ABSTRACT

We extensively reanalyze the effects of a long-lived, negatively charged massive particle, $X^-$, on big bang nucleosynthesis (BBN). The BBN model with an $X^-$ particle was originally motivated by the discrepancy between the $^6\text{Li}$ abundances predicted in the standard BBN model and those inferred from observations of metal-poor stars. In this model, $^7\text{Be}$ is destroyed via the recombination with an $X^-$ particle followed by radiative proton capture. We calculate precise rates for the radiative recombinations of $^7\text{Be}$, $^7\text{Li}$, $^9\text{Li}$, and $^9\text{Be}$ with $X^-$. In nonresonant rates, we take into account respective partial waves of scattering states and respective bound states. The finite sizes of nuclear charge distributions cause deviations in wave functions from those of point-charge nuclei. For a heavy $X^-$ mass, $m_X \gtrsim 100$ GeV, the $d\to 2p$ transition is most important for $^7\text{Li}$ and $^7\text{Be}$, unlike recombination with electrons. Our new nonresonant rate of the $^7\text{Be}$ recombination for $m_X = 1000$ GeV is more than six times larger than the existing rate. Moreover, we suggest a new important reaction for $^8\text{Be}$ production: the recombination of $^7\text{Li}$ and $^7\text{Be}$ followed by deuteron capture. We derive binding energies of $X$ nuclei along with reaction rates and $Q$ values. We then calculate BBN and find that the amount of $^7\text{Be}$ destruction depends significantly on the charge distribution of $^7\text{Be}$. Finally, updated constraints on the initial abundance and the lifetime of the $X^-$ are derived in the context of revised upper limits to the primordial $^6\text{Li}$ abundance. Parameter regions for the solution to the $^7\text{Li}$ problem and the primordial $^9\text{Be}$ abundances are revised.

Key words: atomic processes – early universe – elementary particles – nuclear reactions, nucleosynthesis, abundances – primordial nucleosynthesis – stars: abundances

1. INTRODUCTION

Standard big bang nucleosynthesis (SBBN) is an important probe of the early universe. This model explains the primordial light element abundances inferred from astronomical observations except for the $^4\text{He}$ abundance. Additional nonstandard effects during big bang nucleosynthesis (BBN) may be required to explain the $^7\text{Li}$ discrepancy. However, such models are strongly constrained from the consistency in the other elemental abundances. In this paper, we re-examine in detail one intriguing solution to the $^7\text{Li}$ problem, which is due to a late-decaying, negatively charged particle (possibly the stau as $X^-$). In previous work (Kusakabe et al. 2008), we showed that both a decrease in $^7\text{Li}$ and an increase in $^6\text{Li}$ abundances are possible in this model. Recently, however, the primordial $^6\text{Li}$ abundance has been revised downward (Lind et al. 2013), and there is now only an upper limit. Hence, it is necessary to re-evaluate the $X^-$ solution in light of these new measurements. We show that this remains a viable model for $^7\text{Li}$ reduction without violating the new $^6\text{Li}$ upper limit.

1.1. Primordial Li Observations

The primordial lithium abundance is inferred from spectroscopic measurements of metal-poor stars (MPSs). These stars have a roughly constant abundance ratio, $^7\text{Li}/H = (1 - 2) \times 10^{-10}$, as a function of metallicity (Spite & Spite 1982; Ryan et al. 2000; Meléndez & Ramírez 2004; Asplund et al. 2006; Bonifacio et al. 2007; Shi et al. 2007; Aoki et al. 2009; González Hernández et al. 2009; Shibahashi et al. 2010; Monaco et al. 2010, 2012; Micciche et al. 2012; Aoki et al. 2012, 2013). The SBBN model, however, predicts a value that is higher by about a factor of three to four (e.g., $^7\text{Li}/H = 5.24 \times 10^{-10}$ Coc et al. 2012) than the observational value when one uses the baryon-to-photon ratio determined in the ΛCDM model from analysis of the power spectrum of the cosmic microwave background (CMB) radiation from the Wilkinson Microwave Anisotropy Probe (WMAP; Larson et al. 2011; Hinshaw et al. 2013) or the Planck data (Coc et al. 2013). This discrepancy suggests the need for a mechanism to reduce the $^7\text{Li}$ abundance during or after BBN. Astrophysical processes such as rotationally induced mixing (Pinsonneault et al. 1999, 2002) and the combination of atomic and turbulent diffusion (Richards et al. 2005; Korn et al. 2007; Lind et al. 2009) might have reduced the $^7\text{Li}$ abundance in stellar atmospheres, although this possibility is constrained by the very narrow dispersion in observed Li abundances.

In previous work, the $^6\text{Li}/^7\text{Li}$ isotopic ratios for MPSs have also been measured and $^6\text{Li}$ detections have been reported for the halo turnoff star HD 84937 (Smith et al. 1993, 1998; Cayrel et al. 1999), the two Galactic disk stars, HD 68284 and HD 130551 (Nissen et al. 1999), and other stars (Asplund et al. 2005; Inoue et al. 2005; Asplund & Meléndez 2008; García Pérez et al. 2009; Steffen et al. 2010, 2012). A large $^6\text{Li}$ abundance of $^6\text{Li}/H \sim 6 \times 10^{-12}$ was suggested (Asplund et al.
The Astrophysical Journal Supplement Series, 214:5 (35pp), 2014 September

Kusakabe et al.

2006). That abundance is \( \sim 1000 \) times higher than the SBBN prediction and is also significantly higher than the prediction from a standard Galactic cosmic-ray nucleosynthesis model (cf. Prantzos 2006, 2012). It has been noted for some time, however (Smith et al. 2001; Cayrel et al. 2007), that convective motion in stellar atmospheres could cause systematic asymmetries in the observed atomic line profiles and mimic the presence of \(^6\)Li (Cayrel et al. 2007). Indeed, in a subsequent detailed analyses, Lind et al. (2013) found that most of the previous \(^6\)Li absorption feature could be attributed to a combination of three-dimensional (3D) turbulence and nonlocal thermal equilibrium (NLTE) effects in the model atmosphere. For the present purposes, therefore, we adopt the 2σ upper limit from their G64-12 NLTE model with five parameters corresponding to \(^6\)Li/H < 9.5 \times 10^{-12}.

Abundances of \(^9\)Be (Boesgaard et al. 1999; Primas et al. 2000; Tan et al. 2009; Smiljanic et al. 2009; Ito et al. 2009; Rich & Boesgaard 2009) and B (Duncan et al. 1997; Garcia Lopez et al. 1998; Primas et al. 1999; Cunha et al. 2000) in MPSs have also been measured. The observed abundances linearly scale with Fe abundances. The linear relation between abundances of light elements and Fe is expected in Galactic cosmic-ray nucleosynthesis models (Reeves 1970, 1974; Meneguzzi et al. 1971; Prantzos 2012). Any primordial abundances, on the other hand, should be observed as a plateau in abundance at low metallicities as in the case of \(^5\)Li. Be and B in the observed MPSs are not expected to be primordial. Nonetheless, primordial abundances of Be and B may be found by future observations. The strongest lower limit on the primordial Be abundance at present is \( \log(\text{Be}/\text{H}) < -14 \) which has been derived from an observation of the carbon-enhanced MPS BD+44°493 with an iron abundance \( \text{[Fe/H]} = -3.7 \) with Subaru/HDS (Ito et al. 2009).

1.2. X\(^-\) Solution

As one of the solutions to the lithium problem, effects of negatively charged massive particles (CHAMPs or Cahn-Glashow particles) \( X^- \) (Cahn & Glashow 1981; Dimopoulos et al. 1990; de Rújula et al. 1990) during the BBN epoch have been studied (Pospelov 2007b; Kohri & Takayama 2007; Cyburt et al. 2006; Hamaguchi et al. 2007; Bird et al. 2008; Kusakabe et al. 2007, 2008; Jedamzik 2008a, 2008b; Kamimura et al. 2009, 2010; Pospelov 2007a; Kawasaki et al. 2007, 2008; Jittoh et al. 2007, 2008, 2010; Pospelov et al. 2008; Kholopov & Kouvaris 2008; Bailly et al. 2009; Jedamzik & Pospelov 2009; Kusakabe et al. 2010; Pospelov & Pradler 2010; Kohri et al. 2012; Cyburt et al. 2012; Dapb et al. 2012). Constraints on supersymmetric models have been derived through BBN calculations (Cyburt et al. 2006; Kawasaki et al. 2007, 2008; Jittoh et al. 2007, 2008, 2010; Pradler & Steffen 2008a, 2008b; Bailly et al. 2009). In addition, cosmological effects of fractionally charged massive particles (FCHAMPs) have been studied, although the nucleosynthesis has not yet been studied (Langacker & Steigman 2011).

Such long-lived CHAMPs and FCHAMPs, which are also called heavy stable charged particles, appear in theories beyond the standard model, and have been searched for in collider experiments. Although the particles should leave characteristic tracks corresponding to long times of flight due to small velocities and anomalous energy losses, they have never been detected. The most stringent limit on scalar supersymmetric partner of the tau lepton (stau) has been derived using data collected with the Compact Muon Solenoid detector for \( pp \) collisions at the Large Hadron Collider during the 2011 (\( \sqrt{s} = 7 \text{ TeV}, 5.0 \text{ fb}^{-1} \)) and 2012 (\( \sqrt{s} = 8 \text{ TeV}, 18.8 \text{ fb}^{-1} \)) data taking periods. The data exclude stau mass below 500 GeV for the direct+indirect production model (Chatrchyan et al. 2013b). The limit on spin 1/2 FCHAMPs that are neutral under \( SU(3)_C \) and \( SU(2)_L \) has also been derived from Compact Muon Solenoid searches. It excludes the masses less than 310 GeV for charge number \( q = 2/3 \), and masses less than 140 GeV for \( q = 1/3 \) (Chatrchyan et al. 2013a).

The X\(^-\) particles and nuclei A can form new bound atomic systems (A\(_X\) or X-nuclei) with binding energies \( \sim O(0.1–1) \text{ MeV} \) in the limit that the mass of the X\(^-\), \( m_X \), is much larger than the nucleon mass (Cahn & Glashow 1981; Kusakabe et al. 2008). The X-nuclei are exotic chemical species with very heavy masses and chemical properties similar to normal atoms and ions. The super-heavy stable (long-lived) particles have been searched for in experiments, and multiple constraints on respective X-nuclei have been derived. The spectroscopy of terrestrial water gives a limit on the number ratio of \( X/\text{H} < 10^{-28}–10^{-29} \) for \( m_X = 11–1100 \text{ GeV} \) (Smith et al. 1982), while that of sea water gives the limits of \( X/\text{H} < 4 \times 10^{-17} \) for \( m_X = 5–1500 \text{ GeV} \) (Yamagata et al. 1993) and \( X/\text{H} < 6 \times 10^{-15} \) for \( m_X = 10^4–10^7 \text{ GeV} \) (Verkerk et al. 1992). Limits on the X-to-nucleon ratio have been derived from analyses of other material: (1) \( X/\text{N} < 5 \times 10^{-12} \) for \( m_X = 10^5–10^7 \text{ GeV} \) from Na (Dict et al. 1986), (2) \( X/\text{N} < 2 \times 10^{-15} \) for \( m_X \leq 10^7 \text{ GeV} \) from C (Turkevich et al. 1984), and (3) \( X/\text{N} < 1.5 \times 10^{-13} \) for \( m_X \leq 10^5 \text{ GeV} \) from Tl (Norman et al. 1989).

Furthermore, limits from analyses of H, Li, Be, B, C, O, and F have been derived for \( m_X = 10^4–10^6 \text{ GeV} \) using commercial gases, lake and deep sea water deuterium, plant \( ^{13}\text{C} \), commercial \( ^{18}\text{O} \), and reagent grade samples of Li, Be, B, and F (Hemmick et al. 1990).

If the X\(^-\) particle exits during the BBN epoch, it opens new pathways of atomic and nuclear reactions and affects the resultant nucleosynthesis (Pospelov 2007b; Kohri & Takayama 2007; Cyburt et al. 2006; Hamaguchi et al. 2007; Bird et al. 2008; Kusakabe et al. 2007, 2008; Jedamzik 2008a, 2008b; Kamimura et al. 2009; Pospelov 2007a; Kawasaki et al. 2007, 2008; Jittoh et al. 2007, 2008, 2010; Pospelov et al. 2008; Kholopov & Kouvaris 2008; Bailly et al. 2009; Jedamzik & Pospelov 2009; Kusakabe et al. 2010; Pospelov & Pradler 2010; Kohri et al. 2012; Cyburt et al. 2012; Dapb et al. 2012). As the temperature of the universe decreases, positively charged nuclides gradually become electromagnetically bound to X\(^-\) particles. Heavier nuclei with larger mass and charge numbers recombine earlier since their binding energies are larger (Cahn & Glashow 1981; Kusakabe et al. 2008). The formation of most X-nuclei proceeds through radiative recombination of nuclides A and X\(^-\) (Dimopoulos et al. 1990; de Rújula et al. 1990). However, the \(^7\)Be\(_X\) formation also proceeds through the non-radiative \(^7\)Be charge exchange reaction between a \(^7\)Be\(^3+\) ion and an X\(^-\) (Kusakabe et al. 2013a, 2013b). The recombination of \(^7\)Be with X\(^-\) occurs in a higher temperature environment than that of lighter nuclides. At \(^7\)Be recombination, therefore, the thermal abundance of free electrons \( e^- \) is still very high, and abundant \(^7\)Be\(^3+\) ions can exist. The charge exchange reaction then only affects the \(^7\)Be abundance.

Because of relatively small binding energies, the bound states cannot form until late in the BBN epoch. At low temperatures,\(^7\)

\[ [A/B] = \log(n_A/n_B) - \log(n_A/n_B)_\odot, \] where \( n_i \) is the number density of \( i \) and the subscript \( \odot \) indicates the solar value for elements A and B.
the nuclear reactions are already inefficient. Hence, the effect of the $X^-$ particles is not large. However, the $X^-$ particle can cause efficient production of $^6\text{Li}$ (Pospelov 2007b) with the weak destruction of $^7\text{Be}$ (Bird et al. 2008; Kusakabe et al. 2007) depending on its abundance and lifetime (Bird et al. 2008; Kusakabe et al. 2008, 2010).

The $^6\text{Li}$ abundance can significantly increase through the $X^-$-catalyzed transfer reaction $4\text{He}^*(d, X^-)^6\text{Li}$ (Pospelov 2007b). The cross section of the reaction is six orders of magnitude larger than that of the radiative $^4\text{He}(d, \gamma)^6\text{Li}$ reaction through which $^6\text{Li}$ is produced in the SBBN model (Hamaguchi et al. 2007). Other transfer reactions such as $^7\text{Be}^*(t, X^-)^7\text{Li}$, $^4\text{He}^*(\text{He}, X^-)^7\text{Be}$, and $^6\text{Li}^*(p, X^-)^7\text{Be}$ are also possible (Cyburt et al. 2006). Their rates are, however, not as large as that of the $4\text{He}^*(d, X^-)^6\text{Li}$ since the former reactions involve a $\Delta t = 1$ angular momentum transfer and consequently a large hindrance of the nuclear matrix element (Kamimura et al. 2009).

The most important reaction for a reduction of the primordial $^7\text{Be}$ abundance is the resonant reaction $^7\text{Be}^*(p, \gamma)^8\text{Li}$ through the first atomic excited state of $^9\text{Be}$ (Bird et al. 2008) and the atomic ground state (GS) of $^9\text{B}^*(1^+, 0.770 \text{MeV})\text{X}$, i.e., an atom consisting of the $1^+$ nuclear excited state of $^9\text{B}$ and an $X^-$ (Kusakabe et al. 2007). From a realistic estimate of binding energies for $X$-nuclei, however, the latter resonance has been found to be an inefficient pathway for $^7\text{Be}$ destruction (Kusakabe et al. 2008).

The $^8\text{Be}^*(p, \gamma)^9\text{Be}$ reaction through the $^9\text{Be}$ atomic GS $^9\text{B}^*(1^+, 1.684 \text{MeV})\text{X}$ atomic excited state of $^9\text{Be}$ (Kusakabe et al. 2008) produces the $A = 9$ $X$-nucleus so that it can possibly lead to the production of heavier nuclei. This reaction, however, is not operative because of its large resonance energy (Kusakabe et al. 2008).

The resonant reaction $^8\text{Be}^*(n, X^-)^9\text{Be}$ through the atomic GS of $^9\text{Be}^*(1^+/2^+, 1.684 \text{MeV})\text{X}$ is another reaction producing nuclei with $A = 9$ nuclei (Pospelov 2007a). Kamimura et al. (2009), however, adopted a realistic root mean square charge radius for $^9\text{Be}$ of 3.39 fm, and found that $^9\text{Be}^*(1^+/2^+, 1.684 \text{MeV})\text{X}$ is not a resonance but a bound state located below the $^9\text{Be}^*\text{n}0$ threshold. A subsequent four-body calculation for the $\alpha + \alpha + n + X^-$ system confirmed that the $^9\text{Be}^*(1^+/2^+, 1.684 \text{MeV})\text{X}$ state is located below the threshold (Kamimura et al. 2010). This was also confirmed by Cyburt et al. (2012) using a three-body model. The effect of the resonant reaction is therefore negligible. The detailed BBN calculations of Kusakabe et al. (2008, 2010) precisely incorporate recombination reactions of nuclides and $X^-$ particles, nuclear reactions of X-nuclei, and their inverse reactions. These calculations have also included reaction rates estimated in a rigorous quantum few-body model (Hamaguchi et al. 2007; Kamimura et al. 2009). The most realistic calculation (Kusakabe et al. 2010) shows no significant production of $^9\text{Be}$ and heavier nuclides.

Reactions of neutral $X$-nuclei, i.e., $^9\text{Be}^*(d, X^-)$, and $^6\text{Li}^*(d, X^-)$, can produce and destroy Li and Be (Jedamzik 2008a, 2008b). The rates for these reactions and the charge-exchange reactions $p\alpha(X, d)\alpha X$, $d\alpha(X, d)\alpha X$, and $t\alpha(X, d)\alpha X$ have been calculated in a rigorous quantum few-body model (Kamimura et al. 2009). The cross sections for the charge-exchange reactions are much larger than those of the nuclear reactions so that the neutral $X$-nuclei $p\alpha$, $d\alpha$, and $t\alpha$ are quickly converted to $\alpha X$ before they induce nuclear reactions. The production and destruction of Li and Be is not significantly affected by the presence of neutral $X$-nuclei (Kamimura et al. 2009). This was confirmed in a detailed nuclear reaction network calculation (Kusakabe et al. 2010). It has been shown in our previous work (Kusakabe et al. 2008, 2010) that concordance with the observational constraints on $D, ^3\text{He}$, and $^4\text{He}$ is maintained in the parameter region of $^7\text{Li}$ reduction.

