Heterogeneous nuclear ribonucleoproteins (hnRNPs) are a group of functionally versatile proteins that play critical roles in the biogenesis, cellular localization and transport of RNA. Here, we outline a role for hnRNPs in gene regulatory circuits controlling sterol homeostasis. Specifically, we find that tissue-selective loss of the conserved hnRNP RALY enriches for metabolic pathways. Liver-specific deletion of RALY alters hepatic lipid content and serum cholesterol level. In vivo interrogation of chromatin architecture and genome-wide RALY-binding pattern reveal insights into its cooperative interactions and mode of action in regulating cholesterogenesis. Interestingly, we find that RALY binds the promoter region of the master metabolic regulator Srebp2 and show that it directly interacts with coactivator Nuclear Transcription Factor Y (NFY) to influence cholesterogenic gene expression. Our work offers insights into mechanisms orchestrating selective promoter activation in metabolic control and a model by which hnRNPs can impact health and disease states.
Heterogeneous nuclear ribonucleoproteins (hnRNPs) are a family of multifunctional RNA-binding proteins with critical roles in gene regulation. Cooperative activities of hnRNPs have been shown to impact various aspects of RNA metabolism. Although much of the focus on hnRNPs has been geared to their role in splicing and transcript processing, their direct effects on mRNA biogenesis are far less understood with limited compelling roles for transcriptional contributions of hnRNPs. In addition, several lines of evidence link hnRNP abnormalities to neurodegenerative diseases and cancer, but their impact in metabolic control remains unexplored.

A number of genome-wide association studies have linked variants at the hnRNP RALY (also known as heterogeneous nuclear ribonucleoprotein C-like 2) with cardiometabolic traits, including total cholesterol and coronary artery disease, yet little is known about the function and mechanisms of actions of RALY.

Our previous studies have shown that RALY interacts with LeXis, a noncoding RNA mediating crosstalk between the cholesterol biosynthesis and efflux pathways. LeXis is a direct transcriptional target of LXR, a sterol-sensing nuclear receptor that triggers an "emergency response" to a lipid overload state. Activation of LXR induces the expression of genes involved in cholesterol efflux (ABCA1 and ABCG1), limiting lipid uptake (IDOL), and promoting triglyceride-rich lipoprotein formation (SREBP1c and SCD1).

On the other hand, the sterol regulatory element-binding proteins (SREBPs) are master regulators of sterol metabolism, directly activating the expression of genes involved in cholesterol and fatty acid biosynthesis. Although all SREBP isoforms can influence a large repertoire of genes at extreme perturbations, it is well established that SREBP1c preferentially activates genes involved in fatty acid biosynthesis, whereas SREBP2 influences cholesterol biosynthetic machinery. Consistent with unique epistatic relationship between various SREBPs, loss of SREBP2 in mouse liver reduces SREBP1c and triglyceride levels in addition to impacting cholesterol stores. Despite their unique activation signature both isoforms appear to bind similar DNA response elements and to partner with common transcriptional coactivators, including Nuclear Transcription Factor Y (NFY) and SP1.

In this work, we outline a role for hnRNPs in regulatory circuits controlling sterol homeostasis. Liver-specific deletion of the hnRNP Raly lowers serum cholesterol and hepatic lipid content. By mapping RALY-binding sites and utilizing unbiased chromatin interrogation techniques, we show preferential binding patterns of RALY at gene promoter regions and decipher its cooperative interactions. Intriguingly, we find that RALY binds at the Srebp2 but not Srebp1 promoter region, and show that it interacts directly with NFY to influence transcription of cholesterogenic genes. Our work offers insights into mechanisms orchestrating selective promoter activation and a model by which hnRNPs can impact metabolic disease states.

