OBJECTIVE Spondylosis with or without spondylolisthesis that does not respond to conservative management has an excellent outcome with direct pars interarticularis repair. Direct repair preserves the segmental spinal motion. A number of operative techniques for direct repair are practiced; however, the procedure of choice is not clearly defined. The present study aims to clarify the advantages and disadvantages of the different operative techniques and their outcomes.

METHODS A meta-analysis was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The following databases were searched: PubMed, Cochrane Library, Web of Science, and CINAHL (Cumulative Index to Nursing and Allied Health Literature). Studies of patients with spondylolysis with or without low-grade spondylolisthesis who underwent direct repair were included. The patients were divided into 4 groups based on the operative technique used: the Buck repair group, Scott repair group, Morscher repair group, and pedicle screw–based repair group. The pooled data were analyzed using the DerSimonian and Laird random-effects model. Tests for bias and heterogeneity were performed. The F statistic was calculated, and the results were analyzed. Statistical analysis was performed using StatsDirect version 2.

RESULTS Forty-six studies consisting of 900 patients were included in the study. The majority of the patients were in their 2nd decade of life. The Buck group included 19 studies with 305 patients; the Scott group had 8 studies with 162 patients. The Morscher method included 5 studies with 193 patients, and the pedicle group included 14 studies with 240 patients. The overall pooled fusion, complication, and outcome rates were calculated. The pooled rates for fusion for the Buck, Scott, Morscher, and pedicle groups were 83.53%, 81.57%, 77.72%, and 90.21%, respectively. The pooled complication rates for the Buck, Scott, Morscher, and pedicle groups were 13.41%, 22.35%, 27.42%, and 12.8%, respectively, and the pooled positive outcome rates for the Buck, Scott, Morscher, and pedicle groups were 84.33%, 82.49%, 80.30%, and 80.1%, respectively. The pedicle group had the best fusion rate and lowest complication rate.

CONCLUSIONS The pedicle screw–based direct pars repair for spondylolysis and low-grade spondylolisthesis is the best choice of procedure, with the highest fusion and lowest complication rates, followed by the Buck repair. The Morscher and Scott repairs were associated with a high rate of complication and lower rates of fusion.

KEY WORDS direct repair; Buck repair; Scott repair; Morscher repair; spondylolysis; spondylolisthesis; pedicle screw–rod system; pedicle screw–hook system

The bipedal gait of Homo sapiens has an evolutionary advantage to our survival but has put a biomechanical disadvantage on the lumbar spine. Spondylolysis is defined as a defect of the pars interarticularis, either unilateral or bilateral; it is estimated to occur in 3%–7% of the adult population. Sport activities carry a higher risk of spondylolysis with repetitive axial loading and hyperextension. The incidence of spondylolysis has been reported to be as high as 55% in fast bowlers. The repeated stresses that fall on the pars in highly demanding
sports, such as weight lifting, cricket, soccer, and gymnastics, result in stress fractures. In most cases, spondylolysis and low-grade spondylolisthesis remain asymptomatic. However, in some cases, the pain can become disabling, prevent the patient from working, and progress to spondylolisthesis. Conservative management is the gold standard as the initial treatment of spondylolysis. Surgical treatment is advised in patients who have disabling symptoms despite conservative management or when there is a progression to spondylolisthesis. Intersegmental fusion would unnecessarily lead to stiffness of the spine and adjacent-segment disease and degeneration, especially in young patients. Therefore, there is much interest in direct repair of the pars interarticularis. Direct repair focuses on repair of the pars without causing motion restriction in the adjacent segments. The aim is to preserve spinal segmental motion and restore normal anatomy. There are many types of direct repair, with differing biomechanical properties. However, there is a lack of clarity regarding the surgical procedure of choice. The purpose of this study was to perform a systematic review and investigate differences in the fusion rate, complications, and outcomes between the following 4 types of direct pars repair: Buck repair, Scott repair, Morscher repair, and pedicle screw–based repair.