In this paper, we present an extensive study on effects of a CHAMP, $X^-$, on BBN. First, we study the effects of theoretical uncertainties in the nuclear charge distributions on the binding energies of nuclei and the $X^-$, reaction rates, and BBN. Next, we derive the most precise radiative recombination rates for $^7\text{Be}, ^7\text{Li}, ^9\text{Be}$, and $^4\text{He}$ with an $X^-$. Finally, we suggest a new reaction for $^9\text{Be}$ production, i.e., $^7\text{Li}^*(d, X^-)^9\text{Be}$. Based upon our updated BBN calculation, it is found that the amount of $^7\text{Be}$ destruction depends significantly upon the assumed charge density for the $^7\text{Be}$ nucleus. The most realistic constraints on the initial abundance and the lifetime of the $X^-$ are then derived, and the primordial $^7\text{Be}$ abundance is also estimated.

In Section 2, models for the nuclear charge density are described. In Section 3, binding energies of the $X$-nuclei are calculated with both a variational method and the integration of the Schrödinger equation for different charge densities. In Section 4, reaction rates are calculated for the radiative proton capture of reactions $^7\text{Be}^*(p, \gamma)^8\text{Li}$, and $^8\text{Be}^*(p, \gamma)^9\text{Be}$. Theoretical uncertainties in the rates due to the assumed charge density shapes are deduced. In Section 5, rates for the radiative recombination of $^7\text{Be}, ^7\text{Li}, ^9\text{Be}$, and $^4\text{He}$ with $X^-$ particles are calculated. Both nonresonant and resonant rates are derived. The difference of the recombination rate for $X^-$ particles compared to that for electrons is shown. In Section 6, a new reaction for $^7\text{Be}$ production is pointed out. It is the radiative recombination of $^7\text{Li}$ and an $X^-$ followed by deuteron capture. In Section 7, the rates and $Q$-values for $\beta$-decays and nuclear reactions involving the $X^-$ particle are derived. In Section 8, a new reaction network calculation code is explained. In Section 9, we show the evolution of elemental abundances as a function of cosmic temperature and derive the most realistic constraints on the initial abundance and the lifetime of the $X^-$. Parameter regions for the solution to the $^7\text{Li}$ problem, and the prediction of primordial $^9\text{Be}$ are presented. Section 10 is devoted to a summary and conclusions. In the Appendix, we comment on the electric dipole transitions of $X$-nuclei which change nuclear and atomic states simultaneously.

2. NUCLEAR CHARGE DENSITY

We assume that a CHAMP with a single negative charge and spin zero was present during the BBN epoch. We derive general constraints depending on the mass of the $X^-$, i.e., $m_X$. The mass is treated as one parameter. Although the existence of very light CHAMPs is excluded by searches in collider experiments, their existence during the BBN epoch is also considered in this paper. This could occur, for example, if the mass of the $X^-$ were time dependent. In order to estimate possible uncertainties in the binding energies of nuclei and $X^-$ particles which are associated with the nuclear charge density, we use three different shapes...

---

8 $^7\text{Be}$ produced during the BBN is transformed into $^7\text{Li}$ by electron capture in the epoch of the recombination of $^7\text{Be}$ and electron much later than the BBN epoch. The primordial $^7\text{Li}$ abundance is therefore the sum of abundances of $^7\text{Li}$ and $^7\text{Be}$ produced in BBN. In SBBN with the baryon-to-photon ratio inferred from WMAP, $^7\text{Li}$ is produced mostly as $^7\text{Be}$ during the BBN.

9 Throughout the paper, we use natural units, $\hbar = c = k_B = 1$. For the reduced Planck constant $\hbar$, the speed of light $c$, and the Boltzmann constant $k_B$. We use the usual notation $1(2.3)4$ for a reaction $1 + 2 \rightarrow 3 + 4$. 

---

THE ASTROPHYSICAL JOURNAL SUPPLEMENT SERIES, 214:5 (35pp), 2014 September

KUSAKABE ET AL.
for the charge density. The first is a Woods–Saxon (WS) shape:

\[ \rho_{WS}(r') = \frac{Z e C_{WS}}{1 + \exp[(r' - R)/a]}, \]

where \( r' \) is the distance from the center of mass of the nucleus, \( Z e \) is the charge of the nucleus, \( R \) is the parameter characterizing the nuclear size, \( a \) is nuclear surface diffuseness, and \( C_{WS} \) is a normalization constant. The \( C_{WS} \) value is fixed by the equation of charge conservation, \( Z e = \int \rho_{WS} dr' \), and it is given by

\[ C_{WS} = \left(4\pi \int_0^\infty \frac{r'^2}{1 + \exp[(r' - R)/a]} dr'\right)^{-1}. \]

For a given value of diffuseness \( a, R \) can be constrained so that the parameter set of \((a, R)\) satisfies the root-mean-square (rms) charge radius \( (r'^2)_{\text{C}}^{1/2} \) measured in nuclear experiments. The potential between an \( X^- \) and a nucleus \( A \) (\( XA \) potential) is calculated by folding the Coulomb potential with the charge density:

\[ V(r) = \int -\frac{e\rho(r')}{x} dr', \]

where \( r \) is the position vector from an \( X^- \) to the center of mass of \( A, r' \) is the position vector from the center of mass of \( A, x = r + r' \), is the displacement vector between the \( X^- \) and the position, and \( \rho(r') \) is the charge density of the nucleus. The charge density could be distorted from the density of a normal nucleus by the potential of an \( X^- \). The distortion effect, however, is relatively small because of the weak Coulomb potential. Hence, we neglect it in this study. Under the assumption of a WS charge distribution \( \rho_{WS}(r') \), the potential reduces to the form

\[ V_{WS}(r) = -2\pi C_{WS} Z e^2 \int_0^\infty \frac{dr'r'}{r} \frac{(r + r') - |r - r'|}{1 + \exp[(r - R)/a]} \]

The second charge density adopted in this study is a Gaussian shape described by

\[ \rho_G(r') = \frac{Z e}{\pi^{3/2} b^3} \exp \left[-\left(\frac{r'}{b}\right)^2\right], \]

where the parameter is related to the rms charge radius by \( b = (2/3)^{1/2} (r'_C)^{1/2} \). The \( XA \) potential is given by

\[ V_G(r) = \int dr' -\frac{e\rho_G(r')}{x} = -\frac{Z e^2}{r} \text{erf}\left(\frac{r}{b}\right), \]

where \( \text{erf}(x) = 2/\sqrt{\pi} \int_0^x \exp(-t^2) dt \) is the error function.

The third charge density is a square well given by

\[ \rho_{\pi}(r') = \frac{3Z e}{4\pi r_0^3} H(r_0 - r'), \]

where \( H(x) \) is the Heaviside step function and the surface radius is related to the rms charge radius by \( r_0 = (5/3)^{1/2} (r'_C)^{1/2} \). The \( XA \) potential is then given by

\[ V_{\pi}(r) = -\frac{Z e^2}{2r_0} \left[3 - \left(\frac{r}{r_0}\right)^2\right] \quad (\text{for } r \leq r_0) \]

\[ -\frac{Z e^2}{r} \quad (\text{for } r > r_0). \]

3. BINDING ENERGY

Binding energies and wave functions for bound states of \( X \)-nuclei are calculated for four different \( X \)-particle masses: \( m_X = 1, 10, 100, \) and 1000 GeV. We performed both numerical integrations of the Schrödinger equation with RADCAP (Bertulani 2003)\(^{10}\) and variational calculations with the Gaussian expansion method (Hiyama et al. 2003). It was confirmed that binding energies derived with the two methods generally agree with each other to within \( \sim 1 \% \).

Table 1 shows the adopted experimental rms charge radii, and calculated binding energies of GS \( X \)-nuclides for \( m_X = 100 \) GeV. This mass is chosen as one example in which the \( X^- \) particle is much heavier than the lighter nuclei. Hence, the reduced mass of the \( A + X^- \) system is given by \( \mu = m_A m_X/(m_A + m_X) \rightarrow m_A \), where \( m_A \) is the mass of nucleus \( A \). The second and the third columns show measured rms charge radii and the associated reference, respectively. Results for three different nuclear charge distributions, i.e., Gaussian (fourth column), homogeneous (fifth column), and WS with three values for the diffuseness parameter \( a = 0.45 \) fm (WS45; sixth column), 0.4 fm (WS40; seventh), and 0.35 fm (WS35; eighth), are shown. We have chosen these three values for the diffuseness parameter \( a \) since larger \( a \) values do not lead to simultaneous solutions of \( R \) that reproduce the rms charge radii for all nuclides.

Binding energies of the first atomic excited states, \(^8\)B\(_X^2\) and \(^9\)B\(_X^2\), are also shown since they are important in resonant reactions through the atomic excited states that result in \(^5\)Be\(_X^-\) destruction and \(^9\)B\(_X^2\) production. The superscript * indicates an atomic excited state, which is different from a nuclear excited state indicated by a superscript *. Binding energies for the Gaussian charge distribution are the largest. Those for a homogeneous distribution are the smallest, while those for the WS distribution are intermediate. In addition, with a larger diffuseness parameter, the binding energies are larger. The reason for this ordering of binding energies is as follows. The five cases are arranged as (1) Gaussian, (2) WS with a large \( a \) value, (3) an intermediate \( a \) value, (4) a small \( a \) value, and (5) the homogeneous distribution. These are listed in descending order of nuclear charge density at small radii \( r \). When the charge density at small \( r \) is relatively large, the Coulomb potential between \( A \) and \( X^- \) is large. Then, large values for the binding energies are derived. It is noted that in all cases, the amplitudes of the Coulomb potentials are smaller than those for two point-charges. This is because of the finite size of charge distribution of the nucleus \( A \). Binding energies are therefore smaller than those in the Bohr’s atomic model.

Table 2 shows calculated binding energies of GS \( X \)-nuclides and the first atomic excited states of \(^8\)B\(_X^2\) and \(^9\)B\(_X^2\) in the WS40 model for \( m_X = 1 \) GeV (second column), 10 GeV (third column), 100 GeV (fourth column), and 1000 GeV (fifth column). The WS charge distribution with a diffuseness parameter \( a = 0.4 \) fm is taken as our primary model in this paper. When \( m_X \) is larger, the reduced mass \( \mu = m_A m_X/(m_A + m_X) \) is larger. Binding energies are then larger. However, the binding energies for \( m_X = 100 \) GeV and 1000 GeV do not differ from each other since the reduced masses in both cases are already near the limiting value of \( \mu = m_A m_X/(m_A + m_X) \rightarrow m_A \).

\(^{10}\) In the RADCAP code, there was an error in the numerical value of \( \pi \), which was corrected.
### Table 1

| Nuclei | \( r^2 \langle \rho r^2 \rangle / \rho_{\text{rms}}^2 \) (fm) | Reference | Gaussian | Homogeneous | WS(0.45 fm) | WS(0.4 fm) | WS(0.35 fm) |

---

**Figure 1.** Binding energies of nuclei and \( X^- \) particles with \( m_X = 100 \text{ TeV} \) for different charge distributions. For respective nuclei, calculated results for Gaussian (leftmost lines), Woods–Saxon type with diffuseness parameters \( a = 0.45 \text{ fm} \) (second lines from the left), \( 0.40 \text{ fm} \) (third lines), and \( 0.35 \text{ fm} \) (fourth lines), and a homogeneous well (fifth lines) are shown. Error bars indicate uncertainties determined from uncertainties in the experimental rms charge radii.

(A color version of this figure is available in the online journal.)

Figure 1 shows binding energies of GS X-nuclides and the first atomic excited states of \(^{8}\text{B}\) and \(^{9}\text{B}\) in the five models of nuclear charge distribution for \( m_X = 100 \text{ TeV} \). As the nuclear mass increases, the nuclear charge number and the reduced mass become larger. Therefore, heavier nuclei generally have larger...
binding energies. Error bars indicate uncertainties originating from the experimental 1σ error in the rms charge radii.

Errors in binding energies of nuclides up to 4He are small, while those for heavier nuclides can be O(0.1 MeV). However, Q-values for most reactions involving X-nuclei heavier than 4HeX are large, ≥1 MeV (e.g., Kusakabe et al. 2008). Effects of errors in binding energies on the rates of forward and inverse reactions are then small. Two exceptions are 7BeX(p, γ)8B X (Q = 0.64 MeV) and 8BeX(p, γ)9B X (Q = 0.33 MeV). These reactions are also exceptional because the resonant components in their reaction rates can be dominant. For the reason described above, we adopted data calculated for the WS40 model, such as nuclear masses, reaction rates, coefficients for reverse reactions, and Q-values. Only data for the reactions 7BeX(p, γ)8B X and 8BeX(p, γ)9B X are calculated for three models of charge distribution, i.e., Gaussian, WS, and homogeneous types.

In the limit that the mass of the X− particle is much larger than that of light nuclides ~O(1 GeV), reaction rates of the radiative neutron capture are very small. This is because the electric multipole moments approach zero in this limit and the electric matrix elements are very small. This situation is similar to the case of the long-lived, strongly interacting massive particle X0 (Kusakabe et al. 2009). Therefore, we assume that rates of radiative neutron capture reactions are vanishingly small in this study. This is different from the assumption in Kusakabe et al. (2008, 2010).

Figure 2 shows binding energies of GS X-nuclides and the first atomic excited states, 5B_X^+ and 6B_X^+, for nuclear charge distribution models of Gaussian (dashed lines), WS40 (solid lines), and homogeneous (dot–dashed lines) as a function of m_X. Resonance energies E_r are also shown for 5B_X^+ and 6B_X^+ measured relative to the separation channels, 7BeX+p and 8BeX+p. Binding energies are larger when the value of m_X is larger, and they approach the asymptotic value in the limit of μ → m_Λ. Maxima are observed in the curves of E_r(5B_X^+) and E_r(6B_X^+) at m_X ≲ 10 GeV. The resonance energies increase with increasing m_X in the mass region of m_X ≲ 10 GeV, while they are approximately saturated in the region of m_X ≳ 10 GeV. Since rates of the resonant reactions are sensitive to the resonance energies, results of BBN including the existence of X− significantly depend on the mass m_X, as described below. Open circles show binding energies of E_B(7BeX), E_B(8B X), and the resonance energy E_r(5B_X^+) derived by a quantum many-body calculation for m_X = ∞ (Kamimura et al. 2009). The open circles are consistent with calculated values in the Gaussian model.

Figures 3 and 4 show wave functions of the GS and first atomic excited states of 5B X^+ and 6B X^+ for the case of m_X = 1000 GeV with nuclear charge distribution models of Gaussian (dashed lines), WS40 (solid lines), and homogeneous (dot–dashed lines).
There are differences between the three lines for the GS of $^8\text{B}_X$ and $^9\text{B}_X$, although they are relatively small. On the other hand, differences are hardly seen for the excited states. Shapes of the charge distribution predominantly affect the Coulomb potentials at small $r$ values. When angular momentum exists, such as in the $l = 1$ excited states of $^8\text{B}_{X}^a$ and $^9\text{B}_{X}^a$, however, the effect of the centrifugal potential $l(l+1)/2\mu r^2$ is significant. The effect of the nuclear charge distribution is therefore most important for GS X-nuclei whose amplitudes of wave functions at small $r$ are larger than those of the excited states. The Gaussian type has the largest Coulomb potential, the WS type has the second largest, and the homogeneous type the smallest. Because of the Coulomb attractive force, the wave functions in the Gaussian model are located in a region of smaller $r$ than those in other models, while those in the homogeneous case are the most extended radially.

4. RESONANT PROTON CAPTURE REACTIONS

Two important resonant reactions are

\[
^7\text{Be}_X + p \rightarrow ^8\text{B}_{X}^a(2P) \rightarrow ^8\text{B}_X + \gamma
\]

and

\[
^8\text{Be}_X + p \rightarrow ^9\text{B}_{X}^a(2P) \rightarrow ^9\text{B}_X + \gamma
\]

where $(2P)$ indicates the atomic 2P state and $m(A)$ and $m(A_X)$ are masses of nucleus $A$ and X-nucleus $A_X$, respectively. Resonance rates for these radiative capture reactions can be calculated as follows.

The thermal reaction rate is derived as a function of temperature $T$ by numerically integrating the cross section over a Maxwellian energy distribution,

\[
\langle \sigma v \rangle = \left( \frac{8}{\pi \mu} \right)^{1/2} \frac{1}{T^{3/2}} \int_0^\infty E \sigma(E) \exp \left( -\frac{E}{T} \right) dE,
\]

where $E$ is the center of mass kinetic energy and $\sigma(E)$ is the reaction cross section as a function of $E$.

The thermal reaction rate for isolated and narrow resonances is given (Angulo et al. 1999) by

\[
N_A(\sigma v) = N_A \left( \frac{2\pi}{\mu} \right)^{3/2} \omega T^{-3/2} \exp(\Gamma_i/T) 
\]

where $N_A$ is Avogadro’s number, $\omega$ is the reduced mass of the two interacting mass units (amu) given by $A = A_1A_2/(A_1 + A_2)$ with $A_1$ and $A_2$ the masses of two interacting particles, 1 and 2, in amu, and $T_0 = T/(10^9 \text{K})$ is the temperature in units of $10^9 \text{K}$. The parameter $\omega$ is a statistical factor defined by

\[
\omega = (1 + \delta_{12}) \frac{(2J + 1)}{(2I_1 + 1)(2I_2 + 1)},
\]

where $I_i$ is the spin of the particle $i$, $J$ is the spin of the resonance, and $\delta_{12}$ is the Kronecker delta necessary to avoid the double counting of identical particles. The quantity in Equation (11) $\gamma$ is defined by

\[
\gamma = \frac{\Gamma_i}{\Gamma(E_i)},
\]

where $\Gamma_i$ and $\Gamma_f$ are the partial widths for the entrance and exit channels, respectively. $\Gamma(E_i)$ is the total width for a resonance with resonance energy $E_i$. $\gamma_{\text{MeV}}$ is the $\gamma$ factor in units of MeV, and $E_{\text{r,MeV}}$ is the resonance energy in units of MeV.

When $\omega = 1$ as in the reactions considered here and the radiative decay widths of $^8\text{B}_X^a$ and $^9\text{B}_X^a$ $\Gamma_r$ are much smaller than those for proton emission (as assumed here), the thermal reaction rate is given by

\[
N_A(\sigma v) = 1.5394 \times 10^{11} \text{ cm}^{-3} \text{ mol}^{-1} s^{-1} A^{-3/2} \Gamma_{r,\text{MeV}} 
\]

\[
\times T_0^{-3/2} \exp(-11.605 E_{\text{r,MeV}}/T_0),
\]

where $\Gamma_{r,\text{MeV}} = \gamma_{\text{MeV}}/(1 \text{ MeV})$ is the radiative decay width in units of MeV and $C$ is a rate coefficient determined from $\Gamma_r$ and $\Gamma_r$.

