We investigate the bulk rheology of dense granular flow down a rough slope, where the density profile has been found to show a plateau except for the boundary layers in simulations [Silbert \textit{et al.}, Phys. Rev. E \textbf{64}, 051302 (2001)]. It is demonstrated that both the Bagnold scaling and the framework of kinetic theory are applicable in the bulk, which allows us to extract the constitutive relations from simulation data. The detailed comparison of our data with the kinetic theory shows quantitative agreement for the normal and shear stresses, but there exists slight discrepancy in the energy dissipation, which causes rather large disagreement in the kinetic theory analysis of the flow.

Flowing granular material behaves like a fluid, but comprehensive understanding of its rheology is still far from complete. In the low-density regime with large shear rate, grains interact through instantaneous collisions and are described by a hydrodynamic model based on kinetic theory of inelastic hard spheres [1]. As the system becomes denser, the independent collision assumption becomes questionable and the one particle distribution of grain velocity may not be characterized by a small number of parameters or temperatures. When grains are nearly closed packed, they may experience enduring contacts, and the system behaves as in plastic deformation.

One of a few established laws that hold for granular rheology up to the relatively dense regime is the Bagnold scaling [2], which states that the shear stress is proportional to the square of the strain rate. In fact, this is the only possible form for the stress in the flow of rigid grains characterized by the shear rate $\dot{\gamma}$ and the packing fraction $\nu$, because $\dot{\gamma}^{-1}$ is the only time scale. Simple dimensional consideration gives the Bagnold scaling for the shear stress $S$ as

\[ S = A(\nu)m\sigma^2 - d\dot{\gamma}^2, \]

where $m$ is the grain mass, $\sigma$ is the grain diameter, and $d$ is the spatial dimension, with $A$ being a dimensionless coefficient that depends on $\nu$. Obviously this scaling should have broad range of validity for a simple shear flow of cohesionless hard grains; it should hold until either the system becomes so dense that the elasticity of particles comes into the problem or the shear banding destabilizes the uniform shear flow. In the case of gravitational flow down a slope, the shear is brought about by the gravity and the gravitational acceleration $g$ brings another time scale into the problem, but the Bagnold scaling is expected to hold in the denser region where the effect of gravity on particle orbits between collisions is not significant. Actually the Bagnold scaling is observed in experiments [2, 3] and simulations [4] in the slope flows quite well.

Recently, Silbert \textit{et al.} have performed large scale molecular dynamics simulations on dense slope flows [4] and they found an interesting fact that the grain density is almost constant and independent of the depth except for the boundary layers near the bottom and the surface. This is quite intriguing because the density is not nearly the closed packed density; it depends upon the inclination angle $\theta$ but neither upon the total depth of the flow $H$ [4] nor the roughness of the slope [5]. Somewhere, the system adjusts its temperature to keep the density constant along the depth direction.

This is, however, not difficult to understand if one extends the Bagnold scaling to the pressure; under the same

\[ p = \frac{1}{\rho_s} \frac{3}{2} \nu \dot{\gamma}^2, \]

where $\rho_s$ is the density of the grains. In (2), $\dot{\gamma}$ is the only time scale. Simple dimensional consideration suggests that this scaling should also hold in the bulk and this is the only possible form for the pressure in the flow of rigid grains characterized by the shear rate $\dot{\gamma}$ and the packing fraction $\nu$. In the case of gravitational flow down a slope, the shear is brought about by the gravity and the gravitational acceleration $g$ brings another time scale into the problem, but the Bagnold scaling is expected to hold in the denser region where the effect of gravity on particle orbits between collisions is not significant. Actually the Bagnold scaling is observed in experiments [2, 3] and simulations [4] in the slope flows quite well.

$\PACS$ numbers: 45.70.Mg,45.50.-j,47.50.+d
condition, the pressure, or the normal stress $N$, should have the same form

$$N = B(\nu) m \sigma^2 - d \dot{\gamma}^2$$

(2)

as $S$ with another dimensionless coefficient $B$, thus the ratio of $S/N$ depends upon the packing fraction $\nu$, but not on the shear rate $\dot{\gamma}$. In the gravitational slope flow, the force balance gives $S/N = \tan \theta$, thus we have

$$A(\nu)/B(\nu) = \tan \theta,$$

(3)

which shows the packing fraction is determined by the inclination $\theta$ but does not depend upon the depth $H$. This argument suggests the existence of the bulk region with the density plateau in the gravitational flow is very general and independent of detailed properties of grains.

