Divergent effects of flavone acetic acid on established versus developing tumour blood flow

V. Mahadevan & I.R. Hart

Room 536, Imperial Cancer Research Fund Laboratories, PO Box 123, Lincoln's Inn Fields, London WC2A 3XY, UK.

Summary Flavone Acetic Acid (FAA) exerts much of its effect by reducing tumour blood flow. Previous studies on FAA-induced changes in blood flow have used established tumours with a functional microvasculature. Using radioactive Xenon (133Xe) clearance to monitor local blood flow we show that the effects of FAA are dependent on the presence of this functional microvasculature with no evidence that FAA inhibits the actual development of tumour microcirculation. Thus, administration of multiple doses of FAA around the time of tumour cell injection failed to diminish t1/2 values of 133Xe (e.g. t1/2 16 min for FAA vs 14 min for saline controls at 10 days) or to affect tumour volumes (5.55 ± 0.06 cm³ in FAA-treated animals vs 5.7 ± 1.3 cm³ in controls at 25 days). In marked contrast a single dose of FAA (200 mg kg⁻¹ body weight) 2 weeks after tumour cell injection dramatically extended t1/2 times (47 min for FAA vs 7 min for controls; P < 0.001) and significantly reduced tumour burden. This effect is specific for tumour microvasculature and is not directed simply at new vessels since a similar treatment of animals with implanted-sponge-induced granulation tissue had no effect on t1/2 times (6.8 ± 1.1 min for FAA at 200 mg kg⁻¹ vs 7.2 ± 1.0 min for saline-treated controls).

Materials and methods

Animals

Young adult male Balb/c mice (weighing 24–28 g), used in all experiments, were obtained from the Imperial Cancer Research Fund animal breeding unit, Clare Hall Laboratories, South Mimms, Herts, UK. Animals were housed individually in plastic cages in an air-conditioned room; food and water were available ad libitum and a 12 h light/dark schedule was maintained. All animal procedures were carried out under a Project Licence approved by the Home Office, London, UK.

Chemicals and reagents

Radioactive Xenon (133Xe) in sterile physiologic saline (specific activity 370 MBq in 3 ml) was purchased from Amersham International, Aylesbury, UK.

Clinically formulated FAA (LIPHA, Lyons, France), supplied as a lyophilised powder, was a generous gift from Dr J.A. Double, Clinical Oncology Unit, University of Bradford, UK.

Salmon Protamine sulphate was bought from Calbiochem, Nottingham, UK. Immediately prior to administration, the required doses of Protamine or FAA were dissolved in sterile physiologic saline (0.1 ml 10 g⁻¹ body weight of animal).

Technique of sponge implantation

Circular, polyether polyurethane sponge discs of 1.25 cm diameter × 0.6 cm thickness (Vitafoam Ltd, Manchester, UK) were sterilised by autoclaving prior to use. Mice were anaesthetised by the intramuscular injection of Hypnorm (0.315 mg ml⁻¹ of Fentanyl Citrate and 10 mg ml⁻¹ of Fluanisone; Janssen Pharmaceuticals) and Hypnovel (5 mg ml⁻¹ of Midazolam Hydrochloride; Roche), each at a dose of 0.5 ml kg⁻¹ of body weight.

A 1 cm dorsal, vertical, midline skin incision was made aseptically immediately proximal to the base of the tail and a dorsal subcutaneous pouch was fashioned 4–5 cm cephalad to the incision by gentle, blunt dissection. A sponge disc was then introduced through the incision and placed flat in this subcutaneous pouch. The skin incision was closed with two interrupted 5–0 silk sutures and the animal allowed to recover.

Tumour establishment

Colon 26 cells (Tsuro et al, 1983) were grown as monolayers in Dulbecco’s modification of Eagle’s essential medium

(DMEJ supplemented with 10% foetal calf serum (FCS) and 1% L-glutamine. Cultures were incubated at 37°C in an humidified atmosphere of 95% air and 5% CO₂. Cells were detached from tissue culture flasks with 0.1% Trypsin/0.5 mM EDTA. The cell suspension was washed twice in phosphate buffered saline (PBS) and resuspended to the appropriate concentration in PBS.

