The posterior cranial fossa's dura mater innervation and its clinical implication in headache: a comprehensive review

D. Hage et al., Posterior cranial fossa's dura mater innervation

Abstract
The pathophysiology of migraines and headaches has been a point of interest in research as they affect a large subset of the population, and the exact mechanism is still unclear. There is evidence implicating the dura mater and its innervation as contributing factors, especially at the posterior cranial fossa. Many modes of innervation have been identified, including the dorsal root ganglion (DRG), superior cervical ganglion, vagus nerve, trigeminal nerve, hypoglossal nerve, and glossopharyngeal nerve. While the exact method of innervation is still under investigation, there is strong evidence suggesting that different types of headaches (migraine vs. occipital vs. cervicogenic) are due to specific nerves and inflammatory mediators that contribute to the dura mater in some way. By understanding how these innervation patterns manifest clinically, the course of treatment can be tailored based on the physiological etiology. Here, we present a
comprehensive literature review of the current research regarding the innervation of the dura mater of the posterior cranial fossa and its clinical implications.

Key words: anatomy, nerves, cranium, meninges, headache

INTRODUCTION

The dura mater is the most superficial constituent of the cranial meninges and acts as a protective covering for the brain [1, 33]. It is composed of an inner meningeal and an outer endosteal layer [1, 33]. The outer endosteal layer is occupied by nerves and blood vessels and forms the skull’s periosteum, which can be further divided into an outer fibrous layer and an inner layer with osteoblastic potential [1, 17, 33]. The cranial dura mater’s inner meningeal layer has communication with the dura mater of the spinal cord at the foramen magnum and forms the falx cerebri, falx cerebelli, tentorium cerebelli, and diaphragma sella [1, 33]. The dural venous sinuses can be identified along with various positions of dura mater reflection between the two layers [1, 23, 50, 61]. The innervation of the dura mater has been a point of interest in research due to its clinical implications with various types of headaches [5, 10, 34, 43, 48, 52, 55, 60, 84]. This article reviews the literature regarding the innervation of the dura mater of the posterior cranial fossa, and its associated clinical relevance.

The Posterior Cranial Fossa

The posterior cranial fossa is the largest and deepest fossa within the skull [6, 26, 76]. It serves as a conduit for several cranial nerves and contains important structures such as the brain stem, cerebellum, and foramen magnum [6, 26, 76]. Abnormalities (e.g., hypoplasia) of the posterior cranial fossa are often seen in patients with Chiari and other cerebellar malformations [76].

Dorsal Root Ganglia and Superior Cervical Ganglia

In a study of 54 Sprague-Dawley rats, Noseda et al. utilized a green fluorescent protein (GFP) labeled adeno-associated viral vector to map the innervation of the dura mater of the posterior cranial fossa [51]. The results demonstrated that the dura mater of the posterior cranial fossa receives innervation from axons of sensory neurons in the C2 and C3 DRG [51]. The
axons were observed to gain entry into the cranium through various routes including the foramen magnum, the jugular foramen, and various bony canals (occipital-periotic, emissary, and hypoglossal) within the occipital bone (Fig. 1) [51]. Furthermore, it was noted that the C2-C4 segments of the spinal cord contain the dorsal horn neurons responsible for transmitting nociceptive information from the posterior/occipital dura mater [51].

Keller et al. utilized horseradish peroxidase labeling to examine the innervation of the dura mater of the posterior cranial fossa in cats [32, 33]. After completing nerve resections, they observed a bilateral distribution of labeled cells in both the superior cervical ganglion and C1-C3 of the DRG [32, 33]. Therefore, they concluded that these provided the majority of the innervation to the posterior cranial fossa [32, 33]. Additionally, they noted the presence of some labeled cells within the trigeminal ganglion and the superior ganglion of the vagus nerve, leading them to suspect some innervation involvement from the trigeminal and vagus nerves [32, 33] (Fig. 2).

In an examination of 22 human fetuses, Kimmel et al. observed that the innervation of the dura mater of the posterior cranial fossa was provided by the superior cervical ganglion and C1-C3 of the DRG [33, 36]. They noted that the meningeal branches of C1-C3 of the DRG utilize the foramen magnum to enter the cranium and provide innervation to the anterior portion of the posterior cranial fossa [33, 36]. In contrast, the superior cervical ganglion and C1-C2 of the DRG utilize the hypoglossal canal and the jugular foramen to access and innervate the lateral and posterior portions of the posterior cranial fossa [33, 36]. These nerves may also use the vagus and hypoglossal nerves for access to the posterior cranial fossa [33, 36].

