Acute myocardial infarction (AMI) is a common and lethal heart disease, and the recruitment of fibroblastic cells to the infarct region is essential for the cardiac healing process. Although stiffness of the extracellular matrix in the infarct myocardium is associated with cardiac healing, the molecular mechanism of cardiac healing is not fully understood. We show that periostin, which is a matricellular protein, is important for the cardiac healing process after AMI. The expression of periostin protein was abundant in the infarct border of human and mouse hearts with AMI. We generated periostin−/− mice and found no morphologically abnormal cardiomyocyte phenotypes; however, after AMI, cardiac healing was impaired in these mice, resulting in cardiac rupture as a consequence of reduced myocardial stiffness caused by a reduced number of α smooth muscle actin–positive cells, impaired collagen fibril formation, and decreased phosphorylation of FAK. These phenotypes were rescued by gene transfer of a spliced form of periostin. Moreover, the inhibition of FAK or αv-integrin, which blocked the periostin–promoted cell migration, revealed that αv-integrin, FAK, and Akt are involved in periostin signaling. Our novel findings show the effects of periostin on recruitment of activated fibroblasts through FAK–integrin signaling and on their collagen fibril formation specific to healing after AMI.
the scar phase of an ischemic injury?” and “what is the nature of the factors responsible for the ventricular healing process after AMI?” we focused on periostin, which is a TGFβ-responding factor (1).

RESULTS AND DISCUSSION

To assess the importance of periostin in the cardiac healing process, we examined the expression of human periostin protein in the myocardial tissue of the left ventricle (LV). No expression of it was observed in the normal myocardium (Fig. 1 A), whereas immunoreactivity indicating periostin was detected in Azan-stained myocardial fibrous areas from a patient with AMI (Fig. 1, B and C), thus suggesting that periostin expression was induced in the infarct regions after AMI. In the fibrous area, strong immunoreactivity of periostin was observed around cardiac fibroblasts expressing αv-integrin, which is reported to be a receptor for periostin (Fig. 1 C) (2, 6). Next, we examined the expression of periostin in mice after AMI caused by left anterior descending artery (LAD) ligation (24). Periostin protein was not observed up to day 2, but became detectable at day 3 in the areas showing inflammatory infiltration (Fig. 1 D). This expression in the infarct LV increased significantly at day 4, and was still present at day 28 (Fig. 1 D and not depicted). To identify the cells producing periostin, we performed RNA in situ hybridization to detect periostin mRNA in the infarct LV wall of mice. Periostin mRNA was mainly expressed in fibroblasts in both the infarct and noninfarct regions after AMI (Fig. 1 E).

To confirm the periostin expression in cardiac fibroblasts, we performed RT-PCR analysis on purified cardiac cells, and these results showed the expression to be mainly in cardiac fibroblasts, but not in cardiomyocytes (Fig. S1, available at http://www.jem.org/cgi/content/full/jem.20071297/DC1). Furthermore, these fibroblasts were positive for αv-integrin, as indicated by flow cytometry using cultured cardiac cells (Fig. S1). The mRNA of βig-h3, another fasciclin family member, which is also expressed in the embryonic heart (25), was not observed in

Figure 1. Periostin expression is induced after myocardial ischemia. (A–C) Detection of periostin in myocardium from human patients. LV tissue from a patient with alcoholic cirrhosis (A) and from a patient with AMI (B and C). As seen by immunostaining, periostin protein was detected (B, right) in the myocardial area, which was shown to be fibrous by Azan staining (B, left). Arrowheads in B indicate endocardium. (C) Comparison of the expression pattern between periostin (left) and αv-integrin (right) in the fibrous area. (D–F) Periostin is up-regulated after AMI in mice. (D) Immunostaining of periostin after AMI. (E) Expression of periostin (top) and βig-h3 mRNA (bottom) in the infarct LV wall of mice was analyzed by in situ hybridization. The dashed red line shows the infarct border. (F) Expression of spliced variant forms of periostin at various times after AMI. Periostin ΔΔΔ is indicated by the asterisk. Bars: (A) 25 μm; (B) 2 mm; (C–E) 50 μm.
the same regions (Fig. 1 E), thus suggesting the AMI-induced expression of fascin family molecules to be specific to peristin.

