We analyze transitions between quantum Hall ground states at prominent filling factors \( \nu \) in the spherical geometry by tuning the width parameter of the Zhang-Das Sarma interaction potential. We find that incompressible ground states evolve adiabatically under this tuning, whereas the compressible ones are driven through a first order phase transition. Overlap calculations show that the resulting phase is increasingly well described by appropriate analytic model wavefunctions (Laughlin, Moore-Read, Read-Rezayi). This scenario is shared by both odd \((\nu = 1/3, 1/5, 3/5, 7/3, 11/5, 13/5)\) and even denominator states \((\nu = 1/2, 1/4, 5/2, 9/4)\). In particular, the Fermi liquid-like state at \( \nu = 1/2 \) gives way, at large enough value of the width parameter, to an incompressible state identified as the Moore-Read Pfaffian on the basis of its entanglement spectrum.

We address in this work, via large-scale exact diagonalization (ED) calculations on finite spheres, the important and interesting question of how to tune various fractional quantum Hall (FQH) ground states between ungapped compressible and gapped incompressible phases by continuously varying the effective electron-electron interaction. Such numerical studies have been a standard theoretical tool in FQH physics since the beginning because of the non-perturbative nature of the FQH ground states. In the current work, which is complementary to the pseudopotential description of quantum phase transitions (QPT) in quantum Hall systems as pioneered by Morf and Haldane, we report that a simple single-parameter parametrization of the effective interaction through the so-called Zhang-Das Sarma (ZDS) model provides a flexible and powerful method of studying QPTs between compressible and incompressible phases at both even and odd denominator FQH states. We will show that ZDS interaction possesses a rich structure that can drive the FQH system from parameter regions where it appears to be compressible (manifested by the ground state that breaks rotational invariance i.e. the value of angular momentum \( L \neq 0 \)) towards the incompressible region where the ground state is rotationally invariant \((L = 0)\), along with the corresponding overlap with the trial states like Laughlin or paired states (Moore-Read Pfaffian, Read-Rezayi etc.) jumping to a value close to unity and an energy gap opening up in the excitation spectrum. In agreement with the experimental phenomenology, we find that the well-known (small) odd-denominator incompressible FQH states (e.g. \( 1/3, 1/5, 7/3, 11/5 \)) are robust and usually do not manifest any interaction-tuned QPT whereas the more fragile, even denominator (e.g. \( 1/2, 1/4, 5/2, 9/4 \)) FQH states typically exhibit characteristic QPT from a compressible to an incompressible phase as the Coulomb interaction is softened by increasing the ZDS tuning parameter.

Our calculations are performed in the spherical geometry introduced and described in detail by Haldane here we make only a few essential comments. We consider spin to be fully polarized and use the ZDS model interaction which was originally proposed to study the finite thickness effect of the quasi two-dimensional layer but in our analysis, the thickness parameter \( w \) (expressed in units of the rescaled magnetic length, \( l_B \)) enters simply as the tuning parameter for the Hamiltonian:

\[
V_{ZDS}(r) = \frac{1}{\sqrt{r^2 + w^2}}. \tag{1}
\]

We emphasize that the ZDS interaction appears to have the same qualitative pseudopotential decomposition as the realistic models (e.g. the Fang-Howard, infinite square well, etc.), as has recently been shown in details in Ref. 7. However, it was also observed in Ref. 8 that realistic confinement models do not always reproduce the QPTs induced by the ZDS interaction, suggesting there may be subtle quantitative differences between ZDS and alternative confinement models which are important in the vicinity of a QPT. In this paper we focus on the ZDS model in carrying out our ED studies since a single parameter enables us to study FQH QPTs in a compact manner. In order to establish the connection with the experiments, we should mention that \( w \) in the ZDS model corresponds roughly to the root-mean-square fluctuation in the electron coordinate in the transverse direction.

