SEMIPARAMETRIC BAYESIAN CAUSAL INFECTION
USING GAUSSIAN PROCESS PRIORS

BY KOLYAN RAY* AND Aad van der VAART*

King’s College London and Universiteit Leiden

We develop a semiparametric Bayesian approach for estimating the mean response in a missing data model with binary outcomes and a nonparametrically modelled propensity score. Equivalently we estimate the causal effect of a treatment, correcting nonparametrically for confounding. We show that standard Gaussian process priors satisfy a semiparametric Bernstein–von Mises theorem under smoothness conditions. We further propose a novel propensity score-dependent prior that provides efficient inference under strictly weaker conditions. We also show that it is theoretically preferable to model the covariate distribution with a Dirichlet process or Bayesian bootstrap, rather than modelling the covariate density using a Gaussian process prior.

1. Introduction. In many applications, one wishes to make inference concerning the causal effect of a treatment or condition. Examples include healthcare, online advertising and assessing the impact of public policies amongst many others. The available data are often observational rather than the result of a carefully planned experiment or trial. The notion of “causal” then needs to be carefully defined and the statistical analysis must take into account other possible explanations for the observed outcomes.

A common framework for causal inference is the potential outcome setup [23, 31]. In this framework, every individual possesses two “potential outcomes”, corresponding to the individual’s outcomes with and without treatment. The treatment effect, which we wish to estimate, is thus the difference between these two potential outcomes. Since we only observe one out of each pair of outcomes, and not the corresponding “counterfactual” outcome, we do not directly observe samples of the treatment effect. Because in practice, particularly in observational studies, individuals are assigned treatments in a biased manner, a simple comparison of actual cases (i.e. treated individuals) and controls may be misleading due to selection bias. A typical way

Keywords and phrases: Bernstein–von Mises, Gaussian processes, propensity score-dependent priors, causal inference, Dirichlet process
to overcome this is to gather the values of covariate variables that influence both outcome and treatment assignment (“confounders”) and apply a correction based on the “propensity score”, which is the conditional probability that a subject is treated as a function of the covariate values. Under the assumption that outcome and treatment assignment are independent given the covariates, the causal effect of treatment can be identified from the data. Popular estimation methods include “propensity score matching” [40, 38] and “double robust methods” [31, 37, 39]. In this paper we follow the approach of modelling the propensity score function nonparametrically and posing the estimation of the treatment effect as a problem of estimation of a functional on a semiparametric model [5, 42, 48]. Our methodological novelty is to follow a semiparametric Bayesian approach, putting nonparametric priors on the propensity score and/or on the unknown response function and the covariate distribution, possibly incorporating an initial estimator of the first function.

For notational simplicity we in fact consider the missing data model which is mathematically equivalent to observing one arm of the causal setup. The model is also standard and widely-studied on its own in biostatistical applications, where response variables are frequently missing, and is a template for a number of other models [32, 43]. For a recent review on estimating an average treatment effect over a (sub)population, a problem that has received considerable recent attention in the econometrics, statistics and epidemiology literatures, see Athey et al. [3].

We suppose that we observe $n$ i.i.d. copies $X_1, \ldots, X_n$ of a random variable $X = (Z, R, RY)$, where $R$ and $Y$ take values in the two-point set $\{0, 1\}$ and are conditionally independent given $Z$. We think of $Y$ as the outcome of a treatment and are interested in estimating its expected value $EY$. The problem is that the outcome $Y$ is observed only if the indicator variable $R$ takes value 1, as otherwise the third component of $X$ is equal to 0. Whether the outcome is observed or not may well be dependent on its value, which precludes taking a simple average of the observed outcomes as an estimator for $EY$. The covariate $Z$ is collected to correct for this problem; it is assumed to contain exactly the information that explains why the response $Y$ is not observed except for purely random causes, so that the outcome $Y$ and missingness indicator $R$ are conditionally independent given $Z$, i.e. the outcomes are missing at random (relative to $Z$). The connection to causal inference is that we may think of $Y$ as a “counterfactual” outcome if a treatment were assigned ($R = 1$) and its mean as “half” the treatment effect under the assumption of unconfoundedness.

The model for a single observation $X$ can be described by the distribution
of \( Z \) and the two conditional distributions of \( Y \) and \( R \) given \( Z \). In this paper we model these three components nonparametrically. We investigate a Bayesian approach, putting a nonparametric prior on the three components, in particular Gaussian process and Dirichlet process priors. We then consider the mean response \( EY \) as a functional of the three components and study the induced marginal posterior distribution of \( EY \) from a frequentist perspective. The aim is to derive conditions under which this marginal posterior distribution satisfies a Bernstein–von Mises theorem in the semiparametric sense, thus yielding recovery of the mean response at a \( \sqrt{n} \)-rate and asymptotic efficiency in the semiparametric sense.