Methods
We performed a systematic review to identify the fusion rate, complication rate, and rate of positive outcome in the different techniques of direct pars interarticularis repair. A detailed protocol about the literature search, inclusion/exclusion criteria, selection of cases, and statistical methodology was developed. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines were followed (Fig. 1A). Two investigators (N.M. and V.N.) performed the literature search. To minimize selection bias, 2 reviewers (A.R.S. and D.P.P.) reviewed the articles independently. In case of doubt, a mutual consensus was reached after discussion.

Literature Search Strategy
A computerized Web search was performed of the titles and abstracts from January 1960 to June 2017 in the PubMed, Cochrane Library, Web of Science, and CINAHL (Cumulative Index to Nursing and Allied Health Literature) databases. A combination of key word searches were made to build a search strategy; non–English-language literature was also searched. Three non–English-language articles were reviewed after translation. An independent Web search was performed with the key words to include any unpublished literature. Key words that were used to build the search directory were “spondylolysis,” “spondylolisthesis,” “pars interarticularis,” “direct repair,” “Buck’s fusion,” “Scott’s repair,” and “Morscher’s repair.” Additional search terms used were “repair,” “surgery,” “fusion,” and “complications.”

Bias Assessment
Two investigators independently reviewed all articles to eliminate selection bias. A meta-analysis of proportions was performed. The present study includes only observational studies, and bias would be expected. All included studies were retrospective observational studies; no randomized controlled trials were found. For each subsection of the meta-analysis, bias indicator tests, specifically the Begg-Mazumdar and Egger tests, were performed. Funnel plots were created to check the heterogeneity of the studies (Fig. 1B). The Q statistic and I² were calculated to assess heterogeneity. The I² values in the Buck repair group and the pedicle repair group were low. The I² values in the Scott repair group and Morscher repair group were high, suggesting increased heterogeneity. The Begg-Mazumdar test showed low power in the Scott repair group and Morscher repair group.

Inclusion and Exclusion Criteria
Studies of patients who had spondylolysis with or without low-grade spondylolisthesis and who underwent surgery for direct pars interarticularis repair were selected from the literature and included in this meta-analysis. Age was not considered a criterion for inclusion in the study. Single case reports and small case series with fewer than 5 cases were excluded. Only direct repairs were selected. Patients who underwent fusion with adjacent segments or whose procedures involved facet joint fusion were excluded. Symptomatic spondylolysis not responding to conservative management and low-grade spondylolisthesis (Meyerding classification27 grades I and II) only were considered.

Patients with associated pathologies, such as spinal canal stenosis, disc degeneration, and radiculopathy, were excluded. Patients with both sporting and nonsporting backgrounds were included.

Statistical Analysis
Statistical analysis was done using StatsDirect statistical software (version 2.7.9, StatsDirect Ltd.). Due to the inherent heterogeneity of observational studies, the random-effects model was used for the meta-analysis. The meta-analysis of proportions was carried out, along with the test for heterogeneity, and the I² value and Q statistic were evaluated. The DerSimonian and Laird model was used to calculate the pooled effect. Forest plots were charted for each group, analyzing the pooled fusion rate, complication rate, and outcome. For each subsection of the meta-analysis, bias assessment was done using the Begg-Mazumdar and Egger tests. Funnel plots were generated for each subset of the meta-analysis. The I² value ranged from 0% to as high as 82% in the various groups of meta-analysis, suggesting a wide variation and heterogeneity across the included studies.