The rate for a spontaneous emission via an electric dipole (E1) transition is given (Blatt & Weisskopf 1991) by

\[
\Gamma_{r,\text{MeV}} = \frac{16\pi}{9} e^2 E_\mu^2 \frac{1}{2I_1 + 1} \sum_{M_iM_f} \int r Y_{1\mu}(\hat{r}) Y_1^{\dagger} \Psi_f(r) d^2r,
\]

where

\[
e_1 = e \frac{Z_1m_2 - Z_2m_1}{m_1 + m_2}
\]

is the effective charge with $m_1$ and $Z_2$ the mass and the charge number of species 2 and 1. $E_\mu$ is the energy of the emitted photon, $I_i$ is the angular momentum of the initial state, and $M_i$ and $M_f$ are magnetic quantum numbers of initial and final states with $\mu = M_i - M_f$. $\Psi_i$ and $\Psi_f$ are wave functions of the initial and final states, respectively, and $Y_{1\mu}(\hat{r})$ is the dipole spherical surface harmonic.

We assume that the nuclear states do not significantly change between $^8\text{B}_X^a$ and $^9\text{B}_X^a$. For both resonances of $^8\text{B}_X^a$, the quantity $\Gamma_{r,\text{MeV}}$ is estimated to be

\[
\Gamma_{r,\text{MeV}} = 1.26539 \times 10^{14} \text{ s}^{-1} E_\mu^2 (\gamma_{\text{MeV}})^3 (\tau_{\text{df,em}})^2,
\]

where $e_1 = e(Z_1m_1 - Z_2m_2)/(m_1 + m_2)$ is the effective charge with $Z_2 = 5$ and $Z_1 = -1$ the charge numbers of $^8\text{B}$ and the $X^-$, respectively, and $\tau_{\text{df}} = \int r^2 d^2r \psi_i^2 \psi_f$ is the radial matrix element.

Figure 5 shows thermonuclear reaction rates for resonant reactions $^7\text{Be}_X(p, \gamma)^8\text{B}_X$ (black lines) and $^8\text{Be}_X(p, \gamma)^9\text{B}_X$ (purple lines) as a function of $T_0$ for the case of $m_X = 1000 \text{ GeV}$. Thick dashed, solid, and dot–dashed lines correspond to Gaussian type, WS40, and homogeneous type nuclear charge distributions, respectively. The thin dashed line corresponds to the reaction rate for $^7\text{Be}_X(p, \gamma)^8\text{B}_X$ derived by means of a quantum many-body model calculation for $m_X = \infty$ (Kamimura et al. 2009). Since the resonant reaction rate is proportional to the Boltzmann suppression factor of $\exp(\Gamma_i/T)$, relatively small differences in resonance energies between different charge distribution cases (Figure 2) can lead to significant differences in the reaction rates.

Tables 3 and 4 show calculated parameters for the resonant reactions $^7\text{Be}_X(p, \gamma)^8\text{B}_X$ and $^8\text{Be}_X(p, \gamma)^9\text{B}_X$ for the three model charge distributions and with a fixed mass of $m_X = 1 \text{ TeV}$. The matrix elements, the resonance energies, the energies of emitted photons, the radiative decay widths of the resonances, the rate coefficients, and the reaction $Q$-values are listed in the second to seventh columns, respectively.
The resonance energy, the dipole photon energy, and the reaction Q-value are given by
\[ E_i = -E_B(B_X^2) - [E(Be + p) - E_B(Be_X)]. \]
\[ E_\gamma = E_B(B_X) - E_B(B_X^2), \]
\[ Q = E(Be + p) - E_B(Be_X) + E_B(B_X) \]
\[ = E_\gamma - E_i, \]
(18)
respectively, where the quantities \( E(Be + p) = 0.1375 \) MeV and \( E(B^0 + p) = -0.1851 \) MeV are binding energies of \( ^8\text{B} \) and \(^9\text{B} \) with respect to the energies of the separation channels, respectively.

Tables 5 and 6 show calculated parameters of the resonant reactions \(^7\text{Be}_X(p, \gamma)^9\text{B}_X \) and \(^8\text{Be}_X(p, \gamma)^{10}\text{B}_X \), respectively, obtained with the WS40 model for \( m_X = 1, 10, 100, \) and 1000 GeV. The matrix elements, the resonance energies, the energies of emitted photons, the radiative decay widths of resonances, the rate coefficients, and the reaction Q-values are listed in the second to seventh columns, respectively.

In our BBN calculation, resonant rates for the proton capture reactions are adopted, while the nonresonant rates are taken from Kamimura et al. (2009).

5. Radiative Recombination with \( X^- \)

5.1. \(^7\text{Be} \)

5.1.1. Energy Levels

Table 7 shows the binding energies of \(^7\text{Be}_X \) atomic states with main quantum numbers \( n \) ranging from one to seven. Since the \(^7\text{Be} \) nuclear charge distribution has a finite size, the amplitude of the Coulomb potential at small \( r \) is less than that for two point-charges. Wave functions at small radii and binding energies of tightly bound states with small \( n \) values therefore deviate from those of the Bohr model. Binding energies in the Bohr model are given by \( E_{\text{Bohr}} = Z^2 \alpha^2 \mu/2n^2 \), where \( \alpha \) is the fine structure constant. On the other hand, the binding energies of loosely bound states with large \( n \) values are similar to those of the Bohr model.

5.1.2. \(^7\text{Be}(X^-, \gamma)^7\text{Be}_X \) Resonant Rate

The resonant rates of the reaction \(^7\text{Be}(X^-, \gamma)^7\text{Be}_X \) are calculated for \( m_X = 1, 10, 100, \) and 1000 GeV adopting the WS40 model for the nuclear charge distribution. The normalization of the total charge leads to a radius parameter, \( R = 2.63 \) fm. Radiative decay widths for E1 transitions are calculated taking into account the change of the E1 effective charge as a function of \( m_X \).

In general, the recombination can efficiently proceed via resonant reactions through atomic states \(^7\text{Z}_X^{*}\) composed of a nuclear excited state \(^7\text{Z}^* \) and an \( X^- \) (Bird et al. 2008). In these reactions, the resonances radiatively decay to lower energy states of \(^7\text{Z}_X^{*}, ^7\text{Z}_X^*, ^7\text{Z}_X\), and \(^7\text{Z}_X \) that have larger binding energies. Once bound states are produced in the reaction, subsequent transitions via radiative decays to lower energy states occur quickly. Finally, the GS \(^7\text{Z}_X \) is produced after atomic states are converted to the atomic GS, and the nuclear excited state \(^7\text{Z}^* \) inside the atomic states is converted to the nuclear GS (Bird et al. 2008).

Table 8 shows calculated parameters of important transitions related to the reaction \(^7\text{Be}(X^-, \gamma)^7\text{Be}_X \) for \( m_X = 1, 10, 100, \) and 1000 GeV. There are an infinite number of atomic states of \(^7\text{Be}_X \), composed of the first nuclear excited state \(^7\text{Be}^*[^{16}\text{Be}^*(0.429 \text{ MeV, } 1/2^-)] \) and an \( X^- \). Among them states
that satisfy $E_R \lesssim 0.4291$ MeV are important resonances in the recombination. We take into account atomic resonances with binding energies of 0.23 MeV $\lesssim E_R \lesssim 0.43$ MeV. They are the 1S state for $m_X = 1$ GeV, the 2S and the 2P states for $m_X = 10$ GeV, and the 3S, 3P, and 3D states for $m_X = 100$ GeV and 1000 GeV. The transitions, matrix elements, radiative decay

| $m_X$ (GeV) | $\tau_{\gamma}$ (fm) | $E_\gamma$ (MeV) | $E_\alpha$ (MeV) | $\Gamma_\gamma$ (eV) | $C$ ($10^6$ cm$^3$ mol$^{-1}$ s$^{-1}$) | Q-value (MeV) |

Note. $^a$ Given by $\Gamma_\gamma = \tau_{\gamma}^{-1}$ with a lifetime of 192 fs taken from that of the first excited 1/2$^-$ state in $^7$Be (Tilley et al. 2002).
involves transitions to atomic states of the same nuclear state ($^7Z_X^+$ or $^7Z_X^{++}$). For Type 1, decay widths for the transitions can be approximately calculated by taking into account only the atomic wave functions. Type 2 involves transitions to the nuclear GS of the same atomic state ($^7Z_X^+$ or $^7Z_X^{++}$). For Type 2, the decay widths can be approximately calculated by taking into account only the nuclear wave functions. Type 3 denotes transitions to different atomic states of the nuclear GS ($^7Z_X^+$ or $^7Z_X^{++}$). This transition type simultaneously involves both atomic and nuclear transitions, and the number of possible final states can be very large. In addition, calculations of decay widths for the transitions need both nuclear and atomic wave functions. Although a precise calculation of decay widths is beyond the scope of this study, we show in the Appendix that the E1 widths for Type 3 transitions are significantly smaller than those of Type 1. In the Appendix, we suggest that the E1 width for Type 3 transitions can be interestingly large for exotic atomic systems involving a negatively charged particle with a mass equal to or larger than the nuclear mass. Most importantly, Type 3 transition widths can be much larger than those of normal atomic systems composed of nuclei and electrons.

We suppose that in Type 1 transitions the nuclear states do not significantly change and only their atomic states change. Then, one can simply take atomic wave functions expressed as $\psi_i(r) = \psi_i(2l_i m_i, r)$ and $\psi_f(r) = \psi_f(2l_f m_f, r)$, where $\psi_i$ and $\psi_f$ are radial wave functions of initial and final states, respectively, of the initial state, and $l_i$ and $m_i$ are those of the final state. The radiative decay width (Equation (15)) of the resonance $^7Z_X^{++}$ is then rewritten in the form

$$\Gamma_\gamma = C(l_i, l_f) e^{-\frac{E_{\text{res}}}{T_{\text{B}}}} t_{\text{res}}^2,$$

where $C(l_i, l_f)$ is a constant that depends on angular momenta $l_i$ and $l_f$. The values $C(0, 1) = 4/3, C(1, 0) = 4/9,$ and $C(2, 1) = 8/15$ are used in deriving the following rates.

The thermal resonant rate is given by Equation (11), where in the $^7Z(X^-)$ recombination (for $Z = \text{Li}$ or $\text{Be}$) the reduced mass in amu is $A = A_\text{A}A_\text{X}/(A_\text{A} + A_\text{X})$, and the statistical factor is

$$\omega = \frac{2J + 1}{2l_{\text{res}} + 1}(2l_{\text{res}} + 1) + 1),$$

$$\omega = \frac{2J + 1}{2l_{\text{res}} + 1}(2l_{\text{res}} + 1) + 1),$$

$$\omega = \frac{2J + 1}{2l_{\text{res}} + 1}(2l_{\text{res}} + 1) + 1),$$

where $l_{\text{res}}$ is the azimuthal quantum number of the resonance, and $I(A(3/2^-)) = 3/2$ and $I(A(1/2^-)) = 1/2$ are the spins of the GS and the first nuclear excited state of $^7Z$, respectively.

The resonant rates via Types 1 and 2 for $m_X = 1$ GeV transitions are derived as

$$N_X(\sigma v)_{\text{SR}} = \begin{cases} 2.94 \times 10^2 \text{ cm}^{-1} \text{ mol}^{-1} s^{-1} (1 - 0.344T_9)^{1/2} & \text{(for } m_9 = 1 \text{ GeV}) \\ 7.40 \times 10^4 \text{ cm}^{-1} \text{ mol}^{-1} s^{-1} T_9^{1/2} & \text{(for } m_9 = 10 \text{ GeV}) \\ 3.73 \times 10^4 \text{ cm}^{-1} \text{ mol}^{-1} s^{-1} T_9^{1/2} & \text{(for } m_9 = 100 \text{ GeV}) \end{cases}$$

The rate for $m_X = 1$ GeV corresponds to the pure nuclear transition from the resonance $^7\text{Be}^{++}(1S)$ to the GS $^7\text{Be}(1S)$. The rate of $m_X = 10$ GeV corresponds to the atomic transition from the resonance $^7\text{Be}^{++}(2P)$ to the GS $^7\text{Be}(1S)$. The first terms in the rates for $m_X = 100$ and 1000 GeV correspond to the atomic transition from the resonance $^7\text{Be}^{++}(3D)$ to $^7\text{Be}^{++}(2P)$, while the second terms correspond to sums of the atomic transitions from the resonance $^7\text{Be}^{++}(2P)$ to $^7\text{Be}^{++}(2S)$ and $^7\text{Be}(1S)$.

This calculated rate is compared to the previous rate derived in the limit of infinite $m_9$ (Equation (2.9) of Bird et al. (2008), to nonresonant rates calculated for the recombination of nuclei and $X^-$ particles in the temperature region of $T_9 = [10^{-3}, 1]$, and obtained approximate analytical expressions.

With higher CM energy, the frequencies for the oscillations of continuum-state wave functions increase. Thus, it takes more computational time to precisely calculate the radial matrix elements or cross sections at larger energy. In the present study, we derived the cross sections only in the energy range of $10^{-5} \text{ MeV} < E < 1 \text{ MeV}$, and the resonance rates are calculated in the temperature range of $T_9 < 1$ using the derived cross sections and just setting cross sections for $E > 1 \text{ MeV}$ to be zero. Since the nucleosynthesis as well as recombinations of $^4\text{He}$ and heavier nuclei with $X^-$ proceed after the temperature of the universe decreases down to $T_9 < 1$, the reaction rates for higher temperatures $T_9 > 1$ are not necessary in BBN calculations. Considering that at the relevant temperatures, the contribution to the thermal rates from reactions at CM energies greater than the temperature is small, our reaction rates can be safely used in the desired temperature regime.

The nonresonant rate for the reaction $^7\text{Be}(X^-, \gamma)^7\text{Be}$ is then derived to be

$$N_X(\sigma v)_{\text{NR}} = \begin{cases} 2.44 \times 10^9 \text{ cm}^{-1} \text{ mol}^{-1} s^{-1} (1 - 0.344T_9)^{1/2} & \text{(for } m_9 = 1 \text{ GeV}) \\ 5.98 \times 10^{10} \text{ cm}^{-1} \text{ mol}^{-1} s^{-1} (1 - 0.211T_9)^{1/2} & \text{(for } m_9 = 10 \text{ GeV}) \\ 4.07 \times 10^{10} \text{ cm}^{-1} \text{ mol}^{-1} s^{-1} (1 - 0.196T_9)^{1/2} & \text{(for } m_9 = 100 \text{ GeV}) \\ 3.86 \times 10^{10} \text{ cm}^{-1} \text{ mol}^{-1} s^{-1} (1 - 0.194T_9)^{1/2} & \text{(for } m_9 = 1000 \text{ GeV}) \end{cases}$$

Nonresonant cross sections are calculated with RADCAP taking into account the multiple components of partial waves for scattering states. We show continuum wave functions at the CM energy $E = 0.07 \text{ MeV}$, which is the average energy corresponding to the temperature of the recombination of $^7\text{Be}+X^-$ for the case of $m_X = 1000 \text{ GeV}$, i.e., $E = 0.07 \text{ GeV}$ with $T \sim 0.4 \times 10^9 \text{ K}$.

The total cross section for the absorption of an unpolarized photon with frequency $\nu \text{ via an } E_1 \text{ transition from a bound state}$

11 In Bird et al. (2008), the effect of direct capture to the state $^7\text{Be}(2S)$ is estimated in the extreme assumption that the 2S state lies above the threshold of $^7\text{Be}+X^-$ with a resonance energy of 10 keV (Equation (2.11) of Bird et al. 2008). However, a three-body calculation for the $^7\text{Be}+^4\text{He}+X^-$ system has confirmed that the 2S state is below the energy threshold, and thus not a resonance. The resonant rate without the effect of the 2S state, i.e., Equation (2.9) of Bird et al. (2008), should therefore be used (M. Kamimura 2008, private communication; Section 3.6 in Kamimura et al. 2009).
(n, l) to a continuum state (E) is given (Gaunt 1930; Karzas & Latter 1961) by
\[
\sigma_{nl \rightarrow E} = \frac{16\pi^2}{3} e_{nl}^2 \mu k_v \times \left[ \frac{l + 1}{2l + 1} \left( \frac{r_{nl}^{E,l+1}}{r_{nl}^{E,l-1}} \right)^2 + \frac{l}{2l + 1} \left( \frac{r_{nl}^{E,l-1}}{r_{nl}^{E,l+1}} \right)^2 \right],
\]
where \( k = \sqrt{2\mu E} \) is the wave number and
\[
r_{nl}^{E,l \pm 1} = \int r^2 dr \psi_{nl}(r) \Psi_{nl}(r)
\]
is the radial matrix element for the radius \( r \), and wave functions are normalized as
\[
\int r^2 dr \left| \psi_{nl}(r) \right|^2 = 1,
\]
and asymptotically
\[
\psi_{E,l}(r) \sim \frac{\sin \left[ kr - \eta \ln(2kr) - l\pi/2 + \sigma_l + \delta_l \right]}{kr}
\]
at large \( r \), where \( \eta \) is defined by
\[
\eta = \frac{Z}{\sqrt{k_B B}} = \left( \frac{Z^2 \alpha^2 \mu}{2E} \right)^{1/2}
\]
with \( \alpha_B = 1/(\mu a) \) the Bohr radius, \( \alpha_l \) is the Coulomb phase shift, and \( \delta_l \) is the phase shift due to the difference in Coulomb potential between cases of the point charge and finite size nuclei (Burke 2011). The parameter \( \sigma_l \) is the effective charge as defined in Equation (16). We note that the precise cross section (Equation (29)) includes \( e_{nl}^2 \) instead of \( e_l^2 \) which is usually adopted for hydrogen-like normal atoms.

We compare the calculated cross sections with those for the recombination of two point-charges. Wave functions of scattering and bound states and the bound-free absorption cross section in a pure Coulomb field have been derived analytically.

The bound and continuum state wave functions are given (Karzas & Latter 1961) by
\[
\psi_{nl}(r) = \left( \frac{2Z}{n_B} \right)^{3/2} \frac{\Gamma(n+l+1)}{\Gamma(n-l+2) \Gamma(l+2)} \frac{(2Zr/n_B)^l}{(2l+1)} \times e^{-Zr/n_B} F_1 \left( l + 1 - n; 2l + 2; \frac{2Zr}{n_B} \right),
\]
\[
\psi_{E,l}(r) = \exp \left( \frac{\eta \pi}{2} \right) \left[ \frac{\Gamma(l + 1 - i\eta)}{(2l + 1)} \right] \frac{(2kr)^l}{(2l+1)} e^{ikr} \times F_1 \left( l + 1 - i\eta; 2l + 2; -2ikr \right),
\]
where \( F_1 \) is the regular confluent hypergeometric function.