### Results

#### Ablation of Raly impacts cholesterol biosynthetic genes.

To gain insights into the contribution of hnRNPs in metabolic disease, we generated mice with LoxP sites flanking exons 3 and 4 of Raly (Fig. 1a, Supplementary Fig. 1). Administration of a Cre or control adenovirus to Ralyflx/flx primary murine hepatocytes resulted in the ablation of RALY transcript and protein levels (Supplementary Fig. 2a, b). Since RALY is one of the few hnRNPs linked to human lipid traits, and since our previous studies have shown that disruption of the LeXis-RALY axis perturbs cholesterogenic gene expression, we sought to determine the effect of genetic deletion of Raly on Srebp2 (official gene symbol Srebi2) gene expression. Deletion of Raly from primary murine hepatocytes led to a significant reduction of Srebp2 and its target genes involved in cholesterol biosynthesis, including Hmgcr (Supplementary Fig. 2c). Surprisingly, the deletion of Raly from mouse hepatocytes also led to a significant reduction in Srebp1c, the isoform responsible for triglyceride biosynthesis (Supplementary Fig. 2e). We confirmed reduced protein levels of a nuclear SREBP2 and a number of targets, including 3-Hydroxy-3-Methylglutaryl-CoA Synthase (HMGC), and Farnesyl Diphosphate Synthase (FDPS) (Supplementary Fig. 2d, e). To explore the contributions of Raly in liver metabolism, we generated liver-specific Raly knockout mice (referred to as L-RalyKO while Ralyflx/flx Cre-negative littermates are controls). Quantitative PCR (qPCR) analysis and western blotting confirmed significant and robust decrease in RALY in liver following Cre recombination (Fig. 1b, c). Previous studies have shown that at least a subset of hnRNPs complexes influence gene expression in a non-discriminate fashion. To better define the range of RALY activities in liver, we performed unbiased transcriptional profiling of livers from L-RalyKO and control mice on a chow diet (Fig. 1d). Analysis of differentially regulated genes showed a significant and strong enrichment of lipid metabolic and related pathways (Fig. 1e), as well as substantial overlap with pathways known to be modulated by SREBP2 (Fig. 1e) Ralyflx/flx livers. If there was also a trend to reduced Srebp1c expression although did not reach significance (fattening mice). Consistent with gene expressing results loss of RALY was associated with a reduction in serum cholesterol level (Fig. 1g). Lipid fractionation analysis revealed a reduction in low-density lipoprotein (LDL) and high-density lipoprotein fractions the predominant circulating pool in chow-fed mice (Fig. 1h). Taken together, these results suggest that hnRNPs can regulate the activity of specific gene expression programs and that the effects of RALY on cholesterogenesis are non-redundant.

#### Liver-specific deletion of Raly reduces hepatosteric content.

We noted that loss of Raly from hepatocytes was associated with a decrease in cellular cholesterol and triglyceride content (Fig. 2a, b). To better define the contributions of RALY on hepatic lipid composition, we performed unbiased shotgun lipidomics on mouse liver comparing L-RalyKO and controls. We observed that vast majority of lipid species were unchanged with the exception of hepatic cholesterol and triglyceride content (Fig. 2, Supplementary Fig. 3). Examination of cholesterol esters showed a reduction in most species in L-RalyKO although only a subset reached statistical significance (Fig. 2c, d). Similarly triglyceride content was significantly reduced in L-RalyKO livers (Fig. 2e, f). We observed no changes in the expression of genes involved in lipolysis (Supplementary Fig. 4). Intriguingly, these results partially phenocopy the Chow-fed Srebp2 liver-specific knockout mice, that exhibit mildly reduced liver cholesterol content as well altered SREBP1c and triglycerides levels. These results are also consistent with unique epistatic relationship between various SREBPs. Taken together, the lipidomics findings reinforce the gene expression results and support the notion that RALY may be affecting sterol metabolism through interaction with the Srebp2 pathway. To more thoroughly investigate the contributions of RALY in chronic lipid abundance states, we fed L-RalyKO mice and controls a diet known to induce sterol accumulation and Non-Alcoholic Steatohepatitis (NASH). After 9 weeks of feeding, L-RalyKO showed significant reduction in Oil Red O staining (Fig. 2g, h). These results demonstrate that in a preclinical disease model the hepatic loss of RALY partially protects against lipid overload.
DNA binding of RALY enriches for metabolic regulators. Our previous studies have shown that LeXis and RALY are almost exclusively present in the cell nucleus in association with chromatin and that LeXis may be impacting cholesterogenic gene expression through transcriptional mechanisms\(^7\). Thus, we hypothesized that RALY may also be impacting Srebp2 levels through nascent transcript production. To gain better insight as to how RALY may regulate gene expression, we mapped genomewide RALY-binding sites. We performed chromatin immunoprecipitation sequencing (ChIP-seq) to assess RALY DNA binding of RALY in liver from chow-fed mice (\(n=8\) per group). Global analysis of fragment distribution around the peak summit showed that RALY primarily affects Srebp2 and that perturbations in hepatic triglycerides content are likely a downstream consequence of reduced SREBP2 activity. In addition, motif discovery analysis of RALY-bound peaks identified the transcription factor NFY as a highly enriched motif (Fig. 3e). NFY is a promoter-binding transcription factor (formed with trimeric complex of NFYA, NFYB, and NFYC with all subunits required for proper function) with an established role in mediating SREBP responses\(^16\). Taken together, these results hint that RALY may be influencing cholesterogenesis by modulating collaborative interactions with transcriptional coactivators at the Srebp2 promoter.