In order to determine how the packing fraction $\nu$ depends on $\theta$, we need a theory that gives constitutive relations. This has been done by Louge [8] using a kinetic theory for inelastic hard spheres [7]. It is disappointing, however, to find that the kinetic theory fails to give correct density profiles; two branches of solution for $\nu$ were found, but one gives too small $\nu$ and the other gives opposite $\theta$ dependence of $\nu$ to the one observed in simulations, which implies the branch is a dynamically unstable one. This is a little puzzling situation because the kinetic theory has been shown to hold in the case of sheared flow in the similar density regime [8].

In this paper, we present detailed analysis of our simulations on the bulk region of two-dimensional gravitational flow, assuming the framework of kinetic theory. In contrast to previous works, where the overall profiles from hydrodynamic models were discussed [3], we examine each constitutive relations separately using data in the bulk to avoid the uncertainty in a boundary condition for hydrodynamic equations.

First, we show how the bulk behavior is understood within the framework of kinetic theory. In the granular kinetic theory, the kinetic temperature $T \equiv m \langle (c - \mathbf{v})^2 \rangle / d$ is treated as a separate variable, which introduces an additional time scale. Here, $c$ is the particle velocity, $\langle \cdots \rangle$ represents average over the microscopic scales, and $\mathbf{v} = \langle \mathbf{c} \rangle$. The shear stress is given by the momentum flux; this is $m \ell(\nu) \dot{\gamma} n \sqrt{T/m}$ in the elementary transport theory, where $n$ is the number density and $\ell(\nu)$ represents the mean free path. More generally,

$$S = f_2(\nu) m^{3/2} \sigma^{1-d} T^{1/2} \dot{\gamma},$$

(4)

with a dimensionless function $f_2(\nu)$, which depends on $\nu$ and other material parameters such as a restitution coefficient. Similarly we have for the normal stress $N$, the energy dissipation $\Gamma$, and the heat flux $q$

$$N = f_1(\nu) \sigma^{-d} T,$$

(5)

$$\Gamma = f_3(\nu) m^{-1/2} \sigma^{-d-1} T^{3/2},$$

(6)

$$q = -f_4(\nu) m^{-1/2} \sigma^{-d-1} T^{1/2} \partial_y T,$$

(7)

with $\partial_y = \partial/\partial y$. The forms $f_i(\nu)$ represent the quite general framework of kinetic theory [11], although functional forms $f_i(\nu)$ vary depending upon level of approximation.

These expressions should be compatible with the Bagnold scaling when the only relevant time scale is $\dot{\gamma}^{-1}$. Equation (4) of $S$ indicates that $T \propto \dot{\gamma}^2$ in order that the Bagnold scaling should hold. In the kinetic theory, $T$ is determined by the energy balance equation

$$-\partial_y q + S \dot{\gamma} - \Gamma = 0$$

(8)

in the steady flow. When the divergence of the heat flux $-\partial_y q$ is zero as in the case of the uniform shear flow due to the symmetry in the $y$-direction, $T$ is determined by the local balance between the viscous heating $S^2 \dot{\gamma}$ and the energy loss $\Gamma$; then the time scale that determines $T$ is the shear rate only. $S \dot{\gamma} = \Gamma$ with Eqs. (4) and (6) gives

$$T = [f_2(\nu)/f_3(\nu)] m \sigma^2 \dot{\gamma}^2,$$

(9)

thus the Bagnold scaling holds. In the slope flow, the divergence of the heat flux is not necessarily zero, but it turns out to be small compared with the other terms. Therefore, from Eqs. (4), (6), and $S/N = \tan \theta$, we have

$$\tan \theta = \sqrt{f_2(\nu)/f_3(\nu)},$$

(10)

which gives $\nu$ as a function of $\theta$ if we know $f_i(\nu)$.