With this choice of the interaction, we use the overlap between the exact, numerically diagonalized finite sys-
tem, and a candidate analytical wavefunction (e.g. the Laughlin or the Moore-Read wavefunction) to determine the tentative quantum phase of the system, i.e. if the overlap is ‘large’ (‘small’), the system is supposed to be in the candidate state (or not). We calculate the overlap as a continuous function of the varying Hamiltonian which is being tuned by $w$. All the model wave functions studied in this paper are Jack polynomials that have squeezable configurations which can be efficiently generated and compared with the exact ground state. Note that each FQH state on a finite sphere at the filling factor $\nu$ is characterized, beside the number of electrons $N$ and the number of flux quanta $N_\phi$, also by a topological invariant $\delta$ called shift, defined by $N_\phi = \nu^{-1} N + \delta$. In the thermodynamic limit of an infinite plane, the shift plays no role, but for a finite sphere it is a crucial aspect of the ED technique as it can lead to an “aliasing” problem: at a fixed choice of $(N_\phi, N)$, more than one quantum Hall state (having different $\nu$, $\delta$ and, therefore, different physical properties) may be realized. To avoid such loss of uniqueness for finite sphere ED, we disregard the aliased states from our considerations. Notwithstanding the aliasing problem, the system sizes we analyze are the largest that can be presently handled in ED studies.

We begin with the Laughlin fractions $\nu = 1/3$ and $\nu = 1/5$ in the lowest Landau level (LLL) and in the first excited Landau level ($\nu = 2 + 1/3, 2 + 1/5$), Figs. 1, 2. In agreement with previous studies, we find that the ZDS potential leads to the monotonous decrease in the overlap with the Laughlin wave function with increasing the thickness parameter $w$.

It will be shown in what follows that the induced QPT for $N = 5, \nu = 7/3$ is not an exceptional case. Even denominator fractions, such as $\nu = 5/2$ which is believed to be the Moore-Read Pfaffian or the recently discovered $\nu = 1/4$ and various paired states of the Read-Rezayi sequence like $\nu = 12/5, 13/5$, attract considerable attention because of their unusual ground states and the exotic spectrum of excitations that may be utilized in topological quantum computation. While their realization in the SLL seems a likely possibility, there has been little expectation to observe them in the conditions of the LLL (see however Ref [13]). In particular, at the thin single-layer $\nu = 1/2$ in the LLL only the compressible, Fermi-liquid like state has been observed. In Fig. 3 we show the overlap results of finite-size calculations on $\nu = 1/2$ in the LLL and $\nu = 5/2$ in the SLL with ZDS interaction.

At $\nu = 1/2$ a QPT is induced by increasing the parameter $w$. Certain particle numbers yield good overlap already for zero thickness and their overlap will improve as $w$ increases. Other particle numbers produce ground states with well-defined values of $L > 0$ that undergo a QPT at a critical value of the thickness. For $\nu = 5/2$, the Coulomb ground state for zero thickness is already reasonably well approximated by the Moore-Read Pfaffian and the effect of ZDS interaction is only to increase the overlap in a smooth way. However, the
increase is substantial – up to 20% for the largest system amenable to ED. This adiabatic continuity of the Moore-Read description for the SLL $\nu = 5/2$ has been discussed in Ref. 16 and recently at great length by Storni et al.\textsuperscript{17}

The non-zero values of $L$ that appear at $\nu = 1/2$ in the LLL can be fully understood from the CF theory\textsuperscript{18}. Indeed, former work hinted at the possibility of $p$-wave paired CF state as a result of CF sea being perturbed by ZDS interaction\textsuperscript{19}. However, in Ref. 19 only the variational energies of trial states were compared. In Fig. 4 we will show that one can establish a connection between the ZDS-induced QPT and the Pfaffian and CF sea states in the LLL at $\nu = 1/2$.