A number of studies have shown that noncoding RNA–protein interactions can regulate gene activities by modulating a number of histone modifications at target genes\(^17,18\). To explore the possibility that RALY may influence gene expression by altering epigenetic states, we performed Assay for Transposase-Accessible Chromatin using sequencing (ATAC-seq)\(^19\), a method that allows unbiased interrogation of chromatin architecture, on livers from L-RalyKO and controls (Fig. 3f). Loss of RALY in mouse liver did not globally alter chromatin accessibility (Fig. 3g) arguing against the idea that RALY may be impacting gene expression by impacting histone modifiers, such as polycomb repressive
Fig. 2 Liver-specific deletion of RALY alters hepatic lipid content. a, b Cholesterol level a and triglycerides level b from primary hepatocytes relative to baseline levels (normalized to cell number). c, d Lipidomics investigation of cholesterol ester (CE) species from liver from L-Raly knockout mice and controls (n = 4 per group). e, f Lipidomics investigation of triglycerides species from liver from L-Raly knockout mice and controls (n = 4 per group). Each line on heat map represents an individual triglyceride species of 411 different triglycerides detected (four mice per group). g Oil Red O (ORO) staining of liver from NASH diet-fed mice (scale bar, 20 µm). h Quantification of positive ORO staining area from done with automated image j detection. complex proteins or histone deacetylase\textsuperscript{20}. In addition to directly interrogating changes in nucleosome rearrangements, ATAC-seq allowed us to infer transcriptional activity by examining changes in enhancer landscapes with targeted perturbations. Although globally most ATAC peaks did not change between controls and L-Raly\textsuperscript{KO} samples, a number of peaks were differentially regulated (Fig. 3h). Intriguingly, many of these peaks clustered near genes involved in lipid metabolism (Fig. 3i, j, Supplementary Fig. 6). Furthermore, motif analysis of these differentially altered peaks showed specific enrichment for number of transcription factors known to impact metabolic regulation, including NFY (Fig. 3k). Taken together, the above results suggest that RALY may be regulating cholesterol metabolism by impacting the coactivator NFY at the Srebp2 gene.

