shows the microstructure of the fusion zone at incremental levels of DCF. The fusion zone of the joints welded at 4 kHz DCF shows finer dendritic structure as compared to the other levels. The refinement in the fusion zone is observed up to 12 kHz. Further increase results in the coarsening of the dendrites. The fusion zone at a higher level of DCF (20 kHz) shows coarser dendritic structure. This clearly infers that the average heat input rises during welding.
4 Discussion

4.1 Effect of DC and DCF on macrostructure

Gas tungsten constricted arc (GTCA) welding is the advanced variant of GTAW process in which the welding arc is constricted by the magnetic field produced by DC pulsing at a very high frequency up to 20 kHz. As DC increases, there is an increase in average heat input during welding at incremental levels due to the constant welding speed. When DC increases, the magnetic field increases resulting in increase in magnetic arc constriction. The magnetic arc constriction reduces the wastage of heat on the outer flare and causes localized heating of the metal at the joint. This results in increase in heat intensity of the arc and less time is required for the melting of the metal at the joint. So, the interaction effect exists between the DC and welding speed. The increase in DC must be associated with increase in welding speed. When the DC increased from lower level of 40 A to mid-level of 50 A, the fusion zone area decreased. It is attributed to the increase in magnetic arc constriction. Further increase in DC above 50 A resulted in increased weld bead geometry. It is attributed to the increase in heat input effect. In this investigation, to study the main effect of DC, the interaction effect of welding speed with DC is neglected i.e. welding speed is kept constant. Increase in magnetic arc constriction with incremental levels of DC at constant welding speed results in more melting of the metal at the joint. The benefits of the magnetic arc constriction are not achieved at higher level of DC due to the increased heat input effect and constant welding speed.

The increase in DCF results in an increase in weld bead geometry. It is not significant up to 12 kHz. However, it is more pronounced at a higher level of DCF (20 kHz). It is attributed to the increase in average heat input during welding. As DCF increases the distance between the two consecutive peaks of the DC decreases. This results in reduced rise time and fall time which in turn results in much faster magnetic arc constriction and release. Thus, less time is available for the weld pool to transfer heat to the adjacent regions during welding in each welding thermal cycle. The end effect is that it results in the piling of heat input during welding in each welding thermal cycle. The piling of heat input increases with incremental levels of DCF. It is the main reason that the DC pulsing benefits are not observed at higher levels. As the DC and DCF showed a sig-
significant effect on the weld bead control, the optimum selection of the weld bead is important.

4.2 Effect of DC and DCF on tensile properties

The tensile properties of Inconel 718 alloy joints are mainly controlled by the heat input, welding techniques, and elemental composition. Nb is the alloying element which is mainly used for high temperature strengthening. But the main problem is, it is having a high partition coefficient [28]. It results in the segregation of Nb in interdendritic regions. The tensile failure was observed in the fusion zone of all the joints due to the presence of laves phase in the fusion zone due to the segregation of alloying elements. As segregation is a time-dependent phenomenon, the weld cooling rate and heat input is major factor in controlling the microsegregation and subsequent formation of Laves phase in the weld [29, 30].