Results
Forty-six studies reporting on 900 patients who matched the inclusion criterion were selected for analysis (Table 1). The mean age ranged from 12 to 38 years. The average age was younger than 20 years in 25 studies. In only 4 studies was the average age older than 30 years; the majority of patients were in their 2nd decade of life. The percentage of males was higher in the majority of the studies. Nine studies included patients exclusively from a
sporting background. Preoperative evaluation was done by examining flexion and extension radiographs, CT scans, MR images, and, in some studies, SPECT scans. Five studies included patients who were from sport and nonsport backgrounds. In 4 series, the authors used a minimally invasive approach for the Buck repair. Three studies used bone morphogenetic protein (BMP) to aid the fusion. Eight studies used pedicle screws with laminar hooks, and 4 studies used pedicle screws with a wiring technique. The proportion of patients with low-grade spondylolisthesis ranged from 5.26% to 100% in the included studies.

While most studies included cases of low-grade spondylolisthesis, the exact proportion of cases was mentioned in only 16 studies. Based on the surgical techniques used to repair the pars, the studies were grouped broadly into 4 categories. Buck’s technique of repair was used in the first group. In this technique, a screw is passed across the pars defect. In this group, 19 studies with 305 patients were included. The Scott wiring technique was used in the second group. In this technique, a wire is wound around the transverse process and spinous process to stabilize the pars defect. Eight studies with 162 patients were included in this group. The Morscher method was used in 5 studies with 193 patients. The fourth group included 14 studies accounting for 240 patients who underwent pedicle screw–based repair. The purpose of this study was to investigate differences in the fusion rate, complications, and positive outcomes between the 4 broad categories of the pars repair. There were no prospective randomized studies addressing this issue. The fusion rate, complication rate, and positive outcome rate were compared between the groups (Table 2).

Fusion Rate

Fusion was assessed on radiographs in the majority of studies; CT scans were used in 9 studies; MR images, and, in some studies, SPECT scans. Five studies included patients who were from sport and nonsport backgrounds. In 4 series, the authors used a minimally invasive approach for the Buck repair. Three studies used bone morphogenetic protein (BMP) to aid the fusion. Eight studies used pedicle screws with laminar hooks, and 4 studies used pedicle screws with a wiring technique. The proportion of patients with low-grade spondylolisthesis ranged from 5.26% to 100% in the included studies.

While most studies included cases of low-grade spondylolisthesis, the exact proportion of cases was mentioned in only 16 studies. Based on the surgical techniques used to repair the pars, the studies were grouped broadly into 4 categories. Buck’s technique of repair was used in the first group. In this technique, a screw is passed across the pars defect. In this group, 19 studies with 305 patients were included. The Scott wiring technique was used in the second group. In this technique, a wire is wound around the transverse process and spinous process to stabilize the pars defect. Eight studies with 162 patients were included in this group. The Morscher method was used in 5 studies with 193 patients. The fourth group included 14 studies accounting for 240 patients who underwent pedicle screw–based repair. The purpose of this study was to investigate differences in the fusion rate, complications, and positive outcomes between the 4 broad categories of the pars repair. There were no prospective randomized studies addressing this issue. The fusion rate, complication rate, and positive outcome rate were compared between the groups (Table 2).

Complication Rate

The complications of the different procedures were specified in most studies; 8 studies lacked specification. Both immediate and late complications were included in the analysis. The pooled complication rates for the Buck, Scott, Morscher, and pedicle screw groups were 13.41%, 22.35%, 27.42%, and 12.8%, respectively. The complications were lowest for the pedicle screw–based repairs, followed by the Buck repair. The highest complication rates were observed in the Morscher method.

While some complications, such as superficial wound infections, were common to all 4 groups, some were specific to the type of repair used. Root irritation was more often observed in the Buck group, followed by the Morscher group, than in the other 2 groups. Wire breakage was the prominent complication for the Scott repair and resulted in nonunion. Transverse process fracture and wire protrusions were specific to the Scott group. The Morscher method was associated with a high incidence of nonunion and implant loosening. The pedicle screw–based group had the least incidence of superficial wound infection, nonunion, and implant loosening or pullout (Fig. 3).