In the following, the above analysis is examined in detail in comparison with the data of our two-dimensional simulations on the soft sphere model with the disk mass $m$, the diameter $\sigma$, and the moment of inertia $I = m \sigma^2/10$ as in Ref. [4]. The particles stiffness is taken to be in the region where the flow behavior is already in the hard sphere limit [10], which allows us to employ the constitutive relations for hard disks in the kinetic theory analysis in the following. The linear spring-dashpot model and the Coulomb friction with the coefficient $\mu = 0.5$ are employed, and the periodic boundary condition is imposed along the flow direction. The bottom boundary is made rough by attaching disks of diameter $2\sigma$, which we refer to as BC1: See Ref. [4] for detailed descriptions of the model (Our model corresponds to the model “L2”). We confirmed that our data agree with theirs in the bulk, although our slope length ($20\sigma$) is shorter than theirs ($100\sigma$). We show only the data for $\theta \geq 20^\circ$ with $H = 50$, which is well above the stopping angle $\theta_{\text{stop}}$ ($\theta_{\text{stop}} \approx 18^\circ$ [4]); the boundary effects become significant for $\theta$ closer to $\theta_{\text{stop}}$. The boundary effects are examined by simulating with a slope covered with disks of diameter $\sigma$ (BC2).

To compare our data with the kinetic theory, we use the normal restitution coefficient $e_p = 0.92$ and the tangential restitution coefficient $\beta = 1$, although the tangential restitution coefficient in the simulation is not constant because of sliding collisions with the Coulomb friction [11]. The Coulomb friction is important in simulation, but no kinetic theories have been worked out yet with it in two-dimension [12].
Figure 1 shows the $y$-dependence of $\nu$ (a), $T$ (b), and $\partial_y q/(S_f^2)$ (c) for various inclination angles $\theta$; most of the data are for the system with the depth $H = 50$ and BC1, but the data for BC2 and those for $H = 100$ are also shown for $\theta = 20^\circ$ for comparison. The data are given in the unit system where the length $a$, the mass $m$, and the time $\sqrt{\sigma/g}$ are units. One can see that the packing fraction in the bulk does not depend on the depth, and the effects of the boundary condition are confined within the boundary layer and the bulk properties are independent. Figure 1(c) shows that $\partial_y q$ is much smaller than $S_f^2$ in the bulk, which is consistent with our argument to derive Eq. (9); the heat flux $q$ is estimated by the constitutive relation in Ref. [13]. The plots of $T/T$ in the inset shows that Eq. (9) holds approximately.

We compare our data with the constitutive relations derived by Jenkins and Richman [13] for two-dimensional inelastic hard disks. The functions $f_1(\nu)$, $f_2(\nu)$, and $f_3(\nu)$ in the steady flow are given in Table I. We adopt the radial distribution function $g_0(\nu)$ from Ref. [14]

$$g_0(\nu) = g_c(\nu) + \frac{g_f(\nu) - g_c(\nu)}{1 + \exp(-\nu - \nu_0)/m_0),$$

where $g_c(\nu) = (1 - 7\nu/16)/(1 - \nu)^2$ and $g_f(\nu) = [(1 + e_p\nu/(\nu_c/\nu - 1))^{-1}$ with $\nu_c = 0.82$, $\nu_0 = 0.7006$, and $m_0 = 0.0111$.

In $f_2(\nu)$ and $f_3(\nu)$, the rotational temperature $\hat{T} \equiv I < (w - \omega)^2$ appears as $\hat{T}/T$, where $w$ is the particle angular velocity and $\omega = < w >$. In the kinetic theory, $\omega$ is simply assumed to be $\langle \nabla \times v \rangle \sigma /2$, which holds except for the region near the bottom boundary. $\hat{T}/T$ becomes constant in the kinetic theory [13]; the value should be 1 for our parameters, but is not in the simulations. This should be mainly due to the Coulomb friction, which has strong effects on particle rotations. In Fig. 1(b), $\hat{T}$'s are plotted by marks along with $T$'s (lines): $\hat{T}$'s are divided by factors that give the best fits of $\hat{T}$'s with $T$'s. We see $\hat{T}$'s fit with $T$'s in the bulk region with the factor around 0.5, but the ratio depends on $\theta$. In the following, we try both $\hat{T}/T = 1$ and the values obtained from the simulations for $\hat{T}/T$ in $f_2(\nu)$ and $f_3(\nu)$.

First, we examine Eqs. (9) and (10). Figure 2 shows the simulation data of $N/T$ (a) and $S/(\sqrt{T} T^3)$ (b) against $\nu$ by marks. The data from the bottom layers ($y \leq 10$) are distinguished by filled marks because they follow a different trend. The data outside the bottom layers ($y > 10$, open marks) for various $\theta$ collapse onto a single line.