As DC increases the average heat input during welding decreases. This results in an increase in the cooling rate. The increase in the cooling rate provides less time for the growth of the dendrites and solute redistribution. This causes refinement in the fusion zone. As the dendritic structure becomes finer, the interdendritic spacing reduces which are the preferential sites for segregation of alloying elements and laves phase formation. Thus, the magnetic arc constriction reduces the depletion of alloying elements from the matrix and core of dendrites to interdendritic regions. The reduced segregation effect provides better strength properties. The increase in tensile strength from a lower level of 40 A to mid-level of 50 A is attributed to the refinement in the dendritic structure of fusion zone. However, the tensile properties decrease significantly above 50 A. The benefits of magnetic arc constriction with the increase in DC at a constant welding speed are not obtained at a higher level of 60 A due to the fact that the heat input effect is becoming more dominant, which reduces the cooling rate. It provides enough time for the growth of the dendrites and solute redistribution. This results in increase in the interdendritic spacing with more segregation of alloying elements. The depletion of alloying elements from the matrix and the core of the dendrites in interdendritic regions reduces the strength of the welded joints [15–17]. Thus, the reduced tensile proper-
ties at a higher level of DC is attributed to the coarser dendritic structure. Increase in DCF resulted in a decrease in tensile properties of the welded joints. It is attributed to the coarsening of the dendrites. As there is an increase in the stacking of average heat input during welding in welding thermal cycles with incremental levels of DCF, the cooling rate decrease and coarsening of the dendritic structure occurs. Also, the magnitude of thermal oscillation and agitation is reduced with incremental levels. This effect is more significant above 12 kHz showing significant reduction in tensile properties. Laves phase being a brittle intermetallic compound provides favorable sites for easy crack initiation and propagation \[26, 27\]. Bae et al. \[31\] observed that the brittle microcracks were initiated from the laves particles and causes reduction in the microplastic zone ahead of the crack tip leading to the rapid crack propagation.

4.3 Effect of DC and DCF on microhardness

The microhardness survey showed variation in the microhardness of the fusion zone from the weld centre. The significant variation in microhardness is allocated to the segregation effect. The alloying elements which have a higher partition coefficient are more pronounced for segregation in interdendritic regions \[18\]. The strengthening alloying elements get depleted from the matrix and segregate in the interdendritic regions for laves phase formation. This results in lowering the microhardness at some points in the fusion zone from the weld centre.

The increase in DC from a lower level of 40 A to mid-level of 50 A results in increase in average microhardness of fusion zone. It is attributed to the refinement in the fusion zone due to the decrease in heat input and increase in cooling rate. Refinement in fusion zone results in decrease in interdendritic spacing which are preferential sites for the segregation of alloying elements. Thus, the refinement of the fusion zone microstructure reduces the depletion of the alloying elements from the matrix in the interdendritic region and increases the average microhardness value of the fusion zone. Further increase in DC above 50 A resulted in a decrease in average microhardness of fusion zone. It is attributed to the coarsening of the fusion zone microstructure and larger extent of segregation of alloying elements for lave phase formation. The incremental level of DCF results in a decrease in the average microhardness values of FZ. It is attributed to the coarsening of the fusion zone microstructure due to the increase in stacking of average heat input during welding which results in increased segregation effect and depletion of strengthening elements from the matrix. The grain growth in HAZ leads to the reduced hardness in HAZ as compared to the base metal and fusion zone. Though the HAZ hardness is lower than base metal and fusion zone, failure resulted in the fusion zone of the joints only. It is attributed to the segregation of Nb leading to the laves phase formation in weld metal region. Ram et al. \[9\] stated that laves phase does not provide plastic deformation along with the matrix and provides easy crack initiation and propagation. Furthermore, it depletes the strengthening alloying elements from the matrix which provides the region of lower hardness in the fusion zone which are mainly responsible for the failure of the joints in fusion zone only.