Likewise, studies by Bogduk et al. have reported that the C3 cervical sinuvertebral nerve (SVN) innervates the dura mater of the posterior cranial fossa and follows a prolonged course through the posterior cranial fossa and the vertebral canal [9]. Based on these results, Rennie et al. were able to trace the intraspinal courses of all three SVN’s [68]. They found that smaller branches off the ascending and descending branches provide innervation to the dura mater, adjacent joints, surrounding ligaments, and soft tissues [68]. They observed that the SVN’s were initially formed within the intervertebral foramen, then gave off branches that ran anterior to the DRG within the epidural space [68]. In concurrence with Kimmel at al., they reported that the C1-C2 and C2-C3 levels had long ascending branches that supplied innervation to structures within the vertebral canal and the posterior cranial fossa [36, 68]. Additionally, communication
was found between the ascending branch of the C2 SVN and the hypoglossal nerve, confirming the presence of sensory interaction between cervical and cranial nerves [68]. This was further supported through fetal studies that identified a similar communication loop between the C2-C3 ascending branches and an extradural nerve that emerges from the hypoglossal canal [33, 36, 68].

**Cranial Nerves**

Penfield and McNaughton observed innervation contributions from the hypoglossal nerve and the vagus nerve’s recurrent branches traveling alongside the posterior meningeal artery [62]. The vagus nerve’s recurrent branches were identified coursing to the falx cerebelli and the inferior wall of the transverse sinus [62]. Additionally, Levy et al. noted the presence of unmyelinated C- and thinly myelinated Aδ-fibers from the trigeminal nerve within the dura mater [40]. Both of these are consistent with the suspicions of Keller et al. who predicted some vagus and trigeminal nerve involvement with the innervation of the dura mater of the posterior cranial fossa and Schueler et al. who identified meningeal nerve fibers within the dura mater stemming from the trigeminal ganglion [32, 73].

Kimmel et al. identified branches of the hypoglossal nerve traveling superiorly from the hypoglossal canal to supply the dura mater of the posterior cranial fossa [33, 36]. Kemp et al. has also reported that branches of the facial and glossopharyngeal nerves contribute innervation to the dura mater of the posterior cranial fossa [33]. These studies suggest that there is some cranial nerve innervation component to the dura mater overlying the posterior cranial fossa.

**Clinical Relevance**

**Occipital Headaches**

Occipital headaches have been reported to play a role in both migraine and non-migraine headaches [51]. While the debate regarding its etiology is ongoing, evidence suggests that occipital headaches are caused by compression and irritation of the C2 DRG [13, 30, 34]. This idea is further supported in studies where the administration of anesthetic blockade to the occipital nerve and its branches alleviated occipital pain and headaches [19, 51, 58, 60]. As mentioned earlier, Noseda et al. mapped the innervation of the dura mater of the posterior cranial fossa to the C2-C3 level of the DRG. They found that approximately 50% of the neurons involved contained calcitonin gene-related peptide (CGRP) and transient receptor potential
cation channel subfamily V member 1 (TRPV1) [51]. They also observed that the C2-C4
division of the spinal cord contains the dorsal horn neurons responsible for transmitting
nociceptive information from the posterior/occipital dura mater [51]. These neurons contain
receptive fields that extend from the ears and occipital skin to the superficial and deep muscles of
the neck, and the skin overlying the upper neck [51]. Upon administering pro-inflammatory
mediators to the dura mater of the posterior cranial fossa, a correlation was identified between
the neuronal responsiveness and stimulation of the occipital skin and neck muscles [51]. These
findings demonstrate a direct connection between occipital headaches and the innervation of the
dura mater overlying the posterior cranial fossa.

**Migraines**

Migraine headaches are the most common neurological disability worldwide and are
ranked as the second leading cause of disability [5, 22]. Additionally, women are 2-3 times more
likely to suffer from migraines than men [5, 22]. The cranial meninges and nociceptive signaling
from the dura mater have long been considered as the site of origin for the pain attributed to
migraines [5, 41, 48, 55, 79, 83, 84]. While the exact pathophysiology of this disease and its
sexual dimorphism remains unknown, there is evidence suggesting a correlation between the
peripheral release of neuropeptides such as CGRP, substance P, neurokinin A, and prostaglandin
E2 (PGE2) within the dura mater and the onset of a migraine attack [4, 5, 11, 12, 14, 15, 18, 20,
31, 35, 38, 52, 54, 57, 77, 83, 84].