Initial experiments established that an inoculum of $1 \times 10^5$ to $1 \times 10^6$ cells in 100 μl PBS injected into the sponge 3 to 4 days post sponge implantation gave a 100% tumour take. The tumours were palpable between 12 and 14 days following cell injection.

**Blood flow measurement**

Blood flow measurement was performed as described previously (Mahadevan et al., 1989, 1990). Ten μl of $^{133}$Xe solution in physiologic saline were injected into the centre of the implanted sponge and the washout of radioactivity was monitored at intervals of 1 min for 10 min. The counts were analysed by a Macintosh-Apple computer programme to derive the $T_1$ for $^{133}$Xe clearance from the exponential curve fit.

**Estimation of $^{133}$Xe clearance from sponge implants following tumour cell inoculation**

Sterile sponges were implanted in 20 animals. On day 3 post-implantation, (a) seven animals received injections into the sponge, each of $1 \times 10^6$ Colon 26 cells in 100 μl of PBS, (b) a further seven animals each received $1 \times 10^6$ Colon 26 cells in 100 μl of PBS, and (c) the remaining six animals (control group) were each injected with 100 μl of PBS into the sponge.

Clearance of $^{133}$Xe from implanted sponges was measured on days 4, 6, 11 and 15 post-tumour cell injection.

**Protamine or FAA treatment**

To monitor the effects of protamine and FAA on the development of tumour vascularisation sponges were implanted into 15 animals. Three days after sponge implantation each animal was injected with $1 \times 10^6$ Colon 26 cells in 100 μl of PBS into the centre of the sponge and the mice were assigned arbitrarily to three groups ($n = 5$ per group).

On the next four successive days animals in Group 1 received i.p. injection of FAA, 150 mg kg$^{-1}$ day$^{-1}$; animals in Group 2 received i.p. injections of protamine, 50 mg kg$^{-1}$ day$^{-1}$ and control animals in Group 3 received i.p. injections of similar volumes of saline diluent. Blood flow was measured 3, 6 and 10 days after completion of drug treatment.

The effect of FAA on blood flow of established tumours was assessed by implanting sponges into 20 animals and establishing tumours as detailed above. Fourteen days after cell injection, when all animals had palpable tumours, ten animals received a single i.p. injection i.p. of FAA (200 mg kg$^{-1}$) while ten animals were injected i.p. with a similar volume of saline diluent. Blood flow was assessed on days 1 and 2 post-drug injection.

**Measurement of tumour volume**

Calipers were used to measure the tumours in two dimensions and volumes were calculated from the formula $\frac{a^2 \times b}{2}$

where 'a' and 'b' are the minor and major dimensions respectively (Bibby et al., 1988a).

**Blood flow in non tumour-bearing sponges after FAA administration**

Fifteen animals received sponge implants. Twenty eight days later animals in Group 1 ($n = 5$) received a single i.p. injection of FAA at 200 mg kg$^{-1}$, animals in Group 2 ($n = 5$) received a single i.p. injection of FAA at 250 mg kg$^{-1}$ and animals in Group 3 ($n = 5$) were injected with saline diluent. Blood flow measurements were recorded 4 h post drug injection.

**Statistical evaluation**

All statistical comparisons were made using Student's t-test.

**Results**

**Effect of tumour development on blood flow**

The effects of tumour growth on $^{133}$Xe clearance are illustrated in Figure 1. Developing tumour, whether initiated by the injection of $1 \times 10^5$ or $1 \times 10^6$ cells, caused a significant reduction in mean $T_1$ such that 7 days after sponge implantation (4 days after cell injection) the $T_1$ was 14–15 min compared with 27 min in the control sponges, while on day 14 post-sponge implantation the respective values were 8 min and 21 min ($P < 0.01$).

**Effect of FAA and Protamine Treatment**

Figure 2 depicts the effect of FAA on tumour blood flow depending on whether it was delivered 'early' or 'late' in tumour development. Four consecutive daily injections of FAA initiated 1 day after the implantation of the neoplastic cells had no significant effect on $^{133}$Xe clearance times from the developing tumour when compared to saline treated controls (e.g. $T_1$ at 10 days post sponge implantation was 16 min for FAA vs 14 min for saline-treated sponges). By comparison a single injection of FAA on day 17 after sponge implantation, and 14 days after tumour cell injection, resulted 1 day later in a highly significant ($P < 0.001$) prolongation of $T_1$ from 7 min for control animals to 47 min for FAA treated animals (Figure 2).