Because we previously reported that several peristin transcripts exist in human and mouse, caused by alternative splicing at a 3′ site (1), we examined the expression of the splice variants in a time course experiment by RT-PCR analysis using three combinations of specific primers (Fig. 1 F). We observed four different isoforms, i.e., Δb (deletion of b domain), Δe (deletion of e domain), ΔbΔe (deletion of b and e domains), and Full (full-length), and we found that the pattern of splicing depended on the time after AMI. Interestingly, one specific spliced form, ΔbΔe (Fig. 1 F, asterisk), was dominantly found as the lowest electrophoretic band in the initial stages (3, 4, and 5 d after AMI), indicating the involvement of ΔbΔe peristin in the early healing stage of damaged tissues. By 28 d, all 4 isoforms were equally expressed. We also confirmed the expression of these isoforms at the protein level, and found the proteolytic modification of peristin during infarct healing (Fig. S1).

To investigate the role of peristin in AMI, we generated peristin−/− mice combined with Cre recombination (Fig. 2 A and Fig. S2, available at http://www.jem.org/cgi/content/full/jem.20071297/DC1). The embryogenesis of peristin−/− mice was apparently normal; and after the birth, the mice appeared to be healthy. The observation of peristin in the developing heart prompted us to thoroughly investigate the heart structure and function in the peristin−/− mice; however, no cardiomyocyte abnormalities were found in the myocardium, valve function, pulsation, or blood pressure in the 10-wk-old mice (Fig. S2 and not depicted), which is consistent with no significant expression in the adult myocardium. We then subjected peristin−/− mice to AMI by LAD ligation. There was no significant difference in body weight or heart rate among −/−, +/−, and +/+ in the normal control condition or after the AMI (Fig. S2, Table S1, and not depicted); moreover, there was no difference in infarct size between the peristin+/+ and −/− mice after AMI (Table S1). However, the survival rate of peristin−/− mice after AMI was significantly lower than that of +/+ mice (17.58 vs. 53.76% at day 10; P < 0.0001; Fig. 2 B), whereas this rate of peristin+/+ mice (55%) after AMI was similar to that of +/+ mice. The incidence of mortality in peristin−/− mice, mainly caused by cardiac rupture, which occurred within 7 d, was significantly higher (P < 0.001) than that of +/+ mice: 62/91 (68.1%) in −/− versus 25/80 (31.3%) in +/− (Fig. 3 C), whereas this frequency of +/− mice 6/20 (30%) was similar to that of +/+ mice. Therefore, these survival rates reached a plateau from 8 d up to 4 wk after AMI (unpublished data). To test whether the increased rate of cardiac rupture was caused by abnormal LV wall stiffness, we analyzed the rupture threshold stiffness of the LVs of peristin−/− and +/+ mice 4 d after AMI by conducting an LV distending pressure/rupture threshold study (18). Myocardial tearing was found at the infarct border in all the ruptured LVs, and the mean of the maximum rupture pressure was significantly lower in peristin−/− mice than in +/+ mice after AMI (50.26 ± 2.13 mmHg/100 μl in −/− vs. 65.08 ± 2.55 mmHg/100 μl in +/+; P = 0.001; n = 5; Fig. 2 C). In contrast, no significant difference was observed between +/− control noninfarct mice and peristin−/− control noninfarct mice (maximum rupture pressure was 544.0 ± 6.93 mmHg in −/− vs. 552.7 ± 7.86 mmHg in +/+; P = 0.4546; n = 5; mean passive stiffness was 87.07 ± 4.41 mmHg/100 μl in −/− vs. 88.5 ± 3.14 mmHg/100 μl in +/+; P = 0.5985; n = 5). These biomechanical data indicate that both rupture threshold and passive stiffness in the LV of the peristin−/− infarcted mice were significantly lower than those of the +/− mice after AMI, suggesting that the peristin−/− infarct LV wall was more susceptible to cardiac rupture by mechanical stress. Although peristin deficiency did not affect heart structure, the circulatory system, or cardiac performance under physiological conditions, peristin induced in the infarct myocardium appears to play a pivotal role in the healing process after AMI.