The cross section for absorption or ionization is analytically given (Equations (36) and (37) of Karzas & Latter 1961) by
\[
\sigma_{nl \rightarrow E,l+1} = \frac{\pi e_{nl}^{2l} 2^{4l}}{\mu k_v 3} \times \frac{l^2(n+l)!(l^2 + \eta^2)^2}{(2l+1)!(2l-1)!(n-l-1)!} \times \frac{\exp(-4\eta \cot^{-1} \rho)}{1 - e^{-2\pi \eta}} \frac{\rho^{2l+2}}{(1 + \rho^2)^{2n-2}} \times \left[ G_l(l+1-n; \eta; \rho) - (1 + \rho^2)^2 G_l(l-1-n; \eta; \rho) \right]^2,
\]
where the quantity in the curly brackets is unity when \( l = 1 \), and
\[
\sigma_{nl \rightarrow E,l+1} = \frac{\pi e_{nl}^{2l} 2^{4l+6}}{\mu k_v 3} \times \frac{(l+1)(n+l)!(l^2 + \eta^2)^2}{(2l+1)!(2l-1)!(n-l-1)!} \times \frac{\exp(-4\eta \cot^{-1} \rho)}{1 - e^{-2\pi \eta}} \frac{\rho^{2l+2}}{(1 + \rho^2)^{2n-2}} \times \left[ G_l(l+1-n; \eta; \rho) - (1 + \rho^2)^2 G_l(l-1-n; \eta; \rho) \right]^2.
\]
Equations (36) and (37) correspond to transitions to the continuum states with angular momenta \( l - 1 \) and \( l + 1 \), respectively. The parameter \( \rho \) is defined \( \rho \equiv \eta/n \), and the real polynomial \( G_l \) is given by
\[
G_l(-m, \eta, \rho) = \sum_{s=0}^{2m} b_{l,s} \rho^s,
\]
with coefficients
\[
b_0 = 1, \quad b_1 = \frac{2mn}{l},
\]
\[
\frac{b_s}{s(s + 2l - 1)} \left[ 4\eta(s - 1 - m)b_{s-1} + (2m + 2 - s)(2m + 2l + 1 - s)b_{s-2} \right].
\]

The recombination cross section can be derived using the principle of detailed balance (Blatt & Weisskopf 1991; Rybicki & Lightman 1979)\(^{12} \):
\[
\sigma_{E,l \pm 1 \rightarrow nl} = \frac{|2f(n,l) + 1|}{(2l + 1)(2l - 1)} \frac{E_{\gamma}^2}{\mu E},
\]
where \( f_l \) and \( f_2 \) are spins of particles 1 and 2 constituting the bound state, \( l(n, l) \) is the spin of the bound state \( (n, l) \), and the radiation energy is related to the CM energy and the binding energy by \( E_{\gamma} = E - E_B \).

The thermal recombination rate is derived as a function of temperature \( T \) by integrating the calculated cross section \( \sigma(E) \) over the Maxwellian energy distribution (Equation (10)). The analytical expression for the wave function in the case of a point-charge nucleus (Equations (31) and (32) of Karzas & Latter 1961) is derived using the confluent hypergeometric function calculated with algorithm 707 of Nardin et al. (1992).

Figure 6 shows bound-state wave functions (upper panel) and continuum wave functions (middle panel) at \( E = 0.07 \text{ MeV} \) for the \(^{12}\text{Be} + \chi^-\) system as a function of radius \( r \) for the case of \( m_X = 1 \text{ GeV} \). Solid lines correspond to calculated wave functions while the dotted lines correspond to the analytical formula for hydrogen-like atomic states composed of two point-charges (Equations (34) and (35)). In the upper panel, wave functions for the GS (1S state), 2S, 2P, 3P, 3D, and 4F states

\(^{12} \) It appears that Equation (31) of Bertulani (2003) has an error.
are plotted. Here, one can see that the wave functions for the GS and 2S state in the finite charge distribution case (solid lines) deviate from those of the point-charge case (dotted lines). The wave functions of other states agree with those for the point-charge case. The scattering wave functions for the s-, p-, d-, and f-waves are plotted in the middle panel. Note that the normalization for the amplitude of the wave function adopted in RADCAP is different from that in Karzas & Latter (1961). Hence, the latter wave functions are normalized to satisfy the former normalization. In addition, wave functions derived with RADCAP are multiplied by \( \exp(\frac{i\theta}{\hbar}) \), where \( \theta \) are arbitrary real constants and then transformed into real numbers. Only the wave function of the \( l = 0 \) state for the finite charge distribution case (solid lines) deviates from that of the point-charge case (dotted lines).

The bottom panel shows the recombination cross section as a function of the energy \( E \). The solid lines correspond to the calculated results, while the dotted lines correspond to the analytical solution for the two point-charges (Equations (36), (37), and (41)). Partial cross sections for the following transitions are drawn: scattering \( p \)-wave \( \rightarrow \) bound 1S state (1 black lines); \( p \)-wave \( \rightarrow \) 2S (2 red); \( s \)-wave \( \rightarrow \) 2P (3 green); \( d \)-wave \( \rightarrow \) 2P (4 blue); \( s \)-wave \( \rightarrow \) 3P (5 gray); \( d \)-wave \( \rightarrow \) 3P (6 sky blue); \( p \)-wave \( \rightarrow \) 3D (7 orange); \( f \)-wave \( \rightarrow \) 3D (8 cyan); \( d \)-wave \( \rightarrow \) 4F (9 violet); and \( g \)-wave \( \rightarrow \) 4F (10 magenta). Dotted lines for point-charge nuclei correspond to transitions 1, 4, 8, 2 and 6 overlapping, 10, 3, 5, 7, and 9 in descending order of cross sections at \( E = 10^{-5} \) MeV. This order is true in all figures of recombination cross sections shown in this paper. The cross section of transition 2 is higher than that of transition 6 at high energies although they overlap at low energies. The order of solid lines at \( E = 10^{-5} \) MeV is the same as that of dotted lines. Since the mass \( m_X \) is relatively small, the reduced mass is small and the spatial extent of the bound-state wave functions is large. The effect of a finite size charge distribution is only important for small \( r \) and is therefore small. Small differences in bound and scattering state wave functions lead to small changes in the cross sections through differences in the binding energies and wave function shapes. The largest differences in the cross sections are found for the two transitions starting from an initial \( s \)-wave, i.e., \( s \)-wave \( \rightarrow \) 2P and \( s \)-wave \( \rightarrow \) 3P. This is caused by differences in the scattering \( s \)-wave function.

Figure 7 shows bound-state wave functions (upper panel) and continuum wave functions (middle panel) at \( E = 0.07 \) MeV of the \(^7\)Be+X\(^-\) system as a function of radius \( r \) for the case of \( m_X = 1 \) GeV. The bottom panel shows the recombination cross section as a function of CM energy \( E \). In all panels, the solid lines correspond to calculated results while the dotted lines correspond to analytical formulae for hydrogen-like atomic states composed of two point-charges.

(A color version of this figure is available in the online journal.)
Figure 7. Same as Figure 6, but for $m_X = 10$ GeV.
(A color version of this figure is available in the online journal.)

Figure 8 shows bound-state wave functions (upper panel) and continuum wave functions (middle panel) at $E = 0.07$ MeV for the $^7$Be$+X^-$ system as a function of radius $r$ for the case of $m_X = 100$ GeV. Line types indicate the same quantities as in Figure 6. It is clear from a comparison of Figures 6–8 that deviations of the wave functions from those in the point-charge cases become larger as $m_X$ increases. We can see that deviations of wave functions for bound GS, $2S$, $2P$, and $3P$ states and scattering wave functions of $l = 0$ and $l = 1$ states are very large, and that a deviation exists for the $l = 1$ state, but it is not large. The bottom panel shows the recombination cross section as a function of the energy $E$. Line types indicate the same quantities as in Figure 6. The order of solid lines at $E = 10^{-5}$ MeV is 4, 8, 6, 1, 10, 2, 9, 7, 3, 5. Differences in the solid and dotted lines are even larger than in the case of $m_X = 10$ GeV (Figure 7).

Figure 9 shows bound-state wave functions (upper panel) and continuum wave functions (middle panel) at $E = 0.07$ MeV as a function of radius $r$ for the $^7$Be$+X^-$ system in the case of

Figure 8. Same as Figure 6 for the case of $m_X = 100$ GeV.

The Astrophysical Journal Supplement Series, 214:5 (35pp), 2014 September
Kusakabe et al.

\( m_X \) has a point charge.

The Astrophysical Journal Supplement Series

Figure 9. Same as Figure 6 for the case of \( m_X = 1000 \) GeV. Thin solid lines in the upper and middle panels show results calculated under the assumption that \( ^7\text{Be} \) has a point charge.

(A color version of this figure is available in the online journal.)

\( m_X = 1000 \) GeV. Also shown is the recombination cross section as a function of the energy \( E \) (bottom panel). Thick solid and dotted lines indicate the same quantities as in Figure 6. The order of solid lines at \( E = 10^{-3} \) MeV is 4, 8, 6, 10, 1, 2, 9, 7, 3, 5. Since the reduced mass is similar to that in the case of \( m_X = 100 \) GeV, this figure is rather similar to Figure 8. In order to check our calculations, we also calculate the wave functions and the cross sections for case of point-charge nuclei using the same code (a modified version of RADCAP) as used for the finite charge distribution case. Thin solid lines in the upper and middle panels show the calculated results which agree with analytical solutions (dotted lines) quite well.

We found an important characteristic of the \( ^7\text{Be}^+X^- \) recombination based upon our precise calculation including many transition channels. In the limit of a heavy \( X^- \) particle, i.e., \( m_X \geq 100 \) GeV, the most important transition in the recombination is the \( d\text{-wave} \rightarrow 2P \). This fact does not hold in the case of the point-charge model. In that case, the transition \( p\text{-wave} \rightarrow 1S \) is predominant (see the dotted lines in Figures 6–9). In the case of a finite size charge distribution, in addition to the main pathway of \( d\text{-wave} \rightarrow 2P \), cross sections for the transitions \( f\text{-wave} \rightarrow 3D \) and \( d\text{-wave} \rightarrow 3P \) are also larger than that for the GS formation. It is thus found that estimations of recombination cross section taking into account only the GS as the final state may not be correct.

We note that our rate for \( m_X = 1000 \) GeV is more than six times larger than the previous rate (Bird et al. 2008). We confirmed that the previous rate (Bird et al. 2008) is somewhat close to our rate when only taking into account the transition from the scattering \( p\text{-wave} \) to the bound 1S and 2S states. In Bird et al. (2008), it is described that the capture of \(^7\text{Be}\) directly to the GS of \(^7\text{Be}_X\) has the largest cross section, closely followed by the capture to the 2S level. This is true for hydrogen-like ions composed of point-charged particles. However, we found that the most important transition is from the scattering \( d\text{-wave} \) to the bound 2P state. The previous rate (Bird et al. 2008) was adopted in most previous studies on BBN involving the \( X^- \) particle, including studies by part of the present authors (Kusakabe et al. 2007, 2008, 2010). The nonresonant recombination rate is important for the \(^7\text{Be}\) destruction and also for constraining the parameter region for solving the Li problem. The significant improvement in the rate found in the present work therefore makes it possible to derive an improved constraint on the \( X^- \) particle as shown in Section 8.

5.2. \(^7\text{Li}

5.2.1. Energy Levels

Table 9 shows binding energies for the \(^7\text{Li}_X\) atomic states having main quantum numbers \( n \) from one to seven.

5.2.2. \(^7\text{Li}(X^-, \gamma)^7\text{Li}_X\) Resonant Rate

The resonant rates of the reaction \(^7\text{Li}(X^-, \gamma)^7\text{Li}_X\) were calculated for \( m_X = 1, 10, 100, \) and 1000 GeV in the WS40 model. The radius parameter for the WS40 model is \( R = 2.48 \) fm.

Table 10 shows calculated parameters of important transitions related to the reaction \(^7\text{Li}(X^-, \gamma)^7\text{Li}_X\) for \( m_X = 1, 100, \) and 1000 GeV. Similar to the recombination of \(^7\text{Be}^+X^-\), the recombination can efficiently proceed via resonant reactions involving atomic states of \(^7\text{Li}_X^\ast\) composed of the first nuclear excited state \(^7\text{Li}^\ast\) ([\( ^7\text{Li}(0.478 \text{ MeV}, 1/2^-) \)]). Important resonances for \(^7\text{Li}_X^\ast\) satisfy \( E_B \lesssim 0.47761 \) MeV. We take into account atomic resonances with binding energies of 0.28 MeV \( \lesssim E_B \lesssim 0.48 \) MeV except for the atomic GS for the case of \( m_X = 1 \) GeV. The transitions, matrix elements, radiative decay widths of the resonances, and resonance energies are listed in the second to fifth columns, respectively. For the case of \( m_X = 1 \) GeV, there are no important resonances of atomic excited states because of the relatively small binding energies of \(^7\text{Li}_X\). The most important resonance in the recombination reaction is then the atomic GS of \(^7\text{Li}_X^\ast\) (1S), which can only decay...
into atomic states of the nuclear GS, i.e., \(^7\text{Li}^{\pi}\) and \(^7\text{Li}^\pi\). We take the measured rate for the radiative decay of \(^7\text{Li}^*\) (Tilley et al. 2002) for the decay of \(^7\text{Li}^{\pi}\) into the GS \(^7\text{Li}^\pi(1S)\).

The resonant rates for the reaction \(^7\text{Li}(X^-, \gamma)\,^7\text{Li}^\pi\) via Types 1 and 2 (only for \(m_X = 1\) GeV) transitions are derived to be

\[
N_{\lambda}(\sigma v)_{NR} = \begin{cases} 
5.37 \times 10^2 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} r^{0.3/2} \exp(-3.24/T_{\gamma}) \\
(\text{for } m_X = 1 \text{ GeV}) \\
1.72 \times 10^4 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} r^{-0.2/2} \exp(-1.44/T_{\gamma}) \\
(\text{for } m_X = 100 \text{ GeV}) \\
1.68 \times 10^4 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} r^{-0.2/2} \exp(-1.22/T_{\gamma}) \\
(\text{for } m_X = 1000 \text{ GeV}) 
\end{cases}
\]

The rate for \(m_X = 1\) GeV corresponds to a pure nuclear transition from the resonant \(^7\text{Li}^{\pi}(1S)\) to the GS \(^7\text{Li}^\pi(1S)\) (magnetic dipole transition Tilley et al. 2002). The rate for \(m_X = 10\) GeV is zero since there are no important resonances operating as a path for the recombination reaction. The rates for \(m_X = 100\) and 1000 GeV correspond to the atomic transition from the resonance \(^7\text{Li}^{\pi}(2P)\) to \(^7\text{Li}^\pi(1S)\).

5.2.3. \(^7\text{Li}(X^-, \gamma)\,^7\text{Li}^\pi\) Nonresonant Rate

The thermal nonresonant rate for the reaction \(^7\text{Li}(X^-, \gamma)\,^7\text{Li}^\pi\) was derived as a function of temperature \(T\) by integrating the calculated cross section \(\sigma(E)\) over energy (Equation (10)). The

### Table 9
Binding Energies of \(^7\text{Li}^X\) Atomic States with Main Quantum Numbers \(n = 1–7\) (keV)

| \(m_X = 1\) GeV | \(n = 1\) | \(n = 2\) | \(n = 3\) | \(n = 4\) | \(n = 5\) | \(n = 6\) | \(n = 7\) |
|---|---|---|---|---|---|---|---|
| \(l = 0\) | 198 | 50.7 | 22.7 | 12.8 | 8.23 | 5.73 | 4.21 |
| \(l = 1\) | | 52.0 | 23.1 | 13.0 | 8.31 | 5.77 | 4.24 |
| \(l = 2\) | | | 23.1 | 13.0 | 8.31 | 5.77 | 4.24 |
| \(l = 3\) | | | | 13.0 | 8.31 | 5.77 | 4.24 |
| \(l = 4\) | | | | | 8.31 | 5.77 | 4.24 |
| \(l = 5\) | | | | | | 5.77 | 4.24 |
| \(l = 6\) | | | | | | | 4.24 |

### Table 10
Calculated Parameters for \(^7\text{Li}(X^-, \gamma)\,^7\text{Li}^\pi\) in the WS40 Model

| \(m_X\) (GeV) | Transition | \(\tau_d\) (fm) | \(\Gamma_{\gamma}\) (eV) | \(E_{\gamma}\) (MeV) |
|---|---|---|---|---|
| 1 | \(^7\text{Li}^\pi(1S)\rightarrow^7\text{Li}^\pi(1S)\) | | 0.00627 | 0.280 |
| 100 | \(^7\text{Li}^\pi(2P)\rightarrow^7\text{Li}^\pi(1S)\) | 3.91 | 1.26 | 0.124 |
| 1000 | \(^7\text{Li}^\pi(2P)\rightarrow^7\text{Li}^\pi(1S)\) | 3.81 | 1.34 | 0.105 |

Note. Given by \(\Gamma_{\gamma} = \tau_d^{-1}\) with the lifetime 105 fs taken from that of the first excited \(1/2^-\) state of \(^7\text{Li}\) (Tilley et al. 2002).

Figure 10 shows bound-state wave functions (upper panel) and continuum wave functions (middle panel) at \(E = 0.07\) MeV as a function of radius \(r\) for the \(^7\text{Li}+X^-\) system with \(m_X = 1\) GeV. Also shown is the recombination cross section as a function of energy \(E\) (bottom panel). Line types indicate the same quantities as in Figure 6. The order of solid lines at \(E = 10^{-5}\) MeV is the same as that of dotted lines. In general, the trends of calculated results are similar to those of the \(^7\text{Be}+X^-\) system (Figure 6). However, the Coulomb potential in the \(^7\text{Li}+X^-\) system is smaller than that in the \(^7\text{Be}+X^-\) system. Therefore, the spatial widths of wave functions in the former system are larger. The effect of the finite size of the charge distribution as shown by differences between the solid and dotted lines is then somewhat smaller in the \(^7\text{Li}+X^-\) system than in the \(^7\text{Be}+X^-\) system.

Figures 11–13 show bound-state wave functions (upper panel) and continuum wave functions (middle panel) at \(E = 0.07\) MeV as a function of radius \(r\) for the \(^7\text{Li}+X^-\) system in the case of \(m_X = 10\) GeV, 100 GeV, and 1000 GeV, respectively. Also shown is the recombination cross section as a function of the energy \(E\) (bottom panel). Line types indicate the same quantities as in Figure 6. The order of solid lines at \(E = 10^{-5}\) MeV are 1, 4, 8, 6, 2, 10, 7, 9, 5, 3 in Figure 11, and 1, 4, 1, 8, 6, 10, 2, 5, 9, 3, 5 in Figures 12 and 13, respectively. Similar to the case of the \(^7\text{Be}+X^-\) system, larger \(m_X\) values lead to larger differences in both the wave functions and the recombination cross sections between the finite-size charge and point-charge cases. We also find that this \(^7\text{Li}+X^-\) system has the important characteristic that the transition \(d^-\text{wave} \rightarrow 2P\) is the most important for \(m_X > 100\) GeV.

5.3. \(^9\text{Be}\)

5.3.1. Energy Levels

Table 11 shows the binding energies of \(^9\text{Be}^X\) atomic states that have main quantum numbers \(n\) from one to seven.

5.3.2. \(^9\text{Be}(X^-, \gamma)\,^9\text{Be}^\pi\) Nonresonant Rate

The nonresonant reaction rates for \(^9\text{Be}(X^-, \gamma)\,^9\text{Be}^\pi\) were also calculated for \(m_X = 1, 10, 100,\) and 1000 GeV in the
WS40 model. The radius parameter for the WS40 model is $R = 2.59$ fm.