In contrast to the lack of effect manifested by multiple injections of FAA early in tumour growth Protagmine given at the same points in time caused a significant extension of $T_1$ times. Thus on days 10 and 13 post-sponge implantation proctamine-treated animals showed mean $T_1$ values of 27.5 ± 5.3 min and 22.8 ± 2.7 min which differed significantly

![Figure 1: Clearance of $^{133}$XE from sponges in absence and presence of tumour. Each point for the non-tumour bearing sponges (□) was derived from six individual animals; vertical bars indicate standard errors about the mean. Tumours were initiated by the intrasponge injection of $1 \times 10^6$ (■) or $1 \times 10^5$ (▲) cells ($n = 7$ group). Since animals had to be killed by day 18 post sponge implantation, owing to tumour burden, blood flow estimates were not possible past this time in these groups. Arrow indicates day of tumour cell injection.](image-url)
from corresponding control values at levels of \( P < 0.05 \) and \( P < 0.01 \) respectively.

The effect of administration of FAA or protamine early in the course of tumour growth on subsequent tumour volume is presented in Table I. While the mean tumour volumes of FAA-treated animals were always less than those of the saline-treated control group these differences were not significant. Similarly the volumes recorded for the protamine treated group were also less than the control group values and, at 21 days post sponge implantation, this difference was significant (\( P < 0.05 \)) (Table I).

**Effect of FAA on vascularised non-tumour bearing sponges**

The results of this experiment are presented in Table II. The mean \( T_1 \) values obtained for the two groups injected with FAA were not different from the \( T_1 \) values recorded for the control group.

**Discussion**

We previously have used the \(^{133}\text{Xe} \) clearance technique as the basis for developing a dynamic assessment of blood flow (Mahadevan *et al.*, 1989) and have shown, using this assay, that FAA acts to shut down tumour vascularity via the effects of TNF-\( \alpha \) (Mahadevan *et al.*, 1990).

Using this technique we now show that the effect of FAA is dependent on an established microvasculature within the neoplasm. Thus FAA given prior to the development of vascularisation brought about no prolongation of \( T_1 \) times (Figure 2) nor did it retard tumour growth (Table I). In contrast to these results protamine, which has been shown to be capable of inhibiting the angiogenic response and thereby limiting tumour growth (Taylor & Folkman, 1982; Folkman, 1985), brought about significant inhibition of tumour blood flow development, and retarded tumour growth (Figure 2, Table I).

By 18 days post sponge implantation, at a time when full vascularisation of the sponge/tumour had been achieved (Figure 1), a single dose of FAA produced a highly significant reduction in \(^{133}\text{Xe} \) clearance compared with controls (Figure 2). This inhibition of blood flow was persistent even up to 10 days after drug administration (data not shown). In our previous report we showed that these reductions in vascular flow were associated with a drastic limitation in the size of the treated tumours (Mahadevan *et al.*, 1990).

It seems clear from these experiments that the efficacy of FAA in acting against a sensitive tumour is dependent upon there already being an established microvasculature. Certainly this could account for the observations that FAA is more effective against late stage disease (Bibby *et al.*, 1988b) and help to explain the variation in response to FAA shown by tumours in distinct anatomical locations (Bibby *et al.*, 1989b; Finlay *et al.*, 1988). Interestingly the age, or the development, of the microvasculature per se is not the sole determinant in regulating FAA activity. Thus when fully vascularised sponges, showing similar \( T_1 \) values to those observed in established tumours, were utilised FAA had no effect on blood flow. Since the effects of FAA are mediated, in part at least, via the cytokine TNF-\( \alpha \) (Smith *et al.*, 1987; Mace *et al.*, 1990; Mahadevan *et al.*, 1990) it may be that differences in either the production of or the response to, this molecule underlie the divergent response.