The research on substance P, PGE2, and neurokinin A is less extensive than CGRP;
however, there is a correlation between elevated levels of all three mediators and the onset of
migraine attacks; in fact, elevated levels of PGE2 have been measured in the saliva of migraine
patients [14, 15, 18, 52, 57]. The role of neurokinin A is still unclear; however, there is an
established relationship between histamine release from dural mast cells following elevated
PGE2 and substance P [14, 15, 18, 52, 57]. There is also evidence trigeminal axons’ excitation
stimulates the release of the dural mast cells, further demonstrating the role of the trigeminal
nerve with the innervation of the dura mater [15, 32, 54, 73].

Studies have found that when the dura mater is exposed to CGRP, a dilatory effect can be
seen within the vasculature, which induces migraine symptoms at that location [4, 5]. Similar
dilation events have been reported along with the dura mater on the head’s side, experiencing
spontaneous migraine attacks [5, 35]. Furthermore, elevated levels of CGRP have been found in the venous blood, saliva, and cerebrospinal fluid (CSF) of patients undergoing a migraine attack [5, 20]. There is also evidence that intravenous administration of CGRP can elicit an attack [5, 38], whereas CGRP inhibitors have been successful in the treatment of migraines [5, 77]. Additionally, administrations of nitric oxide (NO) to the dura mater have been shown to elicit migraine attacks in both humans and rats [5, 54, 55, 56], as NO has been found to increase CGRP release [5, 11].

Even though the exact mechanism of peripheral CGRP signaling in migraine headaches is still under investigation, there is evidence implicating extracellular adenosine triphosphate (ATP) as a contributory factor [83]. Through the utilization of rat models, Yegutkin et al. discovered that upon exposure to CGRP, ATP and adenosine diphosphate (ADP) levels increased in both the meninges and trigeminal cells, whereas adenosine levels decreased in the trigeminal cells [83]. The ATP signaling subsequently resulted in a substantial buildup of intracellular Ca2+ within neurons and glial cells [83]. Additionally, high levels of ATP were correlated to nociceptive spikes within the meningeal trigeminal nerve fibers, and ATP was found to have the most prominent and lasting effects when compared to other metabolites, due to ATP activation of ionotropic (P2X) and metabotropic (P2Y) purinergic receptors within these neurons [12, 83]. These findings are corroborated by previous studies that also noted significant ATP releases during migraine attacks, as a result of opened pannexin channels [31, 83].

Avona et al. successfully applied a rat model to understand better the sexual dimorphism of migraine attacks related to CGRP signaling within the dura mater [5]. They observed that only female rats produced a cutaneous periorbital hypersensitivity following the administration of CGRP (0.1pg – 3.8ug) to the dura mater. In contrast, the males were only responsive if the dura mater was initially primed with interleukin-6 or brain-derived neurotrophic factor [5]. Additionally, only female rats displayed priming to a subthreshold administration of dural CGRP (0.1pg) [5]. These findings give us an insight into the sexual dimorphism of the disease and demonstrate the connection between CGRP signaling in the dura mater and migraine headaches.

**Cervicogenic Headaches**

Cervicogenic headaches are defined as pain in the head originating from a location other than the head – typically the cervical spine [10, 59]. These are among the most common types of
headaches affecting weightlifting athletes and are associated with patients who have sustained a whiplash injury [59, 75, 78]. Studies by both Bogduk et al. and Biondi et al. observed that the source of pain originates from the cervical spine and is mediated through the upper cervical nerves [8-10, 69]. They found that the upper cervical nerves supply the dura mater of the posterior cranial fossa and the ligaments of the craniovertebral junction (CVJ) [8-10, 69]. Additionally, it was noted that these nerves share the same root as the dorsal rami responsible for transmitting nociceptive information from the posterior head and neck region [10]. This provides us with a better understanding of how the upper three cervical nerves mediate pain from the ligaments, dura mater, and soft tissues of the posterior cranial fossa and upper cervical column and how symptoms may manifest clinically [8-10, 69].

**Botulinum Toxin**

Botulinum neurotoxin (BoNT) has become a popular treatment option for several headache disorders, especially migraines, due to its anti-nociceptive properties [42]. Several different serotypes are produced by Clostridium Botulinum, however, only serotypes A and B have been approved for clinical use [7, 21]. It exerts its effects by enzymatically cleaving the 25 kDa synaptosomal-associated protein (SNAP-25), thus inhibiting the ability for neurotransmitter-containing vesicles to fuse with the cell membrane [21, 44, 70]. Through this mechanism, studies have demonstrated the inhibitory effect of BoNT on the release of neurotransmitters - substance P and CGRP - involved in the transmission of pain, neurogenic inflammation, and peripheral and central sensitization [16, 21, 28, 42, 66, 81]. Additionally, there is some evidence that administration of BoNT reduces the inflammatory response [28, 42, 64].