To confirm the histomorphological stiffness of the wall in peristin−/− mice just escaping from rupture, we performed echocardiography 7 d after AMI, in addition to 1 d for heart tissue evaluation and 28 d for the analysis of chronic cardiac pathophysiology after AMI (Fig. 2 D and Table S1). Echocardiographic measurements made 7 d after AMI showed decreases in left ventricular end-diastolic dimension (LVEDD) and left ventricular end-systolic dimension (LVESD) in peristin−/− mice (n = 10), as compared with these parameters for +/+ mice (n = 15; LVEDD and LVESD values for −/− were 89.0 and 84.4%, respectively, of those for +/+). These results demonstrate that the absence of peristin attenuated ventricular remodeling after AMI. To further examine tissue stiffness histologically, we performed toluidine blue staining, immunofluorescence analysis using anti-collagen I, -fibronectin, and -vimentin antibodies, and transmission electron microscopic (TEM) observation of sections prepared from peristin+/+ and −/− mice 5 d after AMI. The results showed a lower number of cardiac fibroblasts, along with sparser pericellular ECM density in the peristin−/− mice than in the +/+ mice (Fig. 2, E and F); indeed, the number of vimentin-positive cardiac fibroblasts was decreased in the infarct region of peristin−/− mice 5 d after AMI (7,655 ± 148 cells/mm² in +/+ vs. 6,913 ± 297 cells/mm² in −/−; n = 6; P < 0.02; Fig. 2 C). Furthermore, reduced collagen I and fibronectin immunoreactivity was observed in the infarct border of the −/− mice (Fig. 2 F and Fig. S3, available at http://www.jem.org/cgi/content/full/jem.20071297/DC1), and the collagen fiber cross-sectional area (CSA) in the infarct border of peristin−/− mice was significantly smaller and more uniform than that of +/+ mice 5 d after AMI (CSA of 1,014.6 ± 17.546 mm² for the −/− and 2,233.780 ± 25.731 mm² for the +/+; n = 6; P < 0.001, respectively; Fig. 2 G). To confirm whether peristin deficiency affected the biochemical property of collagen after AMI, we evaluated the amount of collagen (hydroxyproline concentration, percentage of tissue dry weight) and nonreducible mature cross-links (mol pyridinoline per mol collagen) in the infarct zone 4 d after AMI. We detected a significant decrease in the collagen cross-linking in the peristin−/− mice, compared with the +/+ mice.
Figure 2. Cardiac rupture after AMI is caused by periostin disruption. (A) Schema of the targeting strategy deletes the first exon of periostin locus. (B) Decreased survival of periostin−/− mice (n = 91) compared with the survival of +/+ mice (n = 80) after AMI. **, P < 0.0001. (C) Infarct LV wall stiffness was more reduced in periostin−/− mice than in +/+ mice after AMI (left). Mean passive stiffness was also significantly lower in the −/− mice than in the +/+ mice after AMI (right). Open columns, +/+; filled columns, −/−. **, P < 0.005, compared with +/+ mice. (D) Loss of periostin attenuated cardiac dilation after AMI, as shown by echocardiography. Open columns, +/+; filled columns, −/−. *, P < 0.05 compared with +/+ mice. (E) Histological analysis of heart sections from periostin−/− and +/+ mice stained with toluidine blue 5 d after AMI, showing a lower number of cardiac fibroblasts and lower ECM density in −/− mice. (right) The number of vimentin-positive cells. *, P < 0.02, compared with +/+ mice. (F) Images of the infarct border stained with anti-collagen I (left), and TEM images of infarct border, showing evidence of smaller and less abundant collagen in tissues from periostin−/− mice 5 d after AMI compared with the collagen of the +/+ infarct heart. Bar, 50 μM. (G) CSA distribution of collagen fibrils in the infarct border of +/+ and −/− mice, measured from TEM images. (H) Biochemical analysis of the collagen amount and cross-linking. *, P < 0.05; **, P < 0.01, compared with +/+ mice. (I) The number of αSMA-positive cells in the infarct area was reduced in periostin−/− mice 5 d after AMI. (right) The number of αSMA-positive cells. **, P < 0.01, compared with +/+ mice. Error bars represent the mean ± the SEM. Bars, 200 μM.
(1.555 ± 0.461 in −/−, n = 4, vs. 6.433 ± 0.919 in +/+ , n = 7; P = 0.0043; Fig. 2 H). Moreover, the periostin−/− infarct LV tissue exhibited 52.9% less collagen content compared with the +/+ tissue (7.832 ± 2.241% in −/−, n = 4, vs. 14.795 ± 1.565% in +/+ , n = 7; P = 0.0283; Fig. 2 H). In normal heart tissues from mice of either genotype, the collagen amount was under the detection level by our methods (unpublished data), indicating that the detected collagen was newly produced after AMI. In conclusion, we observed the alterations of collagen structure in the periostin−/− mice; they were smaller and more uniform, with the decreased amount and cross-linking of collagen effecting lower stiffness. These results suggest that periostin expression contributed significantly to the amount or cross-linking of newly synthesized collagen, which is essential for the normal mechanical properties of collagen-containing tissues after MI. These findings indicate that impaired collagen fiber formation occurred in periostin−/− mice after AMI. Interestingly, although the total activity of myeloperoxidase and the numbers of Mac-3–positive inflammatory cells, ki67–positive proliferating cells, and active caspase-3–positive apoptotic cells in the infarct border were not significantly different between +/+ and −/− mice (not depicted), we observed a lower number of αSMA–positive cells in the infarct area of periostin−/− mice 5 d after AMI (1,792 ± 193 cells/mm² in +/+ vs. 758 ± 75 cells/mm² in −/−; P < 0.01; n = 6; Fig. 2 I).