RALY is required for NFY-dependent activation of Srebp2. To clarify whether RALY directly interacts with transcriptional machinery at SREBP2, we performed co-immunoprecipitation (Co-IP) studies in murine hepatocytes. Pulldown of RALY enriches for NFY and vice versa confirming a robust interaction between the two factors (Fig. 4a, b). To clarify whether RALY is required for NFY binding at promoter regions, we performed ChIP of NFY in L-RalYKO or control livers. We confirmed NFY enrichment at its known target gene Rnf5 (Fig. 4c), as well as the SREBP2 promoter region (Fig. 4d). Our results suggest that NFY binding is minimally rearranged by the loss of RALY consistent with the idea that RALY does not act as a guide to facilitate NFY complex DNA binding, rather it works cooperatively with NFY at select sites to influence its transcriptional activity. To determine if RALY was sufficient to induce the expression of cholesterogenic genes, we overexpressed RALY using an adenoaviral vector in a murine hepatocyte cell line (Supplementary Fig. 7). We found that cholesterogenic gene expression was increased in response to RALY expression (Fig. 4e). In addition, hepatic RALY overexpression increased serum cholesterol in chow-fed mice (Fig. 4f). To more thoroughly investigate the cooperative relationship between RALY and cis/trans promoter factors, we performed luciferase reporter assays with an Srebp2 promoter construct (Fig. 4g). Adenoviral expression of RALY in hepatocytes enhanced wild-type Srebp2 promoter-driven lucerase activity, but failed to increase lucerase activity when either NFY or SRE sites were mutated (Fig. 4d). These results reinforce the idea that RALY is a coactivator that requires the binding of canonical transcriptional factors at the Srebp2 promoter including SREBP itself. To better clarify the epistatic relationship between NFY and RALY, we performed a knockdown of NFY in RALY-deficient cells. Our results show that reduction of NFY on a Raly-deficient background no longer alters Srebp2 expression (Fig. 4h, Supplementary Fig. 8). These results suggest that RALY is required for NFY-dependent transcription of SREBP2 and is consistent with notion, and RALY and NFY work cooperatively to influence gene expression.

To better explore the relationship between hnRNPs and human lipid traits, we analyzed expression data from the METSIM cohort. Interestingly, expression of RALY was positively associated with a number of metabolic, traits including total and LDL serum cholesterol levels though the strength of association was modest (Fig. 4i). Importantly, other hnRNPs, including ones that contribute to transcriptional control mechanisms (hnRNP K), were not significantly associated with total cholesterol or LDL cholesterol in this cohort (Supplementary Fig. 9). Although hnRNPs are known to form complexes with one another, these observations are consistent with the idea that individual hnRNPs may play functional roles favoring specific pathways.

Discussion
Previous work has identified important roles for hnRNPs in neurodegenerative disease, most prominently amyotrophic lateral sclerosis and frontotemporal lobar degeneration. Our work expands the contributions of hnRNPs in health and disease by showing that a conserved hnRNP can help direct the fundamental metabolic regulatory circuits. In addition, our work offers insights into the precise molecular mechanisms that link hnRNP abnormalities with pathologic states. The functional versatility of hnRNPs is thought to stem from their ability to “dance with different partners” to impact diverse biologic process, such as RNA splicing, polyadenylation, export, and translation. Thus, there are potentially multiple ways by which hnRNPs abnormalities can lead to disease states. Defects in hnRNPs leading to stress granule changes and the accumulation of pathological inclusions are thought to be important in neurodegenerative states. Our work shows that hnRNPs proactively participate in transcriptional control mechanisms regulating cholesterol homeostasis and that loss of a single hnRNP (RALY) influences hepatic lipid stores. It should be noted that our work does not exclude the possibility that RALY may play other functional roles or influence gene regulation though multiple mechanisms. In addition, RALY may be impacting transcript splicing or other redundant functions that may be masked in our knockout model or perhaps more critical in other tissues or cell types. Intriguingly, we find that RALY has multiple isoforms and it is unclear whether different isoforms perform different functions.

It is well established that the predominantly cholesterogenic SREBP2 and lipogenic SREBP1 transcription factors may be differentially processed depending on the environment cues. However, both isoforms are capable of binding diverse SRES and collaborate with common coactivators despite possessing distinct transcriptional effects once in the nucleus. In addition, it is unclear how generic collaborative partners, such as NFY and SP1 are capable of turning on some but not other transcription target genes in response to specific transcription factors. The chaperoning function of RALY offers some important clues into the selective promoter activities of different SREBPs. The fact that RALY binds the promoter of one isoform (Srebp2) and not the other hints that spatial collaborative interactions may favor a specific gene activation signature. The finding that RALY interacts with the SREBP coactivator NFY also raises a number of intriguing questions. How do hnRNPs influence some genes but not others? and what is the biochemical basis for their interactions? can RALY directly collaborate with other transcriptional regulators besides NFY? Future studies will provide more insights into these questions.