In recent years Bayesian approaches have become increasingly popular due to their excellent empirical performance for such problems \([22, 21, 41, 54, 19, 20, 1]\). However, despite their increasing use in practice, there have been few corresponding theoretical results. Indeed, early work on semiparametric Bayesian approaches to this specific missing data problem produced negative results, proving that many common classes of priors, or more generally likelihood-based procedures, produce inconsistent estimates assuming no smoothness on the underlying parameters, see the results and discussion in \([36, 29]\). We attempt to shed light on this apparent gap between the excellent empirical performance observed in practice and the potentially disastrous theoretical performance.

We consider various prior schemes. A straightforward method of prior modelling is to choose the three component parameters a priori independent. We show that under sufficient smoothness assumptions, efficient estimation of \( EY \) using common product priors is indeed possible. These product priors fall within the framework of \([36]\), thereby showing that their negative result is tied to the (almost) full nonparametric model they consider. However, it has also been argued that product priors may not be an optimal choice \([29]\). As the likelihood factorizes over the three component parameters, a product prior will lead to a product posterior, and does not allow the components to share information, which may lead to unnecessarily harsh smoothness requirements on the true parameters. For this reason we also consider dependent priors. In particular, we propose a novel Gaussian process prior that incorporates an estimate of the propensity score function, and show that it performs efficiently under strictly weaker conditions than for standard product priors. Unlike for these latter priors, extra regularity of the binary regression function can compensate for low regularity of the propensity score, that is one direction of so-called “double robustness” \([39, 33]\). A related construction using Bayesian additive regression trees (BART) has been shown to work well empirically \([20]\). It can thus be both practically and
theoretically advantageous to employ propensity score-dependent priors.

For the estimation of \( EY \) at \( \sqrt{n} \)-rate, smoothness of the distribution of the covariate \( Z \) is not needed. Therefore, we also consider modelling this distribution by a Dirichlet process prior. We show that this is theoretically (and computationally) preferable to modelling a density, even when the smoothness of the latter is modelled correctly. Modelling the density, whether using a Gaussian process prior or otherwise, can induce a non-vanishing bias, unless the underlying parameters possess extra smoothness. Heuristic arguments suggest that this effect becomes significantly more pronounced for moderate or high dimensional covariates.

The papers \[32, 35\] consider estimation of the parameter \( EY \) under minimal smoothness conditions on the parameters. By using estimating equations the authors construct estimators that attain an optimal rate of convergence slower than \( \sqrt{n} \) in cases where the component parameters have low smoothness. Furthermore, they construct estimators that attain a \( \sqrt{n} \)-rate under minimal smoothness conditions, less stringent than in earlier literature, using higher order estimating equations. It is unclear whether similar results can be obtained using a Bayesian approach. The constructions in the present paper can be compared to the estimators obtainable for linear (or first order) estimating equations. It remains to be seen whether Bayesian modelling is capable of performing the bias corrections necessary to handle true parameters of low smoothness levels in a similar manner as higher order estimating equations.

For smooth parametric models, the theoretical justification for posterior based inference is provided by the Bernstein–von Mises theorem or property (hereafter BvM). This property says that as the number of observations increases, the posterior distribution is approximately a Gaussian distribution centered at an efficient estimator of the true parameter and with covariance equal to the inverse Fisher information, see Chapter 10 of \[48\]. While such a result does not hold in full generality in infinite dimensions \[13\], semiparametric analogues can establish the BvM property for the marginal posterior of a finite-dimensional parameter in the presence of an infinite-dimensional nuisance parameter \[9, 30, 6, 10\]. In such cases, care is typically required in the choice of prior assigned to the nonparametric part, a feature that manifests itself in particular in our setting through the choice of prior for the distribution of the covariate \( Z \).

While our first main theorem is in the spirit of earlier work, extending this to a structured semiparametric model, our other results are more innovative, in both a modelling and a technical sense. The second theorem uses a combination of a Gaussian and Dirichlet process prior, and the third
theorem concerns a novel prior that incorporates a random perturbation in the least favourable direction, therewith taking away a potential bias.

An important consequence of the semiparametric BvM is that credible sets for the functional are asymptotically confidence regions with the same coverage level. The Bayesian approach thus automatically provides access to uncertainty quantification once one can sample from the posterior distribution. Obtaining confidence statements for average treatment effects is a current area of research and there has been recent progress in this direction, for example using random forests and regression tree methods [2, 53]. Our results show that Bayesian approaches can also yield valid frequentist uncertainty quantification in this setting.