Figure 3. Adenovirus-mediated periostin ΔbΔe gene transfer prevents cardiac rupture in the periostin−/− mice. (A) Whole-mount X-gal staining 4 d after AMI showed strong expression in the border of the Ad-nls-LacZ–infected myocardial infarct (arrowheads). The arrow indicates the ligated portion. (B) Western blot analysis for Ad−ΔbΔe–infected periostin−/− infarct LV. (C) Infection with Ad−ΔbΔe reversed the high incidence of cardiac rupture in the periostin−/− mouse to a lower level, comparable to the incidence in the +/+ mice. *, P < 0.02; **, P < 0.001, compared with control Ad-treated −/− mice. (D) Compared with the Ad-nls-LacZ–infected periostin−/− hearts, the Ad−ΔbΔe–infected hearts increased the number of αSMA–positive cells 5 d after AMI (right) the number of αSMA–positive cells. **, P < 0.01, compared with the mock infection of the −/− mice. Error bars represent the mean ± the SEM. Bars, 200 μm.

However, the number of cells positive for SM1, which is a specific marker of SMCs, was not significantly different, and almost all of the αSMA–positive cells were SM1 negative (unpublished data). These results indicate that not the inflammatory cell recruitment, but rather the recruitment of cardiac fibroblasts in the infarct region, was impaired in these animals.

To determine whether the impaired cardiac healing in response to AMI could be restored by periostin directly, we performed a rescue experiment by using ΔbΔe, which is the main periostin isoform detected early after AMI. The periostin−/− mice were treated with a recombinant adenovirus expressing periostin (Ad−ΔbΔe) or with a control adenovirus (Ad-nls; nuclear localization signal-LacZ). In the control experiment, the Ad-nls–LacZ transfer was detected in the infarct border at 4 d after AMI by whole-mount X-gal staining, proving the experimental feasibility (Fig. 3 A). In periostin−/− mice infected with Ad−ΔbΔe, we first confirmed expression of transferred periostin in the infarct tissue by immunoblot and immunofluorescence analyses (Fig. 3 B and Fig. S4, available at http://www.jem.org/cgi/content/full/jem.20071297/DC1), and then observed an increase in the area reactive with anti-αSMA antibody compared with that area of the control Ad-nls–LacZ–infected periostin−/− mice (597 ± 107 cells/mm² in Ad-nls–LacZ–infected −/− mice vs. 1,535 ± 197 cells/mm² in Ad-nls–LacZ–infected +/+ mice).
Akt was reduced, and only a small amount of phosphorylated FAK was detected in the border of the periostin+/− infarcted mice (Fig. 4, A and B, and Fig. S5).