In the estimation of recombination rate for $^9$Be, the resonant reactions involving atomic states and nuclear excited states for $^9$Be$^*$ were neglected since even the first nuclear excited state has a large excitation energy of 1.684 MeV. We therefore only calculated the nonresonant rate.

The thermal nonresonant rate was derived as a function of temperature $T$ by integrating the calculated cross section $\sigma(E)$ over energy (Equation (10)). It is then

$$N_x(\sigma v)_{NR} = \begin{cases} 
2.07 \times 10^8 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} (1 - 0.339 T_9) T_9^{-1/2} & \text{(for } m_X = 1 \text{ GeV}) \\
3.89 \times 10^8 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} (1 - 0.199 T_9) T_9^{-1/2} & \text{(for } m_X = 10 \text{ GeV}) \\
2.32 \times 10^4 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} (1 - 0.180 T_9) T_9^{-1/2} & \text{(for } m_X = 100 \text{ GeV}) \\
2.14 \times 10^4 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} (1 - 0.179 T_9) T_9^{-1/2} & \text{(for } m_X = 1000 \text{ GeV}). 
\end{cases}$$

(A color version of this figure is available in the online journal.)
Figure 12. Same as Figure 6 for the $^7\text{Li}+X^-\bar{\nu}_e$ system with $m_X = 100$ GeV. (A color version of this figure is available in the online journal.)

Figure 14 shows bound-state wave functions (upper panel) and continuum wave functions (middle panel) at $E = 0.07$ MeV as a function of radius $r$ for the $^9\text{Be}+X^-\bar{\nu}_e$ system for the case of $m_X = 1$ GeV. We also show recombination cross section as a function of the energy $E$ (bottom panel). Line types indicate the same quantities as in Figure 6. The order of solid lines at $E = 10^{-5}$ MeV is the same as that of the dotted lines. Trends of calculated results are similar to those of the $^7\text{Be}+X^-\bar{\nu}_e$ system (Figure 6).

Figures 15–17 show bound-state wave functions (upper panel) and continuum wave functions (middle panel) at $E = 0.07$ MeV as a function of radius $r$, and recombination cross sections as a function of the energy $E$ (bottom panel) of the $^9\text{Be}+X^-\bar{\nu}_e$ system for the cases of $m_X = 10$ GeV, 100 GeV, and 1000 GeV, respectively. Line types indicate the same quantities as in Figure 6. The orders of solid lines at $E = 10^{-5}$ MeV are 4, 1, 8, 6, 10, 2, 7, 9, 3, 5 in Figure 15, and 4, 8, 6, 10, 1, 2, 9, 7, 3, 5 in Figures 16 and 17, respectively. Similar to the case of the

7Be+X− system, larger mX values lead to larger differences in wave functions and recombination cross sections between the finite-size charge and point-charge cases. We also find that the transition, d-wave → 2P, is most important for mX ≳ 100 GeV in this 9Be+X− system.

5.4. 4He

5.4.1. Energy Levels

Table 12 shows the binding energies of 4HeX atomic states that have main quantum numbers n from one to seven.

5.4.2. 4He(X−, γ)4HeX Nonresonant Rate

The nonresonant rates of the reaction 4He(X−, γ)4HeX were calculated for mX = 1, 10, 100, and 1000 GeV using the WS40 model. For this case, the radius parameter is R = 1.31 fm. Since all excited states of 4He* have excitation energies larger than 20 MeV, atomic states of nuclear excited states 4He* are never important resonances in the recombination process. We then calculate only the nonresonant rate.

The thermal nonresonant rates were derived as a function of temperature T by integrating the calculated cross section σ(E) over energy (Equation (10)). The resultant rates are

\[
N_A(\sigma v)_{NR} = \begin{cases} 
5.38 \times 10^4 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} (1 - 0.648T_9) T_9^{-1/2} \\
1.63 \times 10^4 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} (1 - 0.404T_9) T_9^{-1/2} \\
1.32 \times 10^4 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} (1 - 0.367T_9) T_9^{-1/2} \\
1.29 \times 10^4 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} (1 - 0.363T_9) T_9^{-1/2}
\end{cases}
\]

for mX = 1 GeV, 10 GeV, 100 GeV, and 1000 GeV, respectively.
Figure 15. Same as Figure 6 for the $^9$Be+$X^-$ system with $m_X = 10$ GeV. (A color version of this figure is available in the online journal.)

Figure 18 shows bound-state wave functions (upper panel) and continuum wave functions (middle panel) at $E = 0.07$ MeV as a function of radius $r$ for the $^4$He+$X^-$ system in the case of $m_X = 1$ GeV. The recombination cross section is also given as a function of the energy $E$ (bottom panel). Line types indicate the same quantities as in Figure 6. The order of solid lines at $E = 10^{-5}$ MeV is the same as that of the dotted lines. Since the Coulomb potential in the $^4$He+$X^-$ system is small, the wave functions are more extended spatially. Therefore, the effect of the finite-size charge distribution is small as evidenced by the fact that the solid and dotted lines almost overlap in this figure.

Figures 19–21 show bound-state wave functions (upper panel) and continuum wave functions (middle panel) at $E = 0.07$ MeV as a function of radius $r$ for the $^4$He+$X^-$ system in the case of $m_X = 10$ GeV, 100 GeV, and 1000 GeV, respectively. The recombination cross section is also shown as a function of the energy $E$ (bottom panel). Line types indicate the same quantities as in Figure 6. In Figures 19–21, the orders of solid lines at
Figure 17. Same as Figure 6, but for the $^9\text{Be}^+$ system with $m_X = 1000 \text{ GeV}$.

(A color version of this figure is available in the online journal.)

Table 12

| $m_X$ (GeV) | $l = 0$ | $l = 1$ | $l = 2$ | $l = 3$ | $l = 4$ | $l = 5$ | $l = 6$ |

$E = 10^{-5} \text{ MeV}$ are the same as that of the dotted lines. It is apparent that larger $m_X$ values lead to larger differences in the wave functions and recombination cross sections due to a finite-size versus a point-charge distribution. However, because of the small amplitude of the Coulomb potential, the effect of the finite-size nuclear charge does not significantly affect the wave functions and cross sections. As a result, even in the case of heavy $X^-$ particles ($m_X \gtrsim 100 \text{ GeV}$), the dominant transition contributing to the recombination is the $p$-wave $\rightarrow 1S$, similarly to the case of the Coulomb potential for point charges.

5.5. Other $X$-nuclei

As seen in the Sections 5.1–5.4, realistic wave functions and recombination cross sections for $X$-nuclei can be significantly different from those derived using two point-charged particles. Hence, the recombination rates based upon the Bohr atomic model that were utilized in the previous studies (e.g., Dimopoulos et al. 1990; de Rújula et al. 1990; Kohri & Takayama 2007; Kusakabe et al. 2007, 2008) should be considered uncertain by as much as one order of magnitude. Although precise recombination rates for minor nuclei are not yet derived, we assume that the Bohr atom formula (Bethe & Salpeter 1957) for the minor nuclei is sufficient. We adopt cross sections in the limit that the CM kinetic energy, $E$, is much smaller than the binding energy, $E_B$. This is justified since the condition $E = \mu v^2/2 = 3T/2 \ll E_B$ with $v$ the relative velocity of a nucleus $A$ and $X^-$ always holds when the bound-state formation is more efficient than its destruction. The cross sections are thus given by

$$
\sigma_{\text{rec}} = \frac{2\pi^2 e^2}{3\mu^2} E_B \mu^3 v^2,
$$

(57)
where $e = 2.718$ is the base of the natural logarithm. The thermal reaction rate is then given by

$$N_A \langle \sigma \cdot v \rangle = \frac{2^{19/2} \pi^{3/2} N_A e_1^2}{3e^4} \frac{E_B}{\mu^{5/2} T^{1/2}}$$

$$= 1.37 \times 10^4 \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} (e_1/e)^2 \frac{Q_0}{A^{5/2} T_9^{1/2}}$$

$$\equiv C_1 T_9^{-1/2} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}, \quad (58)$$

where $Q_0 = Q/\text{MeV}$ is the $Q$-value in units of MeV, and we defined a rate coefficient $C_1 = 1.37 \times 10^4 (e_1/e)^2 Q_0 / A^{5/2} T_9^{1/2}$. The $Q$-value for the recombination is equal to the binding energy of the $X$-nucleus $E_B$.

The thermal rate for reverse reaction is related to that for the forward reaction through the reciprocity theorem. Using the relation between the reverse rate $(C + D)$ and the forward rate $(A + B)$ (Fowler et al. 1967; Angulo et al. 1999), the reverse rate

Figure 18. Same as Figure 6, but for the $^4\text{He} + X^-$ system with $m_X = 1$ GeV. (A color version of this figure is available in the online journal.)

Figure 19. Same as Figure 6, but for the $^4\text{He} + X^-$ system with $m_X = 10$ GeV. (A color version of this figure is available in the online journal.)
coefficient is defined for a non-radiative reaction $A(B, C)D$ by

$$C_r \equiv \frac{(C + D)}{(A + B)} \frac{g_A g_B}{(1 + \delta_{CD}) g_C g_D} \frac{A_A A_B}{A_C A_D}^{3/2} \exp\left(-\frac{Q}{T}\right),$$  

(59)

where $g_i = 2I_i + 1$ accounts for the spin degrees of freedom with $I_i$ the nuclear spin of species $i$. For a radiative reaction $A(B, \gamma)C$, on the other hand, the reverse rate coefficient is given by

$$C_r \equiv 10^{-10} \text{ cm}^3 \text{ mol}^{-1} n_\gamma (C + \gamma) \frac{N_A}{(A + B)} \left(\frac{T}{10^9 \text{ K}}\right)^{3/2} \exp\left(\frac{Q}{T}\right)$$

$$= 0.987 \frac{g_A g_B}{(1 + \delta_{AB}) g_C} \left(\frac{A_A A_B}{A_C}\right)^{3/2},$$ 

(60)
where \( n_\nu = 2(\zeta(3) \pi^3) / \pi^2 \) is the number density of photons with \( \zeta(3) = 1.202 \) the Riemann zeta function of 3.

Table 13 shows approximate recombination rates for nuclei which are not treated in Section 5. The second and third columns correspond to the rate coefficients \( C_i \) and reverse rate coefficients \( C_r \), respectively (Equations (58) and (60)), for the case of \( m_X = 1 \) GeV. The \( C_i \) and \( C_r \) values for \( m_X = 10, 100 \), and 1000 GeV are listed in the fourth to ninth columns.

### 6. \( ^9\text{Be} \) Production from \( ^7\text{Li} \)

We suggest the possibility of a significant production of \( ^9\text{Be} \) catalyzed by the negatively charged \( X^- \) particle through the deuteron transfer reaction \( \text{^7Li}(d, X^-)^9\text{Be} \). This reaction rate depends on both resonant and nonresonant components.

Since a realistic theoretical estimate of the rate for this reaction is not currently available, we adopt a simple ansatz that the astrophysical \( S \) factor for the reaction can be taken from the existing data for \( \text{^7Li}(d, n\alpha)^8\text{He} \), i.e., \( S \approx 30 \) MeV b (Caughlan & Fowler 1988). We note that the cross section values for \( \text{^7Li}(d, n\alpha)^8\text{He} \) are recommended by the Evaluated Nuclear Data File (ENDF/B-VII.1, 2011; Chadwick et al. 2011) correspond to \( S \approx 10 \) MeV b for an energy range of 0.1 MeV \( \leq \epsilon \leq 1 \) MeV.

Realistic theoretical estimates of the nonresonant cross section for \( \text{^7Li}(d, X^-)^9\text{Be} \) would be difficult (M. Kamimura 2013, private communication). Since the structure of the \( ^9\text{Be} \) nucleus is approximately described as \( \alpha + \alpha + n \), there is no existing study on the probability that the \( ^9\text{Be} \) nucleus is described as \( ^7\text{Li}+d \) bound states. In addition, experiments on the low-energy nuclear scattering of \( ^7\text{Li}+d \) are needed to construct the imaginary potential for \( ^7\text{Li}+d \) elastic scattering in the quantum mechanical calculations. Hence, the cross section for \( \text{^7Li}(d, X^-)^9\text{Be} \) assumed in this study is probably uncertain by as much as an order of magnitude, and could be much smaller.

### 7. \( \beta \)-Decay and Nonresonant Nuclear Reactions

Mass excesses of \( X^- \)-nuclei and \( Q \)-values for possible reactions associated with the \( X^- \) particle were calculated using the binding energies of \( X^- \)-nuclei derived in Section 3. The \( \beta \)-decay rates of \( X^- \)-nuclei (\( A_X \), \( \Gamma_{\beta X} \)) are estimated using experimental values for normal nuclei (\( A \)), \( \Gamma_{\beta} \), taking into account the momentum phase space factor related to the reaction \( Q \)-value.

The adopted rates are then given by \( \Gamma_{\beta X} = \Gamma_{\beta} Q_X/Q^3 \), where \( Q_X \) and \( Q \) are \( Q \)-values for the \( \beta \)-decay of \( A_X \) and \( A \), respectively. The decay rate \( \Gamma_{\beta} \) is related to the half life \( T_{1/2} \), i.e., \( \Gamma_{\beta} = \ln 2/T_{1/2} \). An exception to this is the \( \beta \)-decay rate of \( ^9\text{Be} \). In this case, the \( \beta \)-decay rate is estimated from that of \( ^8\text{He} \) assuming an approximate isospin symmetry. Adopted data values are as follows: (1) \( Q = 3.508 \) MeV and \( \Gamma_{\beta} = 0.859 \) s\(^{-1} \) for \( ^{8}\text{He}(e^-, \nu)^9\text{Li} \) (Tilley et al. 2002), (2) \( Q = 16.005 \) MeV and \( \Gamma_{\beta} = 0.825 \) s\(^{-1} \) for \( ^{8}\text{Li}(e^-, \nu)^9\text{Be} \) (Tilley et al. 2004), and (3) \( Q = 17.979 \) MeV and \( \Gamma_{\beta} = 0.900 \) s\(^{-1} \) for \( ^{9}\text{Be}(e^-, \nu)^8\text{Be} \) (Tilley et al. 2004).

Table 14 shows the adopted \( \beta \)-decay rates for \( X^- \)-nuclei. The second and third columns correspond to the \( Q \)-value and the decay rate \( \Gamma_{\beta X} \), respectively, for the case of \( m_X = 1 \) GeV. The \( Q \) and \( \Gamma_{\beta X} \) values for \( m_X = 10, 100 \), and 1000 GeV are listed in the fourth to ninth columns.

For nonresonant thermonuclear reaction rates between two charged nuclei, the astrophysical \( S \)-factors for \( X^- \)-nuclei reactions are taken to be as the same as those for the corresponding normal nuclear reactions (Caughlan & Fowler 1988; Smith et al. 1993). However, changes in the reduced mass and charge numbers are corrected exactly the same as in Kusakabe et al. (2008). For the reactions \( \text{^5Li}(p, \gamma)^6\text{HeX} \), \( \text{^5Be}(p, \gamma)^6\text{B}_X \), \( \text{^4HeX}(d, X^-)^\text{Li} \), \( \text{^4HeX}(t, X^-)^\text{Li} \), and \( \text{^4HeX}(^3\text{He}, X^-)^\text{Be} \), the cross sections have been calculated in a quantum mechanical model (Hamaguchi et al. 2007; Kamimura et al. 2009). We therefore take those astrophysical \( S \)-factors from the published data.
Table 15
Reverse Reaction Coefficients and \( Q \)-values for Nuclear Reactions in the WS40 Model

| Reaction                  | \( m_X = 1 \) GeV | 10 GeV | 100 GeV | 1000 GeV |
|---------------------------|-------------------|--------|---------|---------|

Results, corrected for changes in the reduced mass. Since both forward and reverse reaction rates depend upon \( m_X \), they are different from the reaction rates estimated under the assumption of \( m_X \rightarrow \infty \), which have been already published (Kusakabe et al. 2008).

For reactions between a neutron and X-nuclei and also those between nuclei and neutral X-nuclei, Coulomb repulsion does not exist. However, the reactions have already been found to be unimportant within the parameter region for which the predicted light element abundances are consistent with observational constraints (Kusakabe et al. 2010). We therefore utilize the same rates as assumed in Kusakabe et al. (2008) for the neutron-induced non-radiative reactions, and those published in Kamimura et al. (2009) for reactions of neutral X-nuclei.

Table 15 shows parameters of nuclear reaction rates for X-nuclei. The second and third columns correspond to the reverse rate coefficient \( C_t \) (Equations (59) and (60)) and the \( Q_0 \)-value, respectively, for the case of \( m_X = 1 \) GeV. The \( C_t \) and \( Q_0 \) values for \( m_X = 10, 100, \) and 1000 GeV are listed in the fourth to ninth columns. Since the baryon density is low in the early universe, the rates for three-body reactions are small. Therefore, the reverse reactions of \(^7\text{Li}(p, \alpha)^X^-\), \(^7\text{Li}(p, \alpha)^X^-\), \(^7\text{Li}(p, \alpha)^X^-\), and \(^7\text{He}(\gamma, X)^2\text{He}_X\) are neglected in our calculation, and the reverse rate coefficients are not shown in this table.

Although the \( Q \)-value for the \(^9\text{Be}(p, \gamma)^{10}\text{Be}_X\) reaction is negative in the case of \( m_X = 1 \) GeV, its rate is estimated by considering only the reduced mass factor. Since the \( |Q| \) value is very small, it can be regarded as effectively zero in the relevant temperature range.

8. BBN REACTION NETWORK

We utilized a modified (Kusakabe et al. 2008, 2010) version of the Kawano reaction network code (Kawano 1992; Smith et al. 1993) to calculate nucleosynthesis for four different X⁻ particle masses, \( m_X \). The nuclear charge distribution was assumed to be given by the WS40 model. The free X⁻ particle and bound X-nuclei are encoded as new species whose abundances are to be calculated. Reactions involving the X⁻ particle are encoded as new reactions. The mass excesses of X-nuclei are input into the code. In this way, the energy generation through the recombination of normal nuclei and an X⁻ particle, and the
nuclear reactions of \( X \)-nuclei are precisely taken into account in the thermodynamics of the expanding universe (Kawano 1992).

Our BBN code includes many reactions associated with the \( X^- \) particle. It then solves the non-equilibrium nuclear and chemical reaction network associated with the \( X^- \) with improved reaction rates derived from quantum many-body calculations (Kamimura et al. 2009). The neutron lifetime was updated to be \( 878.5 \pm 0.7_{\text{stat}} \pm 3.3_{\text{sys}} \) s (Serebryakov & Fomin 2010; Mathews et al. 2005) based upon improved measurements (Serebryakov et al. 2005). Rates for reactions of normal nuclei with mass numbers \( A \leq 10 \) have been updated with the JINA REACLIB Database V1.0 (Cyburt et al. 2010). The baryon-to-photon ratio was taken from the WMAP determination (Spergel et al. 2003, 2007; Larson et al. 2011; Hinshaw et al. 2013) \( \Omega_{\text{CDM}} \) model (WMAP9 data only): i.e., \( \eta = (6.19 \pm 0.14) \times 10^{-10} \) (Hinshaw et al. 2013).