Outcome Analysis

In most of the studies, the outcome was measured using nonstandardized scales, such as the Henderson criteria, Macnab criteria, modified Macnab criteria, and Odom criteria. Only 5 studies reported outcomes on standardized scales, such as the Oswestry Disability Index or the Japanese Orthopaedic Association scale. For analyzing the outcome measures in the present study, cases in which

TABLE 2. Pooled fusion, complication, and favorable outcome rates in 4 groups of direct pars interarticularis repairs

| Technique       | No. of Pts | No. of Studies | Pooled Fusion Rate (95% CI) | Pooled Complication Rate (95% CI) | Pooled Positive Outcome Rate (95% CI) |
|-----------------|------------|----------------|----------------------------|-----------------------------------|---------------------------------------|
| Buck repair     | 305        | 19             | 83.53% (76–89%)             | 13.41% (8–18%)                    | 84.33% (78–89%)                       |
| Scott repair    | 162        | 8              | 81.57% (65–93%)             | 22.35% (14–31%)                   | 82.49% (73–89%)                       |
| Morscher repair | 193        | 5              | 77.72% (66–86%)             | 27.42% (8–51%)                    | 80.30% (80–88%)                       |
| PS-based repair | 240        | 14             | 90.21% (82–96%)             | 12.8% (6–21%)                     | 80.1% (74–85%)                        |

A. Buck’s Repair: Pooled fusion rate 84%

B. Scott’s Repair: Pooled fusion rate 82%

C. Morscher’s Repair: Pooled fusion rate 78%

D. Pedicle Repair: Pooled fusion rate 90%
the patient improved completely without any symptoms of pain and returned to work were considered as positive outcomes. A postoperative Oswestry Disability Index score less than 20 was considered a positive outcome. The excellent and good outcomes in the Henderson, Odom, and Macnab criteria were considered as positive outcomes. Patients who had persisting pain or who were unable to return to work due to pain were considered to have had a negative outcome. The pooled positive outcome rates for the Buck, Scott, Morscher, and pedicle screw groups were 84.33%, 82.49%, 80.30%, and 80.1%, respectively. The favorable outcome rate for the minimally invasive Buck repair was better than that for the open Buck repair (Fig. 4).

Discussion

Direct repair surgeries have gradually evolved from 1968 to the present day use of minimally invasive approaches. Direct repair of the pars interarticularis was first reported by Kimura in 1968 by using bone graft without the use of internal fixation. After this, Scott in 1986 report-
ed the use of a wiring method. In 1970, Buck published his series of direct repairs using a lag screw across the defect in a cohort of fast bowlers.6 Morscher et al.,28 in 1984, reported their method as being especially suited to cases of dysplastic lamina where a Buck repair was not possible. Methods based on pedicle screw insertion and minimally invasive methods are relatively recent (Fig. 5).

A total of 46 studies with 900 patients were finally considered for the study (Fig. 1A).

Buck Repair

In the Buck method, a single lag screw is passed from the inferior edge of the lamina across the defect after placing the autologous graft into the defect. Biomechanical testing in cadaver spines of the intralaminar screw construct has shown good stability of the spondylotic defect in comparison with the other methods.28 The complications of this repair are mainly due to screw loosening or misplacement.1 Of the 19 studies that used this form of repair, fusion rates ranged from 42.85% to 100%.

The pooled fusion rate was 83.53%. The series by Giudici et al.13 reported the lowest fusion rate. The authors opined that accurate screw placement was the main technical difficulty to achieve a good purchase and compression at the site of defect. It was also noted that in some cases, the screw itself occupied much of the space of the defect in the region of the isthmus, which may prevent bony contact