The paper is structured as follows. In Section 2, we provide a review of the model, including the relevant semiparametric theory. Section 3 contains all the results, with discussion in Section 4 and the main proofs in Section 5. Auxiliary results and posterior contraction results are deferred to Sections 6 and 7, respectively.

1.1. Notation. The notation $\lesssim$ denotes inequality up to a constant that is fixed throughout and $\lfloor x \rfloor$ is the largest integer strictly smaller than $x$. The symbol $\Psi$ is used for the logistic function given by $\Psi(x) = 1/(1 + e^{-x})$.

We abbreviate $\int f \, dP$ by $P f$. For probability densities $f$ and $g$ with respect to some dominating measure $\nu$, $h(f; g) = (\int (f^{1/2} - g^{1/2})^2 \, d\nu)^{1/2}$ is the Hellinger distance, $K(f; g)$ is the Kullback-Leibler divergence and $V(f; g) = \int (\log(f/g))^2 \, dF$. We denote by $H_s = H_s([0, 1])$ and $C_s = C_s([0, 1])$ the $L^2$-Sobolev and Hölder spaces respectively. For i.i.d. random variables $X_1, \ldots, X_n$ with common law $P$ the notations $P_n[h] = n^{-1} \sum_{i=1}^n h(X_i)$ and $G_n[h] = \sqrt{n}(P_n - P_h)$ are the empirical measure and process, respectively. The notation $L(Z)$ denotes the law of a random element $Z$. We often drop the index $n$ in the product measure $P^n_\eta$, writing $P_\eta$ instead of $P^n_\eta$, where $\eta_0$ is the true parameter for the data generating distribution. The $\varepsilon$-covering number of a set $\Theta$ for a semimetric $d$, denoted $N(\Theta, d, \varepsilon)$, is the minimal number of $d$-balls of radius $\varepsilon$ needed to cover $\Theta$, and $N^\|\theta(\Theta, d, \varepsilon)$ is the minimal number of brackets of size $\varepsilon$ needed to cover a set of functions $\Theta$.

2. Model details. Recall that we observe i.i.d. copies $X_1, \ldots, X_n$ of a random variable $X = (Z, R, RY)$, where $R$ and $Y$ take values in the two-point set $\{0, 1\}$ and are conditionally independent given $Z$, which itself takes values in a given measurable space $Z$. Denote the full sample by $X^{(n)} = (X_1, \ldots, X_n)$. This model can be parameterized via the marginal density $f$ (with respect to some given measure denoted $dz$) or distribution $F$ of
Z and the conditional probabilities $a(z)^{-1} = P(R = 1|Z = z)$, called the *propensity score*, and $b(z) = P(Y = 1|Z = z)$, the regression of $Y$ on $Z$. The distribution of an observation $X$ is thus fully described by the triple $(a, b, f)$ or $(a, b, F)$.

For prior construction it will be useful to transform the parameters by their natural link functions. Let $\Psi(t) = 1/(1 + e^{-t})$ be the logistic function and consider the reparametrization

$$
\eta^a = \Psi^{-1}(1/a), \quad \eta^b = \Psi^{-1}(b), \quad \eta^f = \log f,
$$

(2.1)

where $\eta^f$ is defined when the density $f$ of $Z$ exists, and set $\eta = (\eta^a, \eta^b, \eta^f)$. In a slight abuse of notation, we also write $\eta = (\eta^a, \eta^b)$ when working only with the distribution function $F$ of $Z$. The parametrization (2.1) is used for our prior construction; we use the two parametrizations interchangeably.

The density $p_{(a,b,f)} = p_\eta$ of $X$ can now be given as

$$
p_\eta(x) = \left(\frac{1}{a(z)}\right)^r \left(1 - \frac{1}{a(z)}\right)^{1-r} b(z)^{ry}(1 - b(z))^{r(1-y)} f(z).
$$

(2.2)

Note that this factorizes over the parameters. If the covariate is not assumed to have a density and $\eta = (\eta^a, \eta^b)$, we use the same notation $p_\eta$, but then the factor $f(z)$ is understood to be 1. Since $p_\eta$ factorizes over the three (or two) parameters, the log-likelihood based on $X^{(n)}$ separates as

$$
\ell_n(\eta) = \sum_{i=1}^n \log p_{(a,b,f)}(X_i) = \ell^a_n(\eta^a) + \ell^b_n(\eta^b) + \ell^f_n(\eta^f),
$$

(2.3)

where each term is the logarithm of the factors involving only $a$ or $b$ or $f$, and $\ell^f_n(\eta^f)$ is understood to be absent when existence of a density $f$ is not assumed. The functional of interest is the *mean response* $E_\eta Y = E_\eta b(Z)$, which can be expressed in the parameters as

$$
\chi(\eta) = \int b dF = \int \Psi(\eta^b)(z) e^{\eta^f(z)} dz,
$$

where the second representation is available if $F$ has a density.