To further investigate the role of periostin in FAK activation and cell motility, we performed immunofluorescence staining for phosphorylated-FAK and rhodamine-phalloidin staining for the actin cytoskeleton in an embryonic mesenchymal cell line, C3H10T1/2, treated or not with periostin ΔbΔε.

The presence of periostin ΔbΔε changed the cytoskeletal arrangement and motility of the cells, resulting in dynamic protrusion of their processes (Fig. 4 C). In a time-course study, the Ad-periostin ΔbΔε-infected mice showed a significant reduction in rupture frequency compared to the Ad-nls-LacZ-treated mice (35.0%) compared with that for the Ad-nls-LacZ-treated −/− mice (65.0%; Fig. 3 C). These results demonstrate that periostin ΔbΔε was essential for in vivo recruitment of αSMA-positive fibroblasts to block rupture after AMI. As cell motility and morphology of fibroblasts are associated with the expression of the phosphorylated forms of Akt and focal adhesion kinase (FAK) (26, 27), we examined the phosphorylation of these proteins in the infarct border 5 d after AMI. The amount of phosphorylated Akt was reduced, and only a small amount of phosphorylated FAK was detected in the border of the periostin+/− infarcted mice (Fig. 4, A and B, and Fig. S5).

Figure 4. Periostin promotes cell migration through integrin-mediated FAK signaling. (A) Phosphorylation of FAK in infarct LV from periostin+/− mice and −/− mice 5 d after AMI. (B) Immunofluorescence for phosphorylated FAK (p-FAKY397) in the border of infarct LV from periostin+/− mice and −/− mice 5 d after AMI. Merged images show an overlay of p-FAKY397 (green) and propidium iodide–stained nuclei (red). The dotted line shows the infarct border. NIZ, noninfarct zone; IZ, infarct zone. (C and D) Promotion of cell spreading and activation of FAK phosphorylation in vitro. The morphology of starved C3H10T1/2 cells was analyzed by immunofluorescence 12 h after adding periostin ΔbΔε (C), and the p-FAKY397 was examined by Western blot analysis at various times after adding periostin ΔbΔε (D). In C, the merged images show an overlay of p-FAKY397 (green) and rhodamine-phalloidin (red), and the arrows point to FAK phosphorylation sites. The insets show higher magnification of the cell processes. (E) Chemotaxis of primary cardiac fibroblasts from periostin+/− mice in the absence (mock) or presence of periostin ΔbΔε, detected by an in vitro cell migration assay. Cardiac fibroblasts were significantly activated by periostin ΔbΔε, and treatment with neutralizing antibodies against periostin and αv-integrin, PP2, or FAK siRNAs reduced the cell migration. **, P < 0.001 vs. periostin ΔbΔε. Error bars represent the mean ± the SEM. (F) Periostin can stimulate FAK and Akt phosphorylation through integrin signaling. Starved C3H10T1/2 cells were incubated for 1 h with periostin ΔbΔε with or without each siRNA or the FAK and Akt inhibitors. Bars: (B) 100 μm; (C) 20 μm.
experiment, periostin ΔβΔε continuously activated the phosphorylation of FAK for 9 h after the addition of it to serum-starved cell cultures, whereas in the control, the signal had decreased by 6 h (Fig. 4 D). These results demonstrate that periostin ΔβΔε activated FAK phosphorylation and promoted formation of dynamic protrusions. Next, we tested the motility of primary cardiac fibroblasts from periostin-/-/- mice in the presence of periostin ΔβΔε. The result showed that periostin ΔβΔε strongly activated the cell migration of these fibroblasts (Fig. 4 E). Moreover, this migration caused by periostin ΔβΔε was significantly reduced by antibodies against either periostin or αv-integrin; by PP2, which is known as a compound that specifically inhibits adhesion-induced FAK phosphorylation (28); and by knockdown of FAK by siRNA (Fig. 4 E), suggesting that periostin ΔβΔε would activate the cell motility of their fibroblasts by FAK signaling through αv-integrin in mice subjected to AMI. Finally, we inhibited the integrin-mediated FAK pathway by using chemical compounds and siRNAs (Fig. 4 F). FAK inhibitors or siRNA down-regulated the Akt phosphorylation, and Akt inhibitors did not change FAK phosphorylation after stimulation by periostin ΔβΔε, indicating that Akt is a downstream molecule of FAK and periostin ΔβΔε. Moreover, αv-integrin siRNA treatment blocked both FAK and Akt phosphorylation after stimulation by periostin ΔβΔε. These results indicate that periostin ΔβΔε can stimulate FAK and Akt phosphorylation through αv-integrin.