4.4 Effect of DC and DCF on microstructure

Inconel 718 alloy is a heavily alloyed material with a large solidification range up to 150°C. It solidifies in the dendritic mode by constitutional supercooling and the growth of the dendrites is dependent on the heat input and cooling rate \[15, 17\]. Increase in DC from a lower level of 40 A to mid-level of 50 A showed refinement in the dendritic structure of fusion zone. Because the increase in DC increases magnetic arc constriction which reduces the effect of average heat input during welding and enhances the cooling rate. The magnetic arc constriction causes localized melting of metal at the joint and reduces average heat input during welding. This increases the cooling rate and reduces the thermal gradient towards the weld centre and base metal. The degree of undercooling in the solidifying weld pool is inversely proportional to the ratio of thermal gradient and growth rate \[26, 27\]. Thus, the thermal gradient towards the weld centre and base metal reduces. It results in significant undercooling which leads to the refinement of the dendritic structure of the fusion zone. The finer dendritic structure observed in 50 A DC is attributed to the increased magnetic arc constriction and optimum interaction effect of DC and welding speed. The magnetic arc constriction and release also enhance the cooling rate by increasing the fluid motion in the weld pool. This provides an increase in the nucleation sites and refinement in the fusion zone. However, the benefits of magnetic arc constriction were not achieved at a higher level due to the significant heat input effect. The increase in DC at the constant welding speed increases the average heat input during welding. The heat input effect is more severe at a higher level of DC due to the constant welding speed. As the magnetic arc constriction increases the heat intensity of the arc, it reduces the time required for the melting of the metal at the joint. Since the welding speed is kept constant to understand the main effect of DC, there is more melting of
metal at the joint at incremental levels of DC. The significant coarsening of a dendritic structure is observed at a higher level of 60 A.

The results showed an increase in the growth of the dendrites and interdendritic regions with incremental levels of DCF. This clearly indicates that the average heat input increases with increase in DCF. As the DCF increases the distance between the two adjacent peaks of the DC decreases, which reduces the time for the heat to transfer in the next welding cycle. Thus, there is a piling of heat input in each welding cycle. The end effect is an increase in average heat input during welding with incremental levels of DCF. The piling of heat input increases the thermal gradient between the weld pool and the base metal. Thus, there is enough time for the heat transfer due to the reduced cooling rate. This provides the preferential conditions for the growth of the dendrites. The coarsening of the fusion zone dendritic structure is mainly responsible for the reduction in mechanical properties of the welded joints at 20 kHz. The increase in growth of the dendrites is not significant up to 12 kHz. This is the reason that there is no notable reduction in mechanical properties up to 12 kHz. The welded joints showed higher mechanical properties at a lower level due to the significant refinement in the dendritic structure of the fusion zone. It is attributed to the optimum heat input and thermal oscillation of the weld pool. The DC pulsing causes thermal oscillation of the molten pool which causes an interruption in the weld pool solidification. It disturbs solidification process and the growth of the dendrites resulting in fragmentation of the dendrites. The broken dendrites also act as nuclei for refinement in the fusion zone during solidification. The beneficial effects are observed up to 12 kHz. At a higher level of DCF, the piling of heat input in weld thermal cycle causes the melting of newly forming nuclei and restricts refinement in the fusion zone.

5 Conclusions

1. Delta Current (DC) is observed to have significant effect on the tensile properties and microstructural characteristics of Inconel 718 alloy welds compared to the Delta Current Frequency.
2. Increase in DC from lower level of 40 A to 50 A results in increase in tensile properties and microhardness of the welded joints. It is attributed to the refinement in dendritic structure of fusion zone. Further increase results in decrease in mechanical properties due to the coarsening of dendritic structure of fusion zone.
3. Increase in Delta Current Frequency (DCF) from lower level of 4 kHz to higher level of 20 kHz results in decrease in the mechanical properties of the welded joints. It is attributed to the coarsening of dendritic structure due to the piling of average heat input during welding.
4. The joints welded at DC of 50 A and DCF of 4 kHz exhibited superior tensile properties. Thus, the selection of DC and DCF at optimum level is important for grain refinement in the fusion zone and to attain superior tensile properties in welded joints.
5. The GTCA welded Inconel 718 alloy joints made using optimized DC and DCF showed joint efficiency of 99.20% and an elongation of 27.93%. These tensile properties are comparatively much higher than the joints made using constant current, pulsed current and magnetic arc oscillation techniques of GTAW process.

Acknowledgement: The authors express their sincere gratitude to the Director, Vikram Sarabhai Space Centre (VSSC), ISRO, Thiruvananthapuram, Kerala for providing the financial support and base material to carry out this investigation through ISRO RESPOND scheme(Project No. ISRO/RES/3/728/16-17).