Reaction rates derived in this paper are included in the code. We note that the nonresonant radiative neutron capture reactions of \( X \)-nuclei considered in the previous study (Kusakabe et al. 2008) are switched off for the following reason. Rates for the reactions generally depend on \( m_X \). When \( m_X \) is much larger than the nucleon mass, the radiative neutron capture reactions via electric multipole transitions are strongly hindered because of the very small effective charges (Kusakabe et al. 2009). In addition, independently of whether or not the mass of the \( m_X \) is large, the nucleosynthesis triggerd by the \( X^- \) particle occurs rather late in the BBN epoch when the neutron abundance is already small. Thus, neglecting the reactions does not significantly change the time evolutions of the nuclear abundances.

Recombination rates for \( ^7\text{Be}(X^-), \gamma \gamma^7\text{Be}_X, ^7\text{Li}(X^-), \gamma \gamma^7\text{Li}_X, ^9\text{Be}(X^-), \gamma \gamma^9\text{Be}_X, \) and \( ^4\text{He}(X^-), \gamma \gamma^4\text{He}_X \) were modified. \( ^8\text{Be}_X \) production through \( ^8\text{Be}_X \), i.e., \( ^4\text{He}(\alpha, \gamma)^8\text{Be}_X(n, \gamma)^9\text{Be}_X \), depends significantly on the energy levels of \( ^8\text{Be}_X \) and \( ^9\text{Be}_X \) (Pospelov 2007a; Kamimura et al. 2009; Cyburt et al. 2012), and precise calculations with a quantum four-body model by another group is under way (Kamimura et al. 2010). In this paper, we neglect those reaction series and leave that discussion as a future work. The reaction \( ^4\text{He}(\alpha, \gamma)^8\text{Be}_X \) is thus not included, and the abundance of \( ^8\text{Be}_X \) is not shown in the figures below.

9. RESULTS

We show calculated results of BBN for four values of \( m_X \). First, we analyze the time evolution for abundances of normal and \( X \)-nuclei. Then, we update constraints on the parameters characterizing the \( X^- \) particle.

The two free parameters in this BBN calculation are the ratio of number abundance of the \( X^- \) particles to the total baryon density, \( Y_X = n_X/n_b \), and the decay lifetime of the \( X^- \) particle, \( \tau_X \). The lifetime is assumed to be much smaller than the age of the present universe, i.e., \( < 14 \) Gyr (Hinshaw et al. 2013). The primordial \( X^- \)-particles from the early universe are thus by now long extinct. When the \( m_X \) value is small, the annihilation cross section for the \( X^- \) and its antiparticle \( X^+ \) is expected to be large. Since a large cross section tends to a small freeze-out abundance of \( X^- \), it is naturally expected that the abundance \( Y_X \) would be very small for small \( m_X \). However, we also perform calculations for large values of \( Y_X \) even in the case of a small \( m_X \) value taking into account the possibility that there may be a difference in number abundances of \( X^- \) and \( X^+ \). If the abundance of \( X^- \) had been larger than \( X^+ \), the freeze-out abundances could have been much larger than that for the case of equal abundances of \( X^- \) and \( X^+ \). In this case, however, charge neutrality still requires the condition of zero net global charge density during the BBN epoch.

As for the fate of \( X \)-nuclei, it is assumed that the total kinetic energy of products generated from the decay of the \( X^- \) is large enough so that all \( X \)-nuclei can decay into normal nuclei plus the decay products of \( X^- \). The \( X \) particle is detached from \( X \)-nuclei with its rate given by the \( X^- \) decay rate. The lifetime of \( X \)-nuclei is therefore given by the lifetime of the \( X^- \) particle itself.

To identify the important reactions that affect the abundances of \( ^6\text{Li}, ^7\text{Li}, ^7\text{Be}, \) and \( ^9\text{Be} \), we tried multiple calculations by switching off respective reactions. A detailed analysis of the nuclear flow is described below.

9.1. Abundance Constraints

Observational constraints on the deuterium abundance are taken from the mean value of 10 quasi-stellar object absorption line systems, and the abundance corresponding to the best measured damped Lyman alpha system of quasi-stellar object SDSS J1419+0829, i.e., \( \log(D/H) = -4.58 \pm 0.02 \) and \( \log(D/H) = -4.596 \pm 0.009 \), respectively (Pettini & Cooke 2012). Constraints on the \( ^3\text{He} \) abundance are taken from the mean value of Galactic H II regions measured through the 8.665 GHz hyperfine transition of \( ^3\text{He}^* \), i.e., \( ^3\text{He}/H = (1.9 \pm 0.6) \times 10^{-5} \) (Bania et al. 2002). Constraints on the \( ^4\text{He} \) abundance are taken from observational values of metal-poor extragalactic H II regions, i.e., \( Y_p = 0.2565 \pm 0.0051 \) (Izotov & Thuan 2010) and \( Y_p = 0.2561 \pm 0.0108 \) (Aver et al. 2010). We take the observational constraint on the \( ^7\text{Li} \) abundance from the central value of \( \log(^7\text{Li}/H) = -12 + (2.199 \pm 0.086) \) derived in the 3D NLTE model of Sbordone et al. (2010). On the other hand, the constraint on the \( ^9\text{Li} \) abundance is chosen more conservatively. We adopted the least stringent \( 2\sigma \) (95\% C.L.) upper limit for all stars reported in Lind et al. (2013), i.e., \( ^9\text{Li}/H = (0.9 \pm 4.3) \times 10^{-12} \) for the G64-12 (NLTE model with five free parameters).

9.2. \( m_X = 1 \) GeV

9.2.1. Nucleosynthesis

Figure 22 shows the calculated abundances of normal nuclei (panel (a)) and \( X \) nuclei (panel (b)) as a function of \( T_9 \) for \( m_X = 1 \) GeV. Curves for \( ^1\text{H} \) and \( ^4\text{He} \) correspond to the mass fractions, \( X_p \left(^1\text{H}\right) \) and \( Y_p \left(^4\text{He}\right) \) in total baryonic matter, while the other curves correspond to number abundances with respect to that of hydrogen. The dotted lines show the result of the SBBN model. The abundance and the lifetime of the \( X^- \) particle are assumed to be \( Y_X = 0.05 \) and \( \tau_X = \infty \), respectively, for this example.

Early in the BBN epoch (\( T_9 \gtrsim 1 \)), \( p_X \) is the only \( X \)-nuclide with an abundance larger than \( A_X/H > 10^{-17} \). Its abundance is the equilibrium value determined by the balance between the recombination of \( p \) and \( X^- \) and the photonization of \( p_X \). When the temperature decreases to \( T_9 \lesssim 1 \), \( ^4\text{He} \) is produced as in SBBN (panel (a)). Simultaneously, the abundance of \( ^4\text{He}_X \) increases through the recombination of \( ^4\text{He} \) and \( X^- \) (panel (b)). As the temperature decreases further, the recombination of nuclei with \( X^- \) gradually proceeds in order of decreasing binding energies of \( A_X \), similar to the recombination of nuclei with electrons.

\( ^7\text{Be} \) first recombines with \( X^- \) via the \( ^7\text{Be}(X^-, \gamma)\gamma^7\text{Be}_X \) reaction at \( T_9 \lesssim 0.1 \). The produced \( ^7\text{Be}_X \) nuclei are then slightly
destroyed via the $^7\text{Be}(p, \gamma)^8\text{B}_X$ reaction. In the late epoch, the $^7\text{Be}$ abundance increases through the reaction $^4\text{He}^4\text{He}(1\text{He}, \gamma)^7\text{Be}$ at $T_9 \sim 0.03-0.02$.

The $^6\text{Li}$ abundance decreases through the recombination reaction $^6\text{Li}(X^-, \gamma)^7\text{Li}_X$ operating at $T_9 \lesssim 0.05$. However, soon after the start of recombination, it is produced through the reaction $^4\text{He}^6\text{He}(d, X^-)^7\text{Li}$ at $T_9 \sim 0.03-0.02$. After this production, the $^4\text{He}^6\text{He}$ abundance also increases through recombination. In the late epoch, the $^6\text{Li}$ abundance increases through the reaction $^3\text{He}(\alpha, X^-)^7\text{Li}$ at $T_9 \sim 4 \times 10^{-3}$.

At $T_9 \lesssim 0.05$, the $^7\text{Li}$ abundance decreases through the recombination reaction $^7\text{Li}(X^-, \gamma)^8\text{Li}_X$. A small amount of $^7\text{Li}$ is later produced through the reactions $^3\text{He}^7\text{He}(t, X^-)^7\text{Li}$ ($T_9 \sim 0.02-0.01$), and $^3\text{He}^7\text{He}(\alpha, X^-)^7\text{Li}$ [$T_9 \sim (6-5) \times 10^{-3}$].

$^9\text{Be}$ is predominantly produced through the reaction $^7\text{Li}^9\text{Be}(d, X^-)^9\text{Be}$ at $T_9 \sim 0.06-0.05$. At $T_9 \lesssim 0.05$, the recombination $^9\text{Be}(X^-, \gamma)^{10}\text{Be}_X$ enhances the abundance of $^9\text{Be}_X$. The abundance of $^9\text{Be}$ is small and not seen in this figure since it is converted to $^{10}\text{Be}$ via the recombination. We note that the proton capture reaction $^9\text{Be}(p, \gamma)^{10}\text{Be}^4\text{He}$ does not work efficiently at this temperature of $^{10}\text{Be}$ production.

The recombination of $^7\text{Be}$ with an $X^-$ particle and the subsequent radiative proton capture of $^7\text{Be}_X$ occurs at $T_9 \sim 0.1$ although the effect of the latter reaction cannot be seen well in this figure. In this case, the abundances of $^7\text{Be}_X$ and $^{10}\text{Be}_X$ only change through the recombination at $T_9 \sim 0.1$. The abundance ratio of $^7\text{Be}$ to $^{10}\text{Be}_X$ is then simply described with chemical equilibrium (Rybicki & Lightman 1979) as

$$\frac{n_{^{10}\text{Be}_X}}{n_{^{7}\text{Be}_X}} = \frac{g_{^{10}\text{Be}_X}}{g_{^{7}\text{Be}_X}} \left( \frac{m_{^{10}\text{Be}_X} T}{m_{^{7}\text{Be}_X} 2\pi} \right)^{3/2} e^{(m_{^{10}\text{Be}_X} - m_{^{7}\text{Be}_X})/T} \approx \left( \frac{\mu T}{2\pi} \right)^{3/2} e^{-E_{\text{th}}(A_X)/T},$$

(61)

where the spin factor of $X^-$ is $g_X = 1$ and only the GS of $^7\text{Be}_X$ is considered so that $g_{^{7}\text{Be}_X} = g_{X}$.

The baryon number density determined from the CMB WMAP measurement is

$$n_b \approx \frac{\rho_b}{m_p} = \frac{\rho_c}{m_p} (1+z)^3 \approx 1.26 \times 10^{10} \text{ cm}^{-3} \left( \frac{h}{0.700} \right)^2 \left( \frac{\Omega_b}{0.0463} \right) T_9^3,$$

(62)

where $\rho_b$ and $\rho_c$ are the baryon density and the present critical density, respectively. $\Omega_b = 0.0463 \pm 0.0024$ is the baryon density parameter, $z$ is the redshift of the universe, which is related to temperature as $(1+z) = T/T_9$ where $T_9 = 2.7255$ K is the present radiation temperature of the universe (Fixsen 2009), and $h = H_0/(100 \text{ km s}^{-1} \text{ Mpc}^{-1}) = 0.700 \pm 0.022$ is the reduced Hubble constant with Hubble constant $H_0$. The cosmological parameters have been taken from values determined from the WMAP (Spergel et al. 2003, 2007; Larson et al. 2011; Hinshaw et al. 2013) (ACDM model; WMAP9 data only).

We define the recombination temperature $T_{\text{rec}}(A)$ at which abundances of the ionized nuclei $A$ and the bound state $A_X$ are equal. The $T_{\text{rec}}(A)$ value is determined as a function of the abundance of $X^-$, $Y_X$, using Equations (61) and (62). For example, the recombination temperature of $^7\text{Be}$ for the case of $m_X = 1$ GeV and $Y_X = 0.05$ is $T_{\text{rec}}(^7\text{Be}) = 8.49$ keV (corresponding to $T_9 = 0.0985$). Since the recombination proceeds at temperatures lower than in the case of larger $m_X$, the number density of protons at recombination is smaller. As a result, the rate for $^{10}\text{Be}_X$ to experience radiative proton capture in the temperature range of $T_9 \lesssim 0.1$ is small. The reduction of the $^{10}\text{Be}_X$ abundance through the proton capture is therefore less efficient than in the cases with $m_X = 100$ GeV and 1000 GeV. However, it is still much more efficient than the case with $m_X = 10$ GeV because of the smaller resonant energy in the resonant reaction $^7\text{Be}(p, \gamma)^8\text{B}_X$ (see Section 4).

9.2.2. Constraints on the $X^-$ Particle

Figure 23 shows contours of calculated final lithium abundances for the case of $m_X = 1$ GeV. These are normalized to the values observed in MPSSs, i.e., $d(^6\text{Li}) = ^6\text{Li}^{\text{Coul}}/^6\text{Li}^{\text{Obs}}$ (blue lines) and $d(^7\text{Li}) = ^7\text{Li}^{\text{Coul}}/^7\text{Li}^{\text{Obs}}$ (red lines). The final $^7\text{Li}$ abundance is a sum of the abundances of $^7\text{Li}$ and $^7\text{Be}_X$ produced in BBN. This is because $^7\text{Be}$ is converted to $^7\text{Li}$ via the electron capture at a later epoch. The dashed lines around the line of $d(^7\text{Li}) = 1$ correspond to the $2\sigma$ uncertainty in the observational constraint. The gray region located to the right of the contours for $d(^6\text{Li}) = 10$ and/or the $2\sigma$ lower limit, $d(^7\text{Li}) = 0.67$, are excluded by the overproduction of $^4\text{Li}$ and underproduction of $^7\text{Li}$, respectively. The orange region is the interesting parameter region in which a significant $^7\text{Li}$ reduction occurs without...
The 6Li constraint is taken from the 2 abundance ratio of 9Be although it is dependent on 4He abundance. The reason is that the amount of 7Be destruction through the reaction 4He \rightarrow 7Be is proportional to the 7Be lifetime. Dotted lines are contours of 7Li/ 7Li\textsubscript{Obs} (red lines) for the case of 6Li/ 6Li\textsubscript{Cal} / 7Li/ 7Li\textsubscript{Obs} (blue lines) and d(\textsuperscript{7}Li) = d(\textsuperscript{7}Li)\textsubscript{Cal} / 7Li/ 7Li\textsubscript{Obs} (red lines) for the case of m\textsubscript{X} = 1 GeV. The adopted observational constraint on the 7Li abundance is the central value of log(7Li/\textsubscript{H}) = -12 \pm (2.199 \pm 0.086) derived in the 3D NLTE model of Sbordone et al. (2010). The 6Li constraint is taken from the 2r upper limit for the G64-12 (NLTE model with five parameters; Lind et al. 2013) of 6Li/\textsubscript{H} = (0.9 \pm 4.3) \times 10^{-12}. Dashed lines around the line of d(\textsuperscript{7}Li) = 1 correspond to the 2σ uncertainty in the observational constraint. The gray region located to the right from the contours of d(\textsuperscript{4}Li) = 10 or the 2σ lower limit, d(\textsuperscript{7}Li) = 0.67, is excluded by the overproduction of \textsuperscript{4}Li and underproduction of \textsuperscript{7}Li, respectively. The orange region is the interesting parameter region in which a significant reduction in \textsuperscript{7}Li is realized without an overproduction of \textsuperscript{4}Li. Dotted lines are contours of the abundance ratio of \textsuperscript{9}Be/\textsubscript{H} predicted when the unknown rate for the reaction \textsuperscript{3}He + (d, X) \rightarrow \textsuperscript{7}Be is adopted as described in the text.

Figure 24 shows the same contours for calculated abundances of \textsuperscript{6}Li located at Y\textsubscript{X} = 0.1 and 7Li/\textsubscript{H} \approx 5 \times 10^{-10} \textsuperscript{10} GeV. The adopted observational constraint on the \textsuperscript{7}Li abundance is the central value of log(7Li/\textsubscript{H}) = -12 \pm (2.199 \pm 0.086) derived in the 3D NLTE model of Sbordone et al. (2010). The 6Li constraint is taken from the 2r upper limit for the G64-12 (NLTE model with five parameters; Lind et al. 2013) of 6Li/\textsubscript{H} = (0.9 \pm 4.3) \times 10^{-12}. Dashed lines around the line of d(\textsuperscript{7}Li) = 1 correspond to the 2σ uncertainty in the observational constraint. The gray region located to the right from the contours of d(\textsuperscript{4}Li) = 10 or the 2σ lower limit, d(\textsuperscript{7}Li) = 0.67, is excluded by the overproduction of \textsuperscript{4}Li and underproduction of \textsuperscript{7}Li, respectively. The orange region is the interesting parameter region in which a significant reduction in \textsuperscript{7}Li is realized without an overproduction of \textsuperscript{4}Li. Dotted lines are contours of the abundance ratio of \textsuperscript{9}Be/\textsubscript{H} predicted when the unknown rate for the reaction \textsuperscript{3}He + (d, X) \rightarrow \textsuperscript{7}Be is adopted as described in the text.

The excluded region is wider than in Figure 23. This region is determined from the underproduction of \textsuperscript{7}Li. This region also involves lower values of \textsuperscript{7}Li/\textsubscript{H} than in Figure 23. The solution to the \textsuperscript{7}Li problem is at Y\textsubscript{X} \approx 8 \times 10^{-4} and \tau\textsubscript{X} \approx 10^{12} s (orange region). In this region, the \textsuperscript{7}Be abundance is calculated to be 3Be/\textsubscript{H} \approx 3 \times 10^{-17}.

\textbf{9.3. m\textsubscript{X} = 10 GeV}

\textbf{9.3.1. Nucleosynthesis}

Figure 24 shows the same contours for calculated abundances of \textsuperscript{6,7}Li and \textsuperscript{9}Be as in Figure 23. In this case, the instantaneous charged-current decay of \textsuperscript{7}Be\textsubscript{X} \rightarrow \textsuperscript{7}Li + X^0 (Jittoh et al. 2007, 2008, 2010; Bird et al. 2008) is also taken into account. In this case, the \textsuperscript{X} particle interacts not only via its charge but also a weak interaction (Jittoh et al. 2007, 2008, 2010). \textsuperscript{7}Be\textsubscript{X} can then be converted to \textsuperscript{3}Li plus a neutral particle X\textsuperscript{0}. Other X-nuclei may also decay depending upon the mass of the X\textsuperscript{0}. The prohibition of \textsuperscript{6}Li overproduction, however, limits the length of the lifetime of the \textsuperscript{X} as seen in Figure 23. Effects of the weak decay catalyzed by the \textsuperscript{X} then appear through the conversion of X-nuclei produced just before the epoch of \textsuperscript{6}Li production.