We demonstrated that in the case of periostin deficiency, the collagen amount was reduced in the infarct myocardium, resulting in frequent cardiac rupture in the AMI. Our results, together with the previous findings by Norris et al. (7) on the role of periostin in collagen fibrillogenesis of skin and tendon, strongly suggest that fibrillar collagen formation, which contributes essentially to a mechanically stable scar formation, was impaired in the early stage of MI in the periostin deficiency, resulting in a high rate of cardiac rupture. Furthermore, we have found that the reduced mechanical strength, rupture of the infarct region, and repression of LV dilation in periostin deficiency were most likely caused by a reduced number of cardiac fibroblasts and by the insufficient creation of a durable collagen network caused by a lower rate of collagen synthesis and cross-linking. To reveal more about the importance of collagen production or collagen cross-linking for protection against heart rupture, after AMI, we treated mice with an inhibitor of lysyl oxidase, thus inhibiting collagen cross-linking. Interestingly, the data showed a high amount of collagen production with a larger number of vimentin-positive cells in the infarct region, resulting in effective blockage of heart rupture (unpublished data). These data suggest that periostin-stimulated migration of cardiac fibroblasts into the infarct region, the cells of which produce a high amount of collagen, is more essential than collagen cross-linking by periostin.

The expression of TGFβ was markedly up-regulated in the infarct border during the scar formation phase after AMI, and the phosphorylation of smad 2/3 was consequently increased (unpublished data), whereas there was no significant difference in the TGFβ transcription level between periostin +/- and +/- mice; TGFβ also enhanced the periostin expression in the infarct border after AMI because anti-TGFβ antibody treatment blocked the periostin expression (Fig. S6, available at http://www.jem.org/cgi/content/full/jem.20071297/DC1). The expression of both TGFβ and periostin is up-regulated by angiotensin II and attenuated by angiotensin receptor blockers after AMI (29, 30), suggesting that periostin may play a role via angiotensin II-TGFβ signaling. The combined results on the biomechanical properties and the collagen content of the isolated infarct heart support the concept that the periostin-linked collagen fibrous skeleton is an important determinant of cardiac rupture.

The results given here indicate that periostin signals activate cell migration of cardiac fibroblasts from outside into the infarct region through FAK phosphorylation, and then the migrated cells differentiate into αSMA-positive fibroblasts, resulting in strengthening of the stiffness of the LV wall through collagen synthesis after AMI. FAK is known to be involved in tyrosine phosphorylation during integrin-mediated signaling, and this molecule plays an important role in the response of migrating cells to mechanical stress (31). Recently, FAK has been implicated as a downstream target associated with angiotensin II–stimulated cell migration (32). The mechanism underlying the periostin action of promoting the recruitment of cardiac fibroblasts followed by healing of the infarct region appears to involve activation of the FAK pathway, indicating that the periostin–induced increase in FAK phosphorylation in the infarct myocardium enhanced the motility of these fibroblasts. In contrast, three-dimensional culture studies imply that the matrix stiffness regulates cell fate by modulating integrin signaling (31, 33). Considering these accumulated results, we suggest that periostin is mainly produced by fibroblasts through angiotensin II–TGFβ signaling and may convey pathologically rapid reinforced mechanical signals to FAK-integrin signaling after AMI. The fibroblastic cells activated by these signals secrete periostin, which in turn increases their motility, contractility, and synthesis of ECM proteins, thus promoting further recruitment and activation of fibroblasts. Periostin may serve as the trigger of these feedback mechanisms in the ongoing healing processes. Additional studies to elucidate in more detail the characteristics of cardiac fibroblasts may lead to a deeper understanding of the role of periostin after AMI, as well as aid in identifying the molecular targets of therapies to augment cardiac performance and wall stiffness after AMI.