Methods
Study approval. All experiments were approved by the UCLA Institutional Animal Care and Research Advisory Committee and performed in strict accordance with the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. Please see supplemental materials for detailed methods.

Animals. All animals used in the study were in C57BL/6 background. Our study used male mice unless otherwise specified. Mice were fed chow diet (Research Diet) and housed temperature-controlled room under a 12-h light/12-h dark cycle and pathogen-free conditions. Ralylox/lox mice were generated by Cyagen using the strategy outlined in Fig. 1a. To generate the RALY liver-specific knockout mice and littermate controls, we treated Ralylox/lox with adeno-associated virus (AAV) with Fbg promoter (AAV8:Fbg:Csa) or (AAV8:Fbg:GF; green fluorescent protein) purchased from Penn Vector Core. AAV administered intraperitoneal injection at dose of 5 × 1011 GC per mice. Mice were euthanized 4 weeks after AAV injection. Liver tissues were frozen in liquid nitrogen and stored at −80 °C or fixed in 10% formalin. Blood was collected by retro-orbital bleeding, and the plasma was separated by centrifugation. Plasma lipids were measured with the Wako-L Type TG M kit, the Wako Cholesterol E kit. All animal experiments were approved by the UCLA Institutional Animal Care and Research Advisory Committee.

Cells culture. Mouse primary hepatocytes were isolated as previously described and cultured in William’s E medium with 5% bovine serum albumin (BSA) and housed temperature-controlled room under a 12-h light/12-h dark cycle and pathogen-free conditions. Ralylox/lox mice were generated by Cyagen using the strategy outlined in Fig. 1a. To generate the RALY liver-specific knockout mice and littermate controls, we treated Ralylox/lox with adeno-associated virus (AAV) with Fbg promoter (AAV8:Fbg:Csa) or (AAV8:Fbg:GF; green fluorescent protein) purchased from Penn Vector Core. AAV administered intraperitoneal injection at dose of 5 × 1011 GC per mice. Mice were euthanized 4 weeks after AAV injection. Liver tissues were frozen in liquid nitrogen and stored at −80 °C or fixed in 10% formalin. Blood was collected by retro-orbital bleeding, and the plasma was separated by centrifugation. Plasma lipids were measured with the Wako-L Type TG M kit, the Wako Cholesterol E kit. All animal experiments were approved by the UCLA Institutional Animal Care and Research Advisory Committee.

Gene expression analysis and immunoblot analysis. Total RNA was isolated using TRIzol reagent (Invitrogen) and reverse transcribed using a homemade RT, as previously described. cDNA was quantified by real-time PCR using SYBR Green Master Mix (Diagenode) on BioRad Real-time PCR instrument. Gene expression levels were determined by using a standard curve. Each gene was normalized to the

NATURE COMMUNICATIONS | https://doi.org/10.1038/s41467-020-14711-4 | www.nature.com/naturecommunications
housekeeping gene 36B4. For immunoblot analysis, whole cell lysate or tissue lysate was extracted using RIPA lysis buffer (Boston Bioproducts) supplemented with complete protease inhibitor cocktail (Roche). For SRBPs, proteins immunoblot analysis, nuclei from primary hepatocytes were prepared using Subcellular Protein Fractionation Kit for Cultured Cells (78840, Thermo Scientific). Proteins were diluted in Nupage loading dye (Invitrogen), heated at 95°C for 5 min, and run on 4–12% NuPAGE Bis-Tris Gel (Invitrogen). Proteins were transferred by electrotransferring to a PVDF or PVDF (pH 7.4) membrane (Thermo Scientific) overnight. Membranes were blocked with 5% BSA and then SRBP2 was added to quench nonspecific protein binding and blotted with the indicated primary antibody. For complete listing of antibodies and primers see please Supplementary Table 1. Uncropped blots are provided in Supplementary Fig. 10.