FIG. 4. Pooled proportional meta-analysis of the positive outcome rate. A: The Buck repair showed a pooled outcome rate of 84%. I² = 36%. Random effects: pooled proportion = 0.843324 (95% CI 0.788331–0.891384). Begg-Mazumdar: Kendall’s tau = –0.625731, p < 0.0001. Egger: bias = –2.559973 (95% CI –3.908265 to –1.211681), p = 0.0009. B: The Scott repair showed a pooled outcome rate of 82%. I² = 42.1%. Random effects: pooled proportion = 0.824903 (95% CI 0.739211–0.896526). Begg-Mazumdar: Kendall’s tau = –0.0312 (low power). Egger: bias = –2.089109 (95% CI –4.044024 to –0.134194), p = 0.0399. C: The Morscher repair showed a pooled outcome rate of 80%. I² = 51.7%. Random effects: pooled proportion = 0.803549 (95% CI 0.701775–0.88835). Begg-Mazumdar: Kendall’s tau = –0.6 (low power). Egger: bias = –1.436749 (95% CI –5.109707 to 2.232209), p = 0.3008. D: The pedicle screw repair showed a pooled outcome rate of 80%. I² = 0%. Random effects: pooled proportion = 0.801237 (95% CI 0.745298–0.851789). Begg-Mazumdar: Kendall’s tau = –0.6, p = 0.0833 (low power). Egger: bias = –1.139245 (95% CI –2.579259 to 0.302767), p = 0.11.

N. Mohammed et al.
with the graft.\textsuperscript{13} Screw loosening and screw breakage were the most common complications noted in our study. The complication rate ranged from 0\%\textsuperscript{21} to 37.5\%.\textsuperscript{12} The positive outcome ranged from 28\%\textsuperscript{13} to 100\%.\textsuperscript{39}

**Scott Repair**

The Scott repair involves a wire that is encircled around the transverse process and spinous process. The procedure is technically less demanding than the other methods of pars repair. However, it requires a wider exposure and muscle dissection, resulting in greater blood loss.\textsuperscript{1} Vascular and nerve root injury can occur when the wire is being encircled across the transverse process, and winding the wire around the transverse process of L-5 might be difficult in cases in which it is close to the sacrum.\textsuperscript{1} In our analysis, the main problem noted in most series employing the Scott method was wire breakage.\textsuperscript{2,5,13,17,19,31,32,43} There were 14 such instances reported. The fusion rates ranged from 43\%\textsuperscript{43} to 100\%,\textsuperscript{2,31} and the overall pooled favorable outcome of the Scott repair was 82.49%.

**Morscher Repair**

In the Morscher method, the screw is inserted in the base of the superior articular process. The screw is attached to a laminar hook to achieve approximation of the pars defect. Our analysis showed a high pooled complication rate with the use of this technique (27.42\%). In the series by Sales de Gauzy et al.,\textsuperscript{42} there were 8 cases of screw loosening. Ivanic et al.\textsuperscript{18} reported a large series of Morscher repairs (113 patients) with a long follow-up period. The series by Winter and Jani\textsuperscript{19} reported a fusion rate of only 50\%. In the same series, 7 cases of screw loosening were documented. The Morscher repair was associated with the lowest fusion rate and highest complication rate in our study. The small screw purchase in the base of the superior articular process could be responsible for many instances of screw pullout and consequent nonfusion.

**Pedicle Screw–Based Repairs**

Pedicle screw–based repairs were first reported by Songer and Rovin in 1988.\textsuperscript{47} In this method, the authors used a pedicle screw to anchor a cable that approximated the pars defect. Other pedicle screw–based methods include using a pedicle screw with laminar hook fixation\textsuperscript{50} and using a pedicle screw with a curved rod running under the spinous process to stabilize the pars defect.\textsuperscript{1,11} In all of these techniques, the common anchor is the pedicle screw. The pedicle screw provides strong support with a low incidence of screw pullout due to larger bony purchase. Pedicle screw insertion has become an increasingly familiar procedure among surgeons and allows for minimally invasive approaches as well. Analysis of this group showed excellent fusion rates; fusion rates of 100\% were noted in several studies.\textsuperscript{20,21,25,30,37,47,50} The pooled fusion rate was 90.21\%. The pedicle screw group had the lowest pooled complication rate of 12.8\%. The common complication associated with pedicle screw–based methods involved wire/cable breakage in screw-wire constructs. The pedicle screw–based techniques are associated with the most favorable fusion and lowest complication rates in comparison with the other groups.