The major source of TNF-\( \alpha \) is the macrophage (Le & Vilcek, 1987). TNF-\( \alpha \) is a multifunctional protein with important biological effects on a variety of target cell types, including the vascular endothelium (Le & Vilcek, 1987). TNF-\( \alpha \) induces endothelial cells to elaborate a tissue factor-like procoagulant, and to suppress an essential anti-coagulant co-factor synthesised by endothelial cells (Fajardo, 1989), thereby causing intravascular thrombosis (Fajardo, 1989). Thrombotic occlusion of the vascular bed is believed to be the mechanism underlying TNF-\( \alpha \)-induced haemorrhagic necrosis of tumours (Smith *et al.*, 1987; Nawroth *et al.*, 1988). In support of this hypothesis, Nawroth *et al.* (1988) showed that tumour-bearing mice anticoagulated with coumarin, exhibited significantly less tumour necrosis in response to

**Table II** Effect of i.p. FAA on the clearance of \(^{133}\text{Xe} \) from vascularised, non-tumour-bearing sponges

| Treatment              | Mean \( T_1 \) (min) ± s.e.m. \( (n) \) at 4 h post injection |
|------------------------|-------------------------------------------------------------|
| FAA (200 mg kg\(^{-1}\)) | 6.8 ± 1.1                                                   |
| FAA (250 mg kg\(^{-1}\)) | 7.0 ± 1.0                                                   |
| Saline                 | 7.2 ± 1.0                                                   |

Animals (five per group) were injected with the appropriate agent 28 days after sponge implantation as detailed in the text.

**Table I** Effect of FAA and protamine on tumour volume

| Days Post Sponge implantation | Mean Tumour Volume \((\text{cm}^3)\) ± s.e.m. | Protamine\(^a\) | FAA\(^a\) | Saline\(^b\) (Control) |
|-----------------------------|------------------------------------------|----------------|----------|---------------------|
| 17                          | 0.9 ± 0.2 \((5)\)                       | 1.4 ± 0.2 \((5)\) | 1.7 ± 0.4 \((5)\) | 4.8 ± 0.4 \((5)\) |
| 21                          | 1.9 ± 0.2 \((5)\)                       | 2.8 ± 0.4 \((5)\) | 3.8 ± 0.8 \((5)\) | 7.0 ± 1.0 \((5)\) |
| 25                          | 3.7 ± 0.7 \((5)\)                       | 5.55 ± 0.6 \((5)\) | 5.7 ± 1.3 \((5)\) |                     |

\(^a\)Animals were injected with the appropriate agent on four successive days after the implantation of tumour cells as detailed in Materials and methods. Numbers in brackets represent individual animals monitored. \(^b\)Significantly different from saline control values (\( P < 0.05 \)) by Student’s \( t \)-test.
TNFα when compared with non-anticoagulated control animals.

It has been shown that some tumours may be composed of a large macrophage population of macromolecules in 65% for example (Russell et al., 1980). The granulation tissue occupying the implanted sponge may not possess the same large macrophage content as is present in the Colon 26 tumour. Accordingly, the divergent responses to FAA seen between tumour-bearing and non-tumour-bearing sponges (Figure 2, Table II) may reflect variation in levels of local TNFα production as a consequence of cellular composition. Alternatively, it may be that local TNFα production are comparable but that the responses of tumour vessels and normal vessels are different. In this context, it is interesting to note that Nawroth et al. (1988) found that the vascular bed in a murine fibrosarcoma, but not adjacent normal microvasculature, was susceptible to the thrombogenic effect of systemically-administered TNFα. These authors showed also that a soluble factor derived from the fibrosarcoma cells in culture, and devoid of intrinsic procoagulant activity, potentiated significantly the induction of endothelial tissue factor by TNFα (Nawroth et al., 1988). Recently Murray et al. (1989) observed that FAA activated the process of coagulation both in tumour-bearing and non-tumour-bearing mice. However, the intensity of this effect was greater in the tumour-bearing animals. Furthermore, the transient nature of the coagulopathy in non-tumour bearing animals contrasted sharply with the prolonged effects on coagulation in animals with tumours (Murray et al., 1989).

Whatever the basis of the observed response it is clear from our studies that FAA does not inhibit the development of tumour blood vessels but acts against established tumour, but not normal, microvasculature.