**Surgical Relevance**

Operative treatment of occipital and migraine headache has existed for centuries with an early focus employed on blood vessels by Al-Zahrawi (936 to 1013 AD) e.g., using caustic skull cauterization to alleviate headache [2], vessel ligation (French barber-surgeon Ambroise Pare (1510 to 1590) [3], arteriotomies, bloodletting (application of temples leeches by Thomas Willis (1621 to 1675) and Robert Whytt (1714 to 1766) and arterial compression by W. Mollendorff in
1867 [47]. Many of these concepts/treatments were used and carried into the Middle Ages in Europe.

These concepts of vessel involvement in occipital and migraine headaches have also been revisited in modern times in 1976 by Greek neurosurgeon Alexander D. Rapidis [67], and more recently by Dr. Elliot Shevel who is an oral and maxillofacial surgeon [74]. Between 1904 and 1955, Alexander Rapidis described sectioning of the trigeminal pathways for permanent facial analgesia and injection of alcohol into the Gasserian ganglion with successful results [67]. In 1964, Bruce C. Martin and Phillip J. Fagan published the first report on the surgical management of occipital neuralgia with satisfactory results by excising segments of the greater occipital nerve, lesser occipital nerve, third occipital nerve, and posterior auricular nerve with injection of alcohol into the area that was excised [45]. Since then, the operative management of headache continues to evolve with theories on the extracranial course and nerve origin. Recently, Bahman Guyuron, in 2000, introduced the current concept of nerve irritation and compression at specific points across the skull and by adjacent structures [24]. He further described the surgical treatment of trigger sites, which evolved since then to include open, endoscopic, and minimally invasive techniques for decompression, neurectomy, arterial ligation, and arterectomy, depending on the anatomical location and underlying pathophysiology with success rates ranging between 68 and 95% in pain improvement [37, 39, 49, 71].

Many anatomical studies have shown that nerves can be compressed by different surrounding tissues such as vessels, bone, muscle, fascia, and fascial bands [29]. However, only some of these tissues have been investigated. Guyuron et al. evaluated nerves removed during migraine surgery by electron microscopy with proteomics and reported deregulation of the myelination process and axonal abnormality in patients with migraine headaches versus controls [25].

Additionally, Perry et al. evaluated calvarial periosteum as a source of chronic migraine, demonstrating decreased expression of genes that suppress inflammation and increased expression of proinflammatory markers [63]. The authors concluded that the trigeminovascular nociceptors that reach the periosteum are activated through intracranial meningeal nociceptors and/or extracranial nerves [63]. Such findings have been supported by human and animal data showing that pain and sensory nerve fibers cross the calvarial periosteum via cranial sutures and connect extracranial and intracranial axons [72, 73].
Weiner and Reed introduced occipital nerve stimulation (ONS) in 1999 [82], a promising treatment for patients with medically intractable and highly disabling chronic headache disorders [82]. The exact mechanisms by which ONS modulate pain are poorly understood; however, multiple sites of action within the central and peripheral nervous systems have been proposed, including the upper spinal segmental level, supraspinal levels, and peripheral nerve levels [27].

Direct effects of neurostimulation on peripheral nerve fiber excitability include an increase in electrical threshold, slowing of conduction velocity, and decrease in response probability have all been reported [46]. Additionally, a widely held theory of neurostimulation is the gate-control theory of pain have been described [46, 80]. Regarding ONS efficacy, Popeney and Alo used C1-C3 peripheral nerve stimulation for migraine headaches, with showed 85% of patients reported at least 50% reduction in headache frequency or severity after the ONS implantation [65]. Oh, and colleagues used ONS in migraine headaches with 90% of the patients reporting more than 90% pain relief, and 10% of the patients reporting 75–90% pain relief at one month after implantation [53]. ONS provided a better life for some patients, gave hope to many more, and suggested that different types of headaches are likely due to specific nerve involvement.

**CONCLUSIONS**

Although various modes of innervation have been identified, there is extensive evidence supporting the involvement of the dura mater and its innervation with the onset of many headaches. These findings are essential to consider when determining the best approaches for treating headaches, as the etiology and innervation patterns may vary.

**Figure 1.** Schematic drawing of the skull base and illustrating entrance sites of meningeal nerves supplying the posterior cranial fossa such as the hypoglossal canal, foramen magnum and jugular foramen. Also, note the innervation of the tentorium cerebelli from primarily the tentorial nerve derived from V1 of the trigeminal nerve.

**Figure 2.** Schematic drawing of the skull base noting the tentorial nerve (yellow arrow) arising from the V1 part of the trigeminal nerve. Regionally, also note the nervus spinosus branch (black arrow) of V3 entering the foramen ovale with the middle meningeal artery (unlabeled)