MATERIALS AND METHODS
Preparation of rabbit polyclonal antibodies against periostin. We raised polyclonal RD1 antibodies against periostin by using the peptide DNLDSDIRRGLESNVN (representing aa 143–158 of human periostin) for human periostin and the peptide ENLDSDIRRGLENNVN (representing aa 145–160 of mouse periostin) for mouse periostin. The antibodies were affinity-purified by using the respective immunogenic peptide.

Histology, immunostaining, and electron microscopy. Human tissue samples were obtained during autopsy and fixed in 4% neutral formalin or 20% formalin. A total of 41 cases, ranging from a fetus to an 89-yr-old patient, including 15 cases of myocardial infarction, were examined. All the cases were approved for use in research by the Ethics Committee of the
University of Tokyo. After having been embedded in paraffin, specimens were cut at a 4-μm thickness. Hematoxylin and eosin, elasta von Gieson, and Azan staining procedures were performed. Immunohistochemistry by the ABC method was done by using an i6000 apparatus (Bioron).

For histological analysis of the injured mice, the animals were killed at 1, 2, 3, 4, 5, 7, 14, or 28 d after surgery under anesthesia, and were perfusion fixed with 4% paraformaldehyde at physiological pressure. Fixed hearts were sectioned transversely into three equal segments from their apex to base and cryosectioned or embedded in paraffin. 4-μm-thick sections were used for histological analysis or for immunostaining. Antibodies against αv-integrin (Laboratory Vision), αSMA (Sigma-Aldrich), FAK (BD Biosciences), pY397FAK (Invitrogen), pS473Akt (Cell Signaling Technology), Akt (Cell Signaling Technology), collagen I (Novotec), fibronectin (34), Ki67 (YLEM), active caspase3 (Promega), vimentin (PROGEN), smooth muscle myosin-1 (SM1; Kyowa Hakko Ltd.), and Mac3 (BD Biosciences) were used for immunostaining. Antigen unmasking techniques were not performed, except for anti-αv-integrin. For immunostaining of pY397FAK and pS473Akt, the Catalyzed Signal Amplification system was used (Dako). In the case of fluorescence studies, the signals were observed under a confocal microscope (FLUOVIEW FV1000; Olympus).

Sections of injured heart were generated from 6 periostin+/− and 6/− male mice at 5 and 28 d after AMI, and they were prepared for electron microscopy as previously described (35). Sham-operated mice were used for the control. Collagen fibril diameters were measured in scanned images generated from electron micrographs with Image J software. Collagen fibrils and the number of vimentin-positive or αSMA-positive cells in at least 6 fields derived from each of the basement-, mid-, and apex-part of the infarct region of heart sections were quantified (6 mice per group). Animal studies were conducted under a protocol approved by the Institutional Animal Use and Care Committee.

Quantification of collagen cross-links and collagen contents. Snap-frozen infant tissues from periostin+/− and /− mice were used. Pyridinoline and hydroxyproline contents were determined by the previously described HPLC method (36).

Adenovirus-mediated gene transfer. Construction of Ad-nsLacZ and Ad-periostin ΔHΔE vectors was performed by use of an Adeno-X Expression System 2 (BD Biosciences). The virus purification method used, involving cesium chloride ultracentrifugation, was previously described (37). 1 d before LAD ligation, a volume of 100 μl containing 1.6 × 1010 PFU of Ad-nsLacZ or Ad-periostin ΔHΔE virus was injected into a tail vein of male periostin−/− mice.

Statistical analysis. All numerical results were presented as the mean ± SEM. Statistical analyses of the echocardiography and cell migration assay were performed with a Student’s unpaired t test. Survival curves after AMI were obtained by the log-rank test. Differences were considered significant at P < 0.05.

Online supplemental material. Fig. S1 shows the confirmation of the periostin expression in cardiac fibroblasts. Fig. S2 indicates the generation of periostin−/− mice. Fig. S3 shows the immunofluorescence analysis of fibroblast after AMI. Fig. S4 shows immunofluorescence analysis for gene-transferred periostin−/− infract heart. Fig. S5 depicts the analysis for the phosphorylation of Akt after AMI. Fig. S6 shows a cause-and-effect relationship between TGFβ and periostin after AMI. Table S1 provides the echocardiographic data. Full methods and associated references are available in the Supplemental materials and methods.