This clearly shows that the expressions (4) and (5) in the kinetic theory are valid outside the bottom layers. The data from the bottom layers show some scatter and different tendency between BC1 and BC2. $f_1(\nu)$ and $f_2(\nu)$ in Table II with $\hat{T}/T = 1$ are shown by the solid lines in Fig. 2(a) and (b), respectively, and they agree with the data. $f_3(\nu)$ depends on $\hat{T}/T$ only weakly and the difference turned out to be negligibly small in the range $0.5 \lesssim \hat{T}/T \lesssim 1$.

Now, we examine $f_3(\nu)$ in Eq. (9). In Fig. 3(a), we plot $S/(\sqrt{T} T^3)$ against $\nu$ from the data; this quantity should give $f_3(\nu)$ from Eqs. (9) and (10). Only the data from the
bulk ($15 < y < 35$) are plotted because Eq. (9) is valid only in the bulk as we have already seen in Fig. 11(c). The lines show $f_3(\nu)$ from kinetic theory with various $\bar{T}/T$. $f_3(\nu)$ depends on $\bar{T}/T$, but the data agrees reasonably well with $f_3(\nu)$ when $\bar{T}/T \sim 0.5$. Note, however, that the singularity at $\nu = \nu_c$ is weaker in the simulation data than in $f_3(\nu)$.

This difference in $f_3(\nu)$ is significant when we see them in the bulk density. In Fig. 8(b), the bulk density $\nu$ is plotted against the inclination angle $\theta$; for the latter, we plot $\sqrt{f_2(\nu)f_3(\nu)/f_1(\nu)}$, which should give $\tan \theta$ from Eq. (10). The bulk density decreases as $\theta$ increases in the simulation, but $\sqrt{f_2(\nu)f_3(\nu)/f_1(\nu)}$ shows opposite tendency; the density increases as $\theta$ increases. This discrepancy comes mainly from the discrepancy in $f_3(\nu)$, more specifically from the fact that the data shows a weaker divergence in $f_3(\nu)$, while the kinetic theory assumes the same singularity in all of $f_1(\nu)$, $f_2(\nu)$, and $f_3(\nu)$ near the random closed packing.

Some parts of the discrepancy might originate from the Coulomb friction, because it is included in the simulation and should have some effects on energy dissipation, but not taken into account in the existing two-dimensional theories. The existing three-dimensional theory [3], however, suggests that the way it changes $f_3(\nu)$ is just to modify the coefficient of $\nu^2g_0(\nu)$ as long as the level of approximation remains the same. Such a change is not enough to make the singularity in $f_3(\nu)$ weaker.

It is a bit puzzling to find clear deviation from the kinetic theory in the energy dissipation while the stresses agree quite well. A possible origin of this is the velocity correlation induced by the inelasticity, which could violate the molecular chaos assumption in the kinetic theory; the decrease of the relative velocity tends to reduce the energy loss per collision. This effect has been noticed in some granular gas simulations, where the energy loss rate is found to be more sensitive to the velocity correlation than stresses [10]. Careful analysis of the velocity correlation in dense flow is awaited.

Before concluding, let us make some comments on the Pouliquen’s flow rule [11]: The flow velocity at the surface scales $u(H)/\sqrt{gH} = bH/H_{\text{stop}}(\theta)$ with $H_{\text{stop}}(\theta)$ being the depth of the flow below which the flow stops for a given inclination angle $\theta$, and a numerical constant $b$ about 0.136. Erta¸s and Halsey [17] argued that the appearance of $H_{\text{stop}}(\theta)$ in the expression of flow velocity for the depth $H$, which can be much larger than $H_{\text{stop}}(\theta)$, implies that the rheology of the dense gravitational flow is not local, and have proposed the eddy mechanism. If the flow is controlled by a non-local mechanism, there is no way that the kinetic theory holds. The Pouliquen flow rule, however, does not necessarily means a non-local mechanism but it simply means the stopping depth is determined by some aspects of the flowing rheology. We do not know yet how it is determined, but the present results suggest that the kinetic theory may well be a good starting point to describe the flow.

In summary, by careful analysis of simulation data, we have demonstrated that the rheology of gravitational dense granular flow can be described within the framework of kinetic theory. Especially, the constitutive relations based on the kinetic theory have been shown to agree quantitatively with the simulations, but there is a slight discrepancy in the energy dissipation. Due to this discrepancy, the kinetic theory fails to give a correct description of the density plateau of the granular flow down a slope.