Above the recombination temperature for \textsuperscript{4}He\textsubscript{X} at which \textsuperscript{6}Li production also proceeds, \textsuperscript{6}Li\textsubscript{X}, \textsuperscript{7}Li\textsubscript{X}, and \textsuperscript{7}Be\textsubscript{X} can all be produced with large fractions of bound states (see Figure 22). Among these three X-nuclei, \textsuperscript{7}Be\textsubscript{X} is the most abundant and its abundance evolution affects the parameter region for a solution to the Li problem. Therefore, for simplicity, we only consider the decay of \textsuperscript{7}Be\textsubscript{X} here.

The contours for the \textsuperscript{6}Li abundance are similar to those in Figure 23. On the other hand, the \textsuperscript{7}Li abundance is much different from that in Figure 23 because of the different processes for \textsuperscript{7}Be destruction. Including the charged-current decay of \textsuperscript{7}Be\textsubscript{X}, the destruction rate of \textsuperscript{7}Be in this model is the same as the recombination rate of \textsuperscript{7}Be itself. In the model without the decay, the destruction rate requires that \textsuperscript{7}Be\textsubscript{X} nuclei produced via the recombination then experience a proton capture reaction without being re-ionized to a \textsuperscript{7}Be+X\textsuperscript{−} free state. The different processes of \textsuperscript{7}Be\textsubscript{X} destruction therefore cause a difference in the efficiency for the final \textsuperscript{7}Li reduction. In this model with the decay, the amount of \textsuperscript{7}Be destruction roughly scales as Y\textsubscript{X} unlike the model without the decay.

The excluded region is wider than in Figure 23. This region is determined from the \textsuperscript{7}Li underproduction. This region also involves lower values of \textsuperscript{7}Li/\textsubscript{H} than in Figure 23. The solution to the \textsuperscript{7}Li problem is at Y\textsubscript{X} \approx 8 \times 10^{-4} and \tau\textsubscript{X} \approx 10^{12} s (orange region). In this region, the \textsuperscript{7}Be abundance is calculated to be 3Be/\textsubscript{H} \approx 3 \times 10^{-17}.

\textbf{9.3. m\textsubscript{X} = 10 GeV}
The $^7$Be nuclide recombines with $X^-$ at $T_{\text{rec}}(7\text{Be}) = 25.1$ keV ($T_9 = 0.291$). Although this temperature is higher than in the case of $m_{X} = 1$ GeV, the resonant peak in the $^7\text{Be}(p, \gamma)^8\text{B}_{X}$ reaction is higher. The efficiency for $^7\text{Be}$ destruction is then smaller than that for $m_{X} = 1$ GeV. During a late epoch, the $^7\text{Be}$ abundance increases mainly through the reaction $^4\text{He}_{X}(3\text{He}, X^-)7\text{Be}$ at $T_9 \lesssim 0.1$. In the same epoch, the $^7\text{Be}$ abundance increases also through the reaction $^6\text{Li}(p, \gamma)^7\text{Be}$. However, in this case the production rate is much smaller than that via $^4\text{He}_{X}(3\text{He}, X^-)^7\text{Be}$. It is thus found that $^7\text{Be}$ is produced by the $^6\text{Li}(p, \gamma)^7\text{Be}$ reaction if the abundance of $^6\text{Li}$ during BBN is much larger than in SBBN as realized in this model by including the $X^-$ particle.

$^6\text{Li}$ is produced through the reaction $^4\text{He}_{X}(d, X^-)^6\text{Li}$ at $T_9 \sim 0.07$. $^6\text{Li}_{X}$ is then produced through the recombination $^6\text{Li}(X^-, \gamma)^6\text{Li}_{X}$.

At first the $^7\text{Li}$ abundance increases through the two reaction pathways of $^7\text{Be}_{X}(n, p^7\text{Li})X^-$ and $^7\text{Be}_{X}(n, p)^7\text{Li}_{X}(X^-, \gamma)^7\text{Li}$ at $T_9 \sim 0.3$--0.2. This is seen as a bump in the abundance curve. The existence of this bump depends upon the reaction rates of $^7\text{Be}_{X}(n, p^7\text{Li})X^-$ and $^7\text{Be}_{X}(n, p)^7\text{Li}_{X}$, which are assumed to be the same as that of $^7\text{Be}(n, p)^7\text{Li}$ in this paper. This possible bump appears during the epoch when the recombination of $^7\text{Be}$ has started but that of $^7\text{Li}$ has not. Then, the $^7\text{Li}$ abundance decreases through the recombination reaction $^7\text{Li}(X^-, \gamma)^7\text{Li}_{X}$ at $T_9 \sim 0.2$--0.1. The proton capture reaction $^7\text{Li}_{X}(p, 2\alpha)X^-$ also partly destroys the $^7\text{Li}_{X}$ nuclei produced via the recombination. Finally, $^7\text{Li}$ is produced through the reaction $^4\text{He}_{X}(p, X^-)^7\text{Li}$ at $T_9 \sim 0.07$--0.06.

$^6\text{Li}_{X}^
u$ is produced through the reaction $^7\text{Li}_{X}(d, X^-)^6\text{Li}$ at $T_9 \sim 0.07$. $^9\text{Be}$ is produced through the reaction $^7\text{Li}_{X}(d, X^-)^6\text{Be}$ at $T_9 \sim 0.2$--0.1. The recombination of $^6\text{Li}$ increases the abundance of $^9\text{Be}_{X}$ at $T_9 \sim 0.2$--0.1. When the proton-capture reaction $^9\text{Be}_{X}(p, ^6\text{Li})^4\text{He}_{X}$ is operative at $T_9 \gtrsim 0.07$, it decreases the abundance of $^9\text{Be}_{X}$.

### 9.3.2. Constraints on the $X^-$ Particle

Figure 26 shows the same contours for calculated abundances of $^6\text{Li}$ and $^9\text{Be}$ as in Figure 23 without the decay of $^7\text{Be}_{X}$, but for $m_{X} = 10$ GeV. The excluded gray region is larger than that in Figure 23 because of the enhanced production rate of $^6\text{Li}$. In addition, there is no parameter region for the solution to the $^7\text{Li}$ problem because of the smaller destruction rate for $^7\text{Be}$.

Figure 27 shows the same contours for calculated abundances of $^6\text{Li}$ and $^9\text{Be}$ as in Figure 23, but for $m_{X} = 10$ GeV and with the decay of $^7\text{Be}_{X}$. The contours for the $^6\text{Li}$ abundance are
similar to those in Figure 26. The $^7$Li abundance is different from that in Figure 25 for the same reason described above for Figure 24. The excluded region is determined from the combination of $^7$Li underproduction and $^6$Li overproduction. It is wider than in Figure 26. The region for the $^7$Li problem is at $T \gtrsim 10^{-3}$ and $\tau X \sim 10^2$–$10^4$ s. The $^9$Be abundance in this region is $^9$Be/H $\lesssim 10^{-15}$.

9.4. $m_X = 100$ GeV

9.4.1. Nucleosynthesis

Figure 28 shows the same abundances as a function of $T_9$ as in Figure 22 without the decay of $^7$Be$X$, but for the case of $m_X = 100$ GeV.

The $^7$Be nuclide recombines with $X^-$ at $T_{rec}(^7$Be) = 30.9 keV ($T_9 = 0.359$). The efficiency of $^7$Be$X$ destruction through the reaction $^7$Be$X(p, \gamma)^8$Be$X$ at $T_9 = 0.3$–0.2 is larger than in the cases with $m_X = 10$ GeV and 10 GeV as seen in this figure. This high efficiency is because of the higher recombination temperature and the relatively smaller peak of the resonant reaction $^7$Be$X(p, \gamma)^8$Be$X$. During the later epoch, the $^7$Be abundance increases mainly through the reaction $^4$He$X(^7$He, $X^-)^7$Be and somewhat less through the reaction $^6$Li$X(p, \gamma)^7$Be$X$. $^6$Li is produced through the reaction $^4$He$X(d, X^-)^6$Li$X$ at $T_9 \sim 0.1$. The abundance of $^6$Li$X$ increases through the recombination reaction $^6$Li($X^-$, $\gamma)^6$Li$X$. Some of the $^6$Li$X$ nuclei are then destroyed through proton capture via the $^6$Li$X(p, \gamma)^7$He$X$ reaction in the temperature range of $T_9 \gtrsim 0.05$.

In the interval of recombination temperatures for $^7$Be and $^7$Li, i.e., $T_9 \sim 0.3$–0.2, the $^7$Li abundance at first increases through the neutron-induced reactions on $^7$Be$X$ as in the case of $m_X = 10$ GeV. Then, the $^7$Li abundance decreases through recombination with $X^-$ at $T_9 \lesssim 0.2$. At $T_9 \gtrsim 0.05$, the proton capture reaction $^7$Li$X(p, 2\alpha)^9$Be$X$ partly destroys $^7$Li$X$ nuclei produced via the recombination. Finally, $^7$Li is produced through the reaction $^4$He$X(t, X^-)^7$Li at $T_9 \lesssim 0.1$.

$^9$Be is produced through the reaction $^7$Li$X(d, X^-)^8$Be at $T_9 \sim 0.3$–0.1. The recombination $^9$Be$(X^-, \gamma)^9$Be$X$ reaction enhances the abundance of $^9$Be$X$ at $T_9 \sim 0.2$–0.1. The proton capture reaction $^9$Be$X(p, ^6$Li)$^4$He$X$ then decreases the abundance of $^9$Be$X$ at $T_9 \gtrsim 0.1$.

9.4.2. Constraints on the $X^-$ Particle

Figure 29 shows the same contours for calculated abundances of $^6$Li and $^9$Be as in Figure 23 without the decay of $^7$Be$X$, but for $m_X = 100$ GeV. The excluded gray region is even larger than that for $m_X = 10$ GeV because of the enhanced production rate of $^9$Be. The parameter region for the solution to the $^7$Li problem is at $Y_X \gtrsim 0.07$ and $\tau X \sim (0.6$–$3) \times 10^3$ s. The $^9$Be abundance in this region is $^9$Be/H $\lesssim 3 \times 10^{-16}$.

Figure 30 shows the same contours for calculated abundances of $^6$Li and $^9$Be as in Figure 23, but for $m_X = 100$ GeV and with the decay of $^7$Be$X$. The excluded region is determined from the combination of the $^7$Li underproduction and the $^6$Li overproduction. The region for the $^7$Li problem is at $Y_X \gtrsim 6 \times 10^{-3}$ and $\tau X \sim 10^2$–$4 \times 10^3$ s. In this region, the $^9$Be abundance is $^9$Be/H $\lesssim 3 \times 10^{-16}$.

9.5. $m_X = 1000$ GeV

9.5.1. Nucleosynthesis

Figure 31 shows the same abundances as a function of $T_9$ as in Figure 22 without the decay of $^7$Be$X$, but for the case of $m_X = 1000$ GeV. This result is very similar to that for $m_X = 100$ GeV except for the abundance of $^7$Be$X$.

The recombination temperature of $^7$Be is the same as in the case of $m_X = 100$ GeV, i.e., $T_{rec}(^7$Be) = 30.9 keV ($T_9 = 0.359$). The efficiency of $^7$Be$X$ destruction through the reaction
Three cases correspond to Gaussian (thick dashed lines), WS40 (solid lines), and square well (dot–dashed lines) models for nuclear charge distributions studied in this paper (Section 4), while one case (thin dashed lines) corresponds to the previous calculation (Kusakabe et al. 2008) in which the adopted reaction rate for $^7\text{Be}_X(p, \gamma)^8\text{B}_X$ was derived from a quantum many-body model (Kamimura et al. 2009). It is found that amounts of $^7\text{Be}_X$ destruction vary significantly when the nuclear charge distributions are changed. The result for our Gaussian charge distribution model (thick dashed line) is close to that for the quantum many-body model (thin dashed line slightly above the thick dashed line) in which the charge distribution of the cluster components has also been assumed to be Gaussian. The differences in the curves for $^7\text{Be}_X$ thus indicate the effect of uncertainties in the charge density inferred from measurements of rms radii.

9.5.2. Constraints on the $X^-$ Particle

Figure 32 shows the same contours for calculated abundances of $^6\text{Li}$ and $^9\text{Be}$ as in Figure 23 without the decay of $^7\text{Be}_X$, but for $m_X = 1000$ GeV. The parameter region for the solution to the $^7\text{Li}$ problem is at $Y_X \gtrsim 0.04$ and $\tau_X \sim (0.6–3) \times 10^3$ s. The $^9\text{Be}$ abundance in this region is $^9\text{Be}/H \lesssim 3 \times 10^{-16}$.

Figure 33 shows the same contours for calculated abundances of $^6\text{Li}$ and $^9\text{Be}$ as in Figure 23, but for $m_X = 1000$ GeV and with the decay of $^7\text{Be}_X$ also included. The region for the solution of the $^7\text{Li}$ problem does not significantly differ from that for $m_X = 1000$ GeV, and is at $Y_X \gtrsim 6 \times 10^{-3}$ and $\tau_X \sim 10^2–4 \times 10^3$ s. The $^9\text{Be}$ abundance in this region is $^9\text{Be}/H \lesssim 3 \times 10^{-16}$.

9.6. Comparison with Previous Constraints

Previous constraints are all derived in the limit of $m_X \to \infty$. It is therefore appropriate to compare them to the new constraints for the largest mass case, i.e., $m_X = 1000$ GeV. We compare rates of nuclear recombination with $X^-$ first, and parameter regions for the $^7\text{Li}$ reduction second.

9.6.1. Recombination Rates

Figure 34 shows rates for the recombination of $^7\text{Be}$, $^7\text{Li}$, $^9\text{Be}$, and $^4\text{He}$ with $X^-$ as a function of temperature $T_9$ in
the case of \( m_X = 1000 \) GeV. Solid lines correspond to the recombination rates derived in this paper: Equations (24) and (28) for \(^7\)Be, Equations (44) and (48) for \(^7\)Li, Equation (52) for \(^9\)Be, and Equation (56) for \(^4\)He. Dashed lines, on the other hand, correspond to the rates adopted in the previous studies (e.g., Kusakabe et al. 2008, 2010). Equation (2.9) of Bird et al. (2008) for \(^7\)Be, and Equation (58) with \( m_X \to \infty \) for other nuclides. The \(^7\)Be rate in the present study is much larger than the previous rate. The present rates for \(^7\)Li and \(^9\)Be are also significantly larger than the previous rates. The present \(^7\)He rate is, on the other hand, not significantly different for temperatures \( T_0 \lesssim 0.1 \) where the recombination effectively proceeds. The new precise rates for \(^7\)Be, \(^7\)Li, and \(^9\)Be are larger than the previous rates, while that for \(^4\)He is smaller than the previous rate.

9.6.2. Case without \(^7\)Be\(_X\) Decay

When the charged-current decay of \(^7\)Be\(_X\) \( \to ^7\)Li\(_X\)\( ^0\) \( X\) is absent, the following reactions predominantly determine the abundance evolution of \(^7\)Be, \(^7\)Li, and \(^8\)Li: (1) \(^7\)Be\(_X\)(\( p, \gamma \))\(^8\)Be\(_X\), (2) \(^7\)Be\(_X\)(\( p, \gamma \))\(^8\)B\(_X\), (3) \(^7\)Li\(_X\)(\( p, \gamma \))\(^8\)Li\(_X\), (4) \(^7\)Li\(_X\)(\( 2\alpha \))\(^6\)He\(_X\), and (5) \(^4\)He\(_X\)(\( X, \gamma \))\(^4\)He\(_X\), and (6) \(^4\)He\(_X\)(\( d, X^{-} \))\(^4\)Li\(_X\). We updated the recombination rates for (1), (3), (5), and also the resonant proton capture rate for (2). The rates for (4) and (6) are taken from the same reference (Kamimura et al. 2009) as adopted in the previous studies.

In the theoretical calculation of \(^7\)Li\(_X\)\( /H\), the most important reactions are (1) and (2). The new recombination rate for (1) is about five times larger than the previous rate (Figure 34) at the recombination temperature of \( T_0 \sim 0.36 \) (Section 9.5.1). On the other hand, the adopted destruction rate for (2) for the WS40 model is about 2.7 times larger than the previous rate (Figure 5) at the destruction temperature of \( T_0 \sim 0.3 \) (Figure 31). Because of increases in the two reaction rates, the effective rate for \(^7\)Be destruction (or reduction in the final \(^7\)Li\(_X\)/\( H\) value) becomes higher than the previous one.

Second, the observational constraint on the abundance of \(^7\)Li\(_X\)/\( H\) has been updated from \( Y_X = (1.23^{+0.68}_{-0.32}) \times 10^{-10} \) (95 % confidence limits; Ryan et al. 2000) to \( \log(Y_X) = -12.0 + (2.199 \pm 0.086) \) (Sbordone et al. 2010). As a result, curves of \( d(Y_X) = 2 \) correspond to different abundances:

\(^7\)Li\(_X\)/\( H = 3.16 \times 10^{-10} \) in this study, while \( \sim 2.46 \times 10^{-10} \) in the previous studies. In this study, therefore, we need less destruction of \(^7\)Be to realize \( d(Y_X) = 2 \).

Both the theoretical and observational improvements indicate that it is easier to reduce the primordial \(^7\)Li abundance to the level of \( d(Y_X) = 2 \). The contours of \( d(Y_X) \) therefore move left by a factor of about 20 in the parameter plane of Figure 32. In the parameter region around \( d(Y_X) = 2 \), a partial destruction of \(^7\)Be is realized. In this region, the destruction rate of \(^7\)Be is proportional to the product of reaction rates (1) and (2). The factor of \( \sim 20 \) can be explained by this proportionality and the difference in the destruction fraction of \(^7\)Be required from observations.

The \(^8\)Li\(_X\)/\( H\) abundance, on the other hand, is not much changed from that in the previous studies both theoretically and observationally. In the theoretical part, the most important reactions are (5) and (6). The new recombination rate of (5) is lower than the previous rate by about 10% (Figure 34) at the recombination temperature of \( T_0 \sim 0.1 \) (Figure 31). In the observational part, the constraint has been updated from \( Y_X = (7.1 \pm 0.7) \times 10^{-12} \) (the average of stars with \(^8\)Li detections in Asplund et al. 2006) to \( Y_X = (0.9 \pm 4.3) \times 10^{-12} \) (the least stringent \( 2\sigma \) upper limit from Lind et al. 2013). Curves of \( d(Y_X) = 10 \) then correspond to \( Y_X = 9.5 \times 10^{-11} \) in this study, and \( Y_X = 7.1 \times 10^{-11} \) in the previous studies. These slight changes do not move the contour of \( d(Y_X) = 10 \) much. The contour then moves left only by a factor of about 1.4.

The interesting parameter region for the \(^7\)Li reduction subsequently moves upper left. The constraint on the \(^8\)Li abundance is significantly changed while that on the \(^6\)Li abundance is not changed. The parameter region is therefore exclusively affected by the change of the \(^7\)Li contour. The minimum \( X^{-}\) abundance required for the effective \(^7\)Li reduction is \( Y_X = 0.04 \) in this study. This value is only about four percent of the previous estimate \( Y_X \sim 1 \) (Kusakabe et al. 2010).