Because the CF sea state and the Moore-Read Pfaffian occur at different shifts on the sphere (-2 and -3, respectively), one cannot simultaneously study their evolution with $w$. However, by analyzing the excitations of CF sea occurring at the Pfaffian shift, one can show (using Hund’s rule) that the $L$ values obtained in ED at the Pfaffian shift (Fig. 3) are indeed those stemming from the CF sea excitations. Moreover, assuming that the Coulomb ground state in the LLL for zero thickness is exceedingly well approximated by Rezayi-Read wave function\textsuperscript{20}, we define the CF sea state for our purposes as the interacting Coulomb ground state for zero thickness and study its overlap with the $w \geq 0$ ground states, Fig. 4. CF theory tells us that (at the shift of -2) the $L = 0$ configurations are obtained when the CF shells are completely filled i.e. for $N = n^2$, $n = 1, 2, 3, \cdots$. These configurations are particularly robust and adding/subtracting electrons from them ($\Delta N = N - n^2 = \pm 1, \pm 2, \cdots$) creates a configuration that is destroyed at some critical value of the width which depends on how far away the system is from the filled shell. Obviously, there is ambiguity in defining precisely the critical width where the CF sea is destroyed, but this argument nonetheless provides further support for the claim that the ZDS-induced compressible–incompressible transition indeed proceeds via destruction of CF sea towards the Moore-Read Pfaffian. Transition of the same kind can be relevant for the multicomponent candidates\textsuperscript{21} at $\nu = 3/8$. We emphasize that the possible finite-width-induced LLL $\nu = 1/2$ FQH state that we find arising out of the destabilization of the CF sea, even if it exists, is likely to be extremely fragile with a neutral excitation gap smaller than $0.03\epsilon_l/\ell_B$. However, numerically extrapolated gap is generally known to be difficult to relate to the experimental value$^{22}$ and in our data we cannot rule out the possibility that it goes to zero in thermodynamic limit.

Another way to look at the QPT towards the Moore-Read Pfaffian is to analyze the entanglement spectrum proposed in Ref. 23. This is a powerful way to identify topological order in the given ground state wave function and establish a direct connection with the underlying CFT that produces the given ground state as its correlator and thus offering more information than the simple overlap calculation.\textsuperscript{24} In Fig. 4 we show the change in the entanglement spectrum for $N = 18$ particles at $\nu = 1/2$ in the LLL, before and after QPT. For $w < \ell_B$, there is no visible CFT branch in the entanglement spectrum – the generic Coulomb part dominates, leading to a likely compressible ground state. After the QPT, a CFT branch separates from the Coulomb part of the spectrum and the level counting begins to match the first few Virasoro levels of the Ising CFT. This is additional evidence in favor of the possibility of a finite-width-induced QPT to an incompressible half-filled single-layer LLL FQH state.
FIG. 5: Entanglement spectrum of the exact ground state for \( N = 18 \) particles at \( \nu = 1/2 \) in the LLL, just before \( (w/l_B = 0.8) \) and after \( (w/l_B = 1.0) \) the QPT, and the spectrum of Moore-Read Pfaffian for comparison. Vertical axes show the quantity \( \xi = -\log \lambda_A \), where \( \lambda_A \) are the eigenvalues of the reduced density matrix of the subsystem \( A \) which comprises of 8 particles and 15 orbitals, given as a function of angular momentum \( L_z^A \). Data shown is only for the partitioning denoted by [00] in Ref. 22; other sectors give a similar result.

that the usual odd denominator states are robust in both the LLL and the SLL, whereas the fragile even denominator FQH states are stable only in a regime of the interaction strength where the bare electron-electron interaction is considerably softer than the pure 2D Coulomb interaction. We find that the ZDS interaction allows for the existence of non-Abelian incompressible FQH states even at unusual even fractions such as 1/2, 1/4, and 9/4, raising the intriguing possibility that such exotic non-Abelian states may indeed exist if one can sufficiently soften the interaction along the ZDS prescription. Whether this can be physically achieved in 2D semiconductor systems remains an interesting open question and may require some ‘reverse engineering’ of the quasi-2D samples to achieve a suitable density profile using the fact that the width parameter in the ZDS model corresponds roughly to the variance of the electron position in the transverse direction.

11. Another example where ZDS potential “rectifies” the problem of compressibility is the supposedly interacting composite fermion (CF) state at \( \nu = 4/11 \) where the ground state for \( N = 8 \) electrons is compressible with \( L = 2 \). We have verified that turning on ZDS potential in this case causes a QPT to the \( L = 0 \) state beyond \( w \sim 4l_B \).