Four studies employing the minimally invasive Buck repair with 37 patients were also analyzed.\textsuperscript{10,12,21,51} The minimally invasive series had low complication rates and excellent outcomes. BMP was used to aid fusion in 3 studies.\textsuperscript{10,21,46} All of these studies reported good fusion rates. Analysis of the data from this study has shown that in patients with spondylolysis and low-grade spondylolisthesis in whom conservative treatment has failed, surgical management substantially improves the outcome and return to activity. Among all studied groups, pedicle screw–based repairs have the best fusion rates and lowest complication rates. Based on this finding, we conclude that the pedicle screw–based repairs are recommended as the repair of choice, followed by the Buck repair. Neither the Scott repair nor the Morscher repair is recommended as the first choice of repair of the pars defect. Patient selection is important in the management of direct repairs. The ideal candidate should have no significant disc degeneration, be young, and have a low-grade spondylolisthesis. Direct repairs are especially suited for young athletes and have shown excellent outcomes.

**Justification for Our Analysis**

There are a number of surgical procedures that address direct pars repair with different modifications. Moreover, newer, minimally invasive techniques have been introduced. Because of the large variety of different procedures for direct repair, the procedure of choice becomes unclear. To date, there have been systematic reviews that addressed this issue, but no meta-analysis has been carried out. However, this study attempts to statistically define the differences in types of direct repairs in reference to the rates of fusion, complications, and outcomes. We were unable to find any randomized controlled trials that addressed this issue.
Limitations of the Study

There are a number of limitations of the present study. There were no randomized controlled trials available comparing the different groups. The statistical power of a meta-analysis is highest when randomized controlled trials are included. The present study is a meta-analysis of observational studies. There is a lack of control groups, which can introduce bias. In clinical scenarios, it is not always possible to conduct a meta-analysis. The information in the existing literature, however, cannot be disregarded, and best attempts need to be made to analyze the available data, with an understanding of the included bias that may influence the overall results. The assessment of outcome measures was not standardized in most of the studies. This may introduce discrepancy in the overall assessment of outcome in the study groups. In this study, we combined studies of patients involved in sport activities and those who were not involved in sports into a single analysis. These 2 groups are heterogeneous subsets with different risk factors, and the criteria for assessment of fusion are not well defined in the studies. In some studies, radiography was used, while in others CT scanning was performed. The assessment of fusion using radiographs is less sensitive than that using CT scans, and cases of nonfusion can be potentially missed and judged as fused.

Conclusions

Pedicle screw–based direct repairs for spondylolysis and low-grade spondylolisthesis are the best choice of procedure, with the highest fusion rate and lowest complication rate, followed by the Buck repair. The Morscher repair and Scott repair had high rates of complications and lower fusion rates.

Acknowledgments

We thank Ms. Julia Esparza, associate librarian, LSU-HSC, for assisting in the search strategy, and Ms. Gloria Caldito, associate professor of statistics and research, LSU-HSC, for assistance with the statistical analysis.

Disclosures
The authors report no conflict of interest concerning the materials or methods used in this study or the findings specified in this paper.

Author Contributions
Conception and design: Nanda, Mohammed. Acquisition of data: Mohammed, Narayan. Analysis and interpretation of data: Nanda, Mohammed, Patra, Narayan. Drafting the article: Nanda, Mohammed, Patra. Critically revising the article: Nanda, Mohammed, Patra. Reviewed submitted version of manuscript: Nanda, Mohammed, Patra. Approved the final version of the manuscript on behalf of all authors: Nanda. Statistical analysis: Mohammed. Administrative/technical/material support: Nanda, Mohammed, Patra, Sivaradekar, Dossani, Bollam. Study supervision: Nanda, Mohammed, Sivaradekar, Bollam, Bir.