9.6.3. Case with \(^7\)Be\(_X\) Decay

When the charged-current decay of \(^7\)Be\(_X\) \( \to ^7\)Li\(_X\)\( ^0\) \( X\) is operative, the \(^7\)Be destruction rate is determined only by (1)

Figure 33. Same as in Figure 23, but for the case of \( m_X = 1000 \) GeV and the charged-current decay of \(^7\)Be\(_X\) \( \to ^7\)Li\(_X\)\( ^0\) is also included.

(A color version of this figure is available in the online journal.)

Figure 34. Rates for recombination of \(^7\)Be, \(^7\)Li, \(^9\)Be, and \(^4\)He with \( X^{-}\) in the case of \( m_X = 1000 \) GeV as a function of temperature. Solid lines show the recombination rates derived in this paper, while dashed lines show the rates adopted in the previous studies (see the text).

(A color version of this figure is available in the online journal.)
of 7Be produced during BBN, this 7Be destruction leads to a
stantaneously destroyed.

The Astrophysical Journal Supplement Series
stant without 7Be
reaction, i.e., 4He(γ, d) 3He. Since the primordial 7Li abundance is mainly from the abundance of 7Be produced during BBN, this 7Be destruction leads to a reduction of the primordial 7Li abundance, and it can explain the observed abundances. In addition, 6Li is produced via the recombination of 4He and X − followed by a deuteron capture reaction, i.e., 4He(X −, γ) 7Be(p, γ) 8B. Although the effects of many possible reactions have been studied, the 9Be abundance is not significantly enhanced in this BBN model.

In this paper, we have also made a new study of the effects of uncertainties in the nuclear charge distributions on the binding energies of nuclei and X − particles, the reaction rates, and the resultant BBN. We also calculated new radiative recombination rates for 7Be, 7Li, 9Be, and 4He with an X − particle properties (Section 9). This reaction was found to significantly enhance the primordial 9Be abundance from our BBN network calculation (Section 9).

Using the binding energies of X-nuclei calculated in Section 3, mass excesses of X-nuclei along with rates and Q-values for reactions involving the X − particle were calculated for four cases of mX. The reaction network included the β-decays of X-nuclei, nuclear reactions of X-nuclei and their inverse reactions. Q-values and reverse reaction coefficients were found to be heavily dependent on mX (Section 7). The X − particle mass dependence of the Q-value is especially important for the resonant reaction 7Be(p, γ) 8B (Section 9).

1. We assumed three shapes for the nuclear charge density, i.e., WS, Gaussian, and homogeneous sphere types which were parameterized to reproduce the experimentally measured rms charge radii. The potentials between the X − and nuclei were then derived by folding the Coulomb potential and the nuclear charge densities (Section 2). Binding energies for nuclei plus X − were calculated for the different nuclear charge densities and different masses of the X −, mX. Along with the binding energies of the GS X-nuclei, those of the first atomic excited states of 7BeX and 9BeX were derived since these states provide important resonances in the 7Be(p, γ) 8B and 9Be(p, γ) 10Be reactions (Section 3). Resonant rates for radiative proton capture were then calculated. We found that the different charge distributions result in reaction rates that can differ by significant factors depending upon the temperature. This is because the rates depend on the resonance energies that are sensitive to relatively small changes in binding energies of X-nuclei caused by the different nuclear charge distributions (Section 4).

2. We also calculated new precise rates for the radiative recombinations of 7Be, 7Li, 9Be, and 4He with an X − for four choices of the mass, mX. For that purpose, binding energies and wave functions of the respective X-nuclei were derived for several bound states. In the recombination process for 7Be and 7Li, bound states of the nuclear first excited states, 7Be* and 7Li*, with X − can operate as effective resonances. These resonant reaction rates as well as transition matrices, radiative decay widths of the resonances, and resonance energies were calculated using derived wave functions. For 9Be and 4He, however, there are no important resonances in the recombination processes since the resonance energies are much higher than the typical temperatures corresponding to the recombination epoch. (Section 5)

3. For the four nuclei 7Be, 7Li, 9Be, and 4He, we calculated continuum-state wave functions for l = 0 to 4, and nonresonant recombination rates for the respective partial waves of scattering states and bound states. It was found that the finite sizes of the nuclear charge distributions causes deviations in the bound and continuum wave functions compared to those derived assuming that nuclei are point charges. These deviations are larger for larger mX and for heavier nuclei with a larger charge. In addition, the effect of the fine charge distribution predominantly affects the wave functions for tightly bound states and those for scattering states with small angular momenta l. We found the important characteristics of the 7Be+X − recombination. That is, for the heavy X −, mX ≥ 100 GeV, the most important transition in the recombination is the d-wave → 2P. Transitions f-wave → 3D and d-wave → 3P are also more efficient than that for the GS formation. This fact is completely different from the formation of hydrogen-like electronic ions described by the point-charge distribution. In this case the transition p-wave → 1S is predominant. The same characteristics that the transition d-wave → 2P is most important was found for the recombinations of 7Li and 9Be. Since 4He is lighter and its charge is smaller than 7Li and 7Be, the effect of a fine charge distribution is smaller. In the 4He recombination, therefore, the transition p-wave → 1S is dominant as in the case of a point-charge nucleus. Recombination rates for other nuclei were estimated using a simple Bohr atomic model formula (Section 5).

4. Our nonresonant rate for the 7Be(X −, γ) 8B reaction with mX = 1000 GeV is more than six times larger than the previously estimated rate (Bird et al. 2008). This difference is caused by our treatment of many bound states and many partial waves for the scattering states (Section 5). This improvement in the rate provides an improved constraint on the X − particle properties (Section 9).

5. We have also suggested a new reaction for 9Be production, i.e., 7LiX(d, X −) 7Be. We adopted an example reaction rate using the astrophysical S-factor for the reaction 7Li(d, nα) 4He as a starting point (Section 6). This reaction was found to significantly enhance the primordial 9Be abundance from our BBN network calculation (Section 9).

10. SUMMARY

We have completed a new detailed study of the effects of a long-lived negatively CHAMP, i.e., X −, on BBN. The BBN model including the X − particle is motivated by the discrepancy between the 7Li abundances predicted in SBBN model and those inferred from spectroscopic observations of MPSs. In the BBN model including the X −, 7Be is destroyed via a recombination reaction with the X − followed by a radiative proton capture reaction, i.e., 7Be(X −, γ) 7BeX(p, γ) 8BX. Since the primordial 7Li abundance is mainly from the abundance of 7Be produced during BBN, this 7Be destruction leads to a reduction of the primordial 7Li abundance, and it can explain the observed abundances. In addition, 6Li is produced via the recombination of 4He and X − followed by a deuteron capture reaction, i.e., 4He(X −, γ) 7BeX(d, X −) 7Li. Although the effects of many possible reactions have been studied, the 9Be abundance is not significantly enhanced in this BBN model.

In this paper, we have also made a new study of the effects of uncertainties in the nuclear charge distributions on the binding energies of nuclei and X − particles, the reaction rates, and the resultant BBN. We also calculated new radiative recombination rates for 7Be, 7Li, 9Be, and 4He with an X − taking into account the contributions from many partial waves of the scattering states. We also suggest a new reaction of 9Be production that enhances the primordial 9Be abundance to a level that might be detectable in future observations of MPSs.

In detail, this work can be summarized as follows.

1. We assumed three shapes for the nuclear charge density, i.e., WS, Gaussian, and homogeneous sphere types which were parameterized to reproduce the experimentally measured rms charge radii. The potentials between the X − and nuclei were then derived by folding the Coulomb potential and the nuclear charge densities (Section 2). Binding energies for nuclei plus X − were calculated for the different nuclear charge densities and different masses of the X −, mX. Along with the binding energies of the GS X-nuclei, those of the first atomic excited states of 7BeX and 9BeX were derived since these states provide important resonances in the 7Be(p, γ) 8B and 9Be(p, γ) 10Be reactions (Section 3). Resonant rates for radiative proton capture were then calculated. We found that the different charge distributions result in reaction rates that can differ by significant factors depending upon the temperature. This is because the rates depend on the resonance energies that are sensitive to relatively small changes in binding energies of X-nuclei caused by the different nuclear charge distributions (Section 4).

2. We also calculated new precise rates for the radiative recombinations of 7Be, 7Li, 9Be, and 4He with an X − for four choices of the mass, mX. For that purpose, binding
7. We constructed an updated BBN code that includes the new reaction rates derived in this paper (Section 8). BBN calculations based on this code were then shown for four cases of \( m_X \). It was found that the amounts of \(^7\)Be destruction depend significantly on the assumed charge distribution function of the \(^7\)Be nucleus for the \( m_X = 1000 \) GeV case. Finally, we derived new most realistic constraints on the initial abundance and the lifetime of the \( X^- \) particle. Parameter regions for the solution to the \(^7\)Li problem were identified for the \( \alpha \) and \(^3\)He, and in part by Grants-in-Aid for Scientific Research (Special Criminal) (20105003548), and in part by Grants-in-Aid for Scientific Research on Innovative Areas of MEXT (20105004). Work at the University of Notre Dame (G.J.M.) was supported by the U.S. Department of Energy under Nuclear Theory grant DE-FG02-95-ER40934.

We are grateful to Professor Masayasu Kamimura for discussion on the reaction cross sections. This work was supported by the National Research Foundation of Korea (grant Nos. 2012R1A1A2041974, 20141A2A2A05003548, 2012M7A1A2055605), and in part by Grants-in-Aid for Scientific Research of JSPS (2440060), and Scientific Research on Innovative Areas of MEXT (20105004). Work at the University of Notre Dame (G.J.M.) was supported by the U.S. Department of Energy under Nuclear Theory grant DE-FG02-95-ER40934.

APPENDIX

TRANSITIONS OF EXOTIC ATOMS THAT SIMULTANEOUSLY CHANGE BOTH NUCLEAR AND ATOMIC STATES

Here we discuss in detail the Type 3 transitions in the \(^7\)Be\((X^-)\gamma\)\(^7\)Be\(^\ast\) reaction that was addressed in Section 5.1.

A.1. Electric Dipole Transition Rate

The reduced probability for a transition from an initial state \( i \) to a final state \( f \) is given by

\[
B(I_i \rightarrow I_f) = \frac{1}{2I_i + 1} \sum_{M_i, M_f} \left| \langle \psi^{M_f}_{I_f} | \mathcal{O}(E1, \mu) | \psi^{M_i}_{I_i} \rangle \right|^2,
\]

(A1)

where \( I_i, M_i \), and \( \psi^{M_i}_{I_i} \) are the spins, the magnetic quantum numbers, and the wave functions, respectively, of state \( k \) for initial (i) and final (f) states, with \( \mu = M_f - M_i \). We consider the three-body system of \( \alpha \), \(^3\)He, and \( X^- \) located at the position vectors \( x_i \) for \( i = 1 (\alpha) \), 2 (\(^3\)He), and 3 (\( X^- \)), respectively. This system has bound states of \(^7\)Be\(^\ast\). The system of \(^7\)Li\(^\ast\) can be considered similarly to this system. The electric dipole (E1) operator is given by \( \mathcal{O}(E1, \mu) = \sum_{i} q_i x_i Y_{\mu|1}(\hat{x}_i) \) where \( q_i \) is the electric charge, \( x_i = |x_i| \) is the distance from the origin to the position of particle \( i \), and \( Y_{\mu|1}(\hat{x}_i) \) are the spherical surface harmonics.

A.2. Hindrance of the Matrix Element

The wave function describing atoms composed of a nucleus with \( A = 7 \) and a negatively CHAMP \( X^- \) is approximately given by a product of functions of a \(^7\)Z nuclear state and a \(^7\)Z\(_X\) atomic state, i.e.,

\[
\Psi^{M_f}_{I_f}(r, r') = \sum_{m_i, m_f} \langle j_m l_1 m_l | I_i M_i \rangle \Psi^{m_i}_{j_l}(r) \Psi^n_{n_l m_l}(r')
\]

where \( \Psi^{m_i}_{j_l}(r) \) is the nuclear wave function for the two-body system of particles 1 and 2, with the spin \( j_\beta \) and magnetic quantum numbers \( m_\beta \) for \( \beta = 1 \) (for state i) and 2 (for state f).

\[
\Psi^n_{n_l m_l}(r') = \text{the atomic wave function for the two-body system of particles (1+2)+3, with } n_k, l_k, \text{ and } m_k \text{ the main, azimuthal, and magnetic quantum numbers, respectively.}
\]

These \( \psi \) are Jacobi coordinates, where \( M_i \) is the mass of particle \( i \). The atomic wave function is then simply given by

\[
\Psi^{n_k}_{n_l m_l}(r') = \psi^{n_k}_{n_l m_l}(r') \hat{Y}_{n_l m_l}(\hat{r}') \text{ for } k = 1 \text{ and } 2.
\]

One can consider transitions which change the atomic and nuclear states simultaneously. This type of transition proceeds from states \( (\alpha \gamma)\)(\(^7\)Be\(^\ast\)) to \( (\alpha \gamma)\)(\(^7\)Be\(^\ast\)) or \( \alpha \gamma \) \(^7\)Be\(^\ast\), where the initial states are atomic excited states or GS composed of the first nuclear excited state \( ^7\)Be\(^1(1/2^-)\), and the final states are atomic excited states or GS of the nuclear \(^7\)Be\(^3(2^-)\). We show that the E1 rates for such transitions are smaller than those for typical E1 allowed nuclear transitions. For simplicity, we approximately neglect the finite-size charge distributions of \( \alpha \) and \(^3\)He, and assume that all three particles are point charges. Then, the electric dipole moment is given by

\[
d(x_1, x_2, x_3) = \frac{(q_1 + q_2) M_3 - q_3 (M_1 + M_2)}{M_1 + M_2 + M_3} r' + M_1 q_1 - M_2 q_2 \frac{r}{M_1 + M_2}
\]

(A4)

where \( q_\ell \) and \( q_r \) are defined as coefficients of \( r' \) and \( r \), respectively.

Using Equations (A2) and (A4), the matrix element in Equation (A1) can be rewritten by

\[
\langle \psi^{M_f}_{I_f} | \mathcal{O}(E1, \mu) | \psi^{M_i}_{I_i} \rangle = \sum_{m_i, m_f, m_l, m_l'} \sum_{j_m l_1 m_l} \langle j_m l_1 m_l | I_i M_i \rangle \langle j_m l_1 m_l | I_f M_f \rangle \int dr \int dr' \times \psi^{m_{l'} m_i}_{j_{l'}}(r) \psi^{n_l m_l}_{n_l m_l}(r') [q_{r'} Y_{1\mu}(\hat{r}') + q_j Y_{1\mu}(\hat{r})] \times \psi^{n_{l'} m_i}_{l m_i}(r')
\]

\[
= \sum_{m_i, m_f, m_l, m_l'} \sum_{j_m l_1 m_l} \langle j_m l_1 m_l | I_i M_i \rangle \langle j_m l_1 m_l | I_f M_f \rangle \int dr \int dr' \times \psi^{m_{l'} m_i}_{j_{l'}}(r) \psi^{n_l m_l}_{n_l m_l}(r') [q_{r'} Y_{1\mu}(\hat{r}') + q_j Y_{1\mu}(\hat{r})] \times \psi^{n_{l'} m_i}_{l m_i}(r')
\]

\[
= \langle \psi^{M_f}_{I_f} | \mathcal{O}(E1, \mu) | \psi^{M_i}_{I_i} \rangle = \sum_{m_i, m_f, m_l, m_l'} \int dr \int dr' \times \psi^{m_{l'} m_i}_{j_{l'}}(r) \psi^{n_l m_l}_{n_l m_l}(r') [q_{r'} Y_{1\mu}(\hat{r}') + q_j Y_{1\mu}(\hat{r})] \times \psi^{n_{l'} m_i}_{l m_i}(r')
\]

(A5)
The orthogonality of the wave functions satisfies the conditions of \( \langle \Psi_{n_{1}} \mid \Psi_{n_{2}} \rangle = 0 \) and \( \langle \Psi_{n_{1}} \mid \Psi_{n_{2}} \rangle = 0 \) if both the nuclear and atomic states change in the reaction. This E1 matrix element is thus found to be zero.

A.3. E1 Rate Enhanced by a Heavy \( X^- \) Particle

Contrary to the approximate estimation described above, the E1 transition rate is not expected to vanish, although it is hindered compared to the E1 rate for allowed nuclear transitions. This is because particles can have charge distributions of finite size. In the present case, \( \alpha \) and \( ^3\text{H} \) have a finite charge distribution. We explain this effect by comparing the electronic ion, \(^7\text{Be}^3+\), and the exotic ion of the massive \( X^- \) particle, \(^7\text{Be}_X\).

Average radii of electronic ions composed of an electron and light nuclei are \( \sim O(10^{-8}) \) cm while the average radii of nuclear wave functions for light nuclei are \( \sim O(10^{-13}) \) cm. Since the two radius scales are different from each other by a large factor, the atomic and nuclear wave functions can be separately considered for the following reason: (1) nuclear wave functions are not affected by the existence of the electrons which are far away from the nuclei, and (2) atomic wave functions are not affected by the nuclear charge distribution since the Coulomb potential between the electron and the nucleus does not depend on the nuclear charge distribution except at very small atomic radii \( r' \) comparable to the nuclear radius charge.

When the mass of the \( X^- \) is larger than \( \sim 1 \) GeV, however, the average radii of \(^7\text{Be}_X\) atomic states approach \( O(1 fm) \). This is roughly the same order of magnitude as the charge radius of the \(^7\text{Be}^+\) nucleus. At large nuclear radii, therefore, effects of the Coulomb forces by the \( X^- \) particle are not completely negligible in nuclear wave functions. Nuclear wave functions then depend not only on the nuclear radii but also on atomic radii. In addition, at small atomic radii the effects of the finite nuclear charge distribution reflecting a nuclear cluster structure are not completely negligible in atomic wave functions. Atomic wave functions then depend not only on atomic radii but also on nuclear radii. Therefore, nuclear and atomic wave functions are not strictly orthogonal, and the E1 matrix element is finite.

It is physically interesting that rates for E1 transitions simultaneously changing nuclear and atomic states can be larger if the \( X^- \) particle is heavier. The rates are expected to be large for not only the hypothetical \( X^- \) particle predicted in beyond the standard model physics, but also known negatively charged heavy particles such as \( \mu^- \), \( \pi^- \), \( \bar{\nu}_\tau \), and so on. For example, ordinary and radiative muon captures on a proton, in which the latter just corresponds to the recombination process in this work, were performed in TRIUMF (Jonkmans et al. 1996), but the theoretical interpretation is still under discussions (Cheoun et al. 2003).

In addition to the pure Coulomb force, spin-dependent interactions can exist between an \( X^- \) particle and nuclear clusters if the \( X^- \) particle has a spin. In this paper, we assumed a spinless \( X^- \) particle. In general, however, spin dependent interactions can mix states of \( A + X^- \) and \( A^* + X^- \) so that the overlap integrals can be non-zero (M. Kamimura 2013, private communication).