**Dual lucerase assay.** DNA transfection of Hepa1-6 cells was performed with LipofectamineTM 3000 (Invitrogen) according to user’s manual on 24-well plates with 5% cell density of 1.5 × 10^5 cells/well. The cells were transfected with 200 ng of the Sreb2 promoter reporter plasmid, 50 ng of Renilla reporter plasmid (Promega), and 200 ng of nSREBP2 expression vector. At 12 h after transfection, the cells were cultured in DMEM supplemented with 1% (v/v) FBS and adenosine was administered. After 24 h, assays for both luciferase and Renilla activities were performed. The reporter activities were expressed as the relative firefly lucerase activity/Renilla lucerase activity.

**RNA-seq.** Libraries for RNA-Seq were prepared with KAPA Stranded RNA-Seq Kit on RNA isolated from livers of chow diet feeding mice with AAV-GFP or AAV-Cre transduction. The data were sequenced on Illumina HiSeq 3000 for a pair-end 150 bp read run. Data quality check were done on Illumina SAV. Demultiplexing was performed with illumina Bcl2fastq v 2.17 program. RNA-seq reads were aligned with TopHat2 v 0.2.4 to the mouse genome, version mm9. Transcripts were assessed and quantities were determined by Cufflinks v2.0.2, using a GTF file based on Ensemble mouse NCBI37. Expression comparison levels were made using Fragments Per Kilobase of transcript per Million (FPKM) values using Cuffdiff from the Cufflinks package 26.

**NASH diet feeding and Oil Red O staining.** Twelve-week-old male mice were fed with diet containing 60 kcal% fat with 0.1% methionine and no added choline (A06071302, Research Diets) for 9 weeks. Oil Red O histochemistry staining were performed using frozen sections from mouse liver. Briefly, frozen sections were fixed in 10% neutral formalin for 10 min, followed by treatment in 60% isopropanol for 10 min and then staining in Oil Red O working solution (O-0625, Sigma Aldrich) for 15 min. This procedure was followed by washing with 60% isopropanol for 5 s and then water 1 min. Finally, sections were stained with Mayer’s Hematoxylin for 3 min.

**Lipidomics.** A total of 50–100 mg of frozen liver were homogenized in the Omni Bead Ruptor Elite with 2 mL homogenizer tube system (Omni, 19-628D). Samples were homogenized in cold phosphate-buffered saline (PBS) for 3 cycles of 10 s each and then centrifuged at 1100 × g for 10 min at 4°C. Pellet was resuspended in 50 μL RSB buffer (10 mM Tris-HCl, 10 mM NaCl, 3 mM MgCl2 and pH 7.4) followed by centrifugation at 500 × g for 5 min at 4°C and resuspension in PBS. A total of 75,000 nuclei pellet were used for transposase reaction. The rest of the protocol followed that described by Buentener. ATAC-Seq libraries were prepared using the Nextera Transposase (Illumina) and the original Buenstero protocol19. A total of 100 mg of frozen liver were grinded to powder using cellcrusher and 1 mL of ice cold nuclei isolation buffer was added (20 mM Tris-HCl, 50 mM EDTA, 5 mM sperrmine, 0.15 mM spermidine, 0.1% mercaptoethanol, 40% glycerol, pH 7.5, mM EDTA, and 60 mM KCI). After 5 min of cooling on ice, cell suspension was filtered through Miracloth (Calbiochem) followed by centrifugation at 1100 × g for 10 min at 4°C. Pellet was resuspended with 50 μL RSB buffer (10 mM Tris-HCl, 10 mM NaCl, 3 mM MgCl2 and pH 7.4) followed by centrifugation at 500 × g for 5 min at 4°C and resuspension in PBS. A total of 75,000 nuclei pellet were used for transposase reaction. The rest of the protocol followed that described by Buentener. ATAC-Seq libraries were prepared using the Nextera Transposase (Illumina) and the original Buenstero protocol19. Libraries were made using Fragments Per Kilobase of transcript per Million (FPKM) values using Cuffdiff from the Cufflinks package 26.