Estimators that are $\sqrt{n}$-consistent and asymptotically efficient for $\chi(\eta)$ have been constructed using various methods, but only if $a$ or $b$ (or both) are sufficiently smooth. In the present context, under the assumption that $a \in C^\alpha$ and $b \in C^\beta$, Robins et al. [35] have constructed estimators that are $\sqrt{n}$-consistent if $(\alpha + \beta)/2 \geq 1/4$. They have also shown that the latter condition is sharp: the minimax rate becomes slower than $1/\sqrt{n}$ when $(\alpha + \beta)/2 < 1/4$. 

The estimators in [35] employ higher order estimating equations to obtain better control of the bias. First-order estimators, based on linear estimators or semiparametric maximum likelihood, have been shown to be \( \sqrt{n} \)-consistent only under the stronger condition

\[
\frac{\alpha}{2\alpha + 1} + \frac{\beta}{2\beta + 1} \geq \frac{1}{2}
\]

see e.g. [37, 39]. In both cases the conditions show a trade-off between the smoothness levels of \( a \) or \( b \): higher \( \alpha \) permits lower \( \beta \) and vice-versa. This trade-off results from the multiplicative form of the bias of linear or higher-order estimators. So-called double robust estimators are able to exploit this structure, and work well if either \( a \) or \( b \) is sufficiently smooth. (More generally, it suffices that the parameters \( a \) and \( b \) can be estimated well enough, where the combined rates are relevant. The inequalities even remain valid with \( \alpha = 0 \) or \( \beta = 0 \) interpreted as the existence of \( \sqrt{n} \)-consistent estimators of \( a \) or \( b \), as would be the case given a correctly specified finite-dimensional model.) We shall henceforth also assume that the parameters \( a \) and \( b \) are contained in Hölder spaces \( C^\alpha \) and \( C^\beta \), respectively.

For estimation of \( EY \) at \( \sqrt{n} \)-rate the covariate density \( f \) need not be smooth, which makes sense intuitively, as the functional can be written as an integral relative to the corresponding distribution \( F \). (Counter to this intuition [34, 35] show this to be false for optimal estimation at slower than \( \sqrt{n} \)-rate.) This may motivate modelling \( F \) nonparametrically, in the Bayesian setting for instance with a Dirichlet process prior.

All these observations are valid only if the estimation problem is not affected by the parameters \( a \), \( b \) or \( f \) taking values on the boundary of their natural ranges. For simplicity we throughout make the following assumption.

**Assumption.** The true functions \( 1/a_0 \) and \( b_0 \) are bounded away from 0 and 1 and \( f_0 \) is bounded away from 0 and \( \infty \).

We finish by reviewing the tangent space and information distance of the model, which is well known to play an important role in semiparametric estimation theory [4, 5, 42]. (See [9] or Chapter 12 of [16] for general reviews in the context of Bayesian estimation.)

With regards to the parametrization (2.1), consider the one-dimensional submodels \( t \mapsto \eta_t \) induced by the paths

\[
\frac{1}{a_t} = \Psi(\eta^a + t\alpha), \quad b_t = \Psi(\eta^b + t\beta), \quad f_t = \exp(\eta^f + t\phi - \log \int e^{\eta^f + t\phi} dz)
\]
for given directions \((\alpha, \beta, \phi)\) with \(\int \phi = 0\), and given “starting” point \(\eta = \eta_0\). Inserting these paths in the likelihood (2.2), and computing the derivative at \(t = 0\) of the log likelihood, we obtain the “score functions”

\[
\begin{align*}
B^a_\eta \alpha(X) &= (R - \frac{1}{a(Z)}) \alpha(Z), \\
B^b_\eta \beta(X) &= R(Y - b(Z)) \beta(Z), \\
B^f_\eta \phi(X) &= \phi(Z).
\end{align*}
\]

The operators \(B^a_\eta, B^b_\eta, B^f_\eta\) are the score operators for the three parameters. The overall score \(B_\eta(\alpha, \beta, \phi)(X)\) when perturbing the three parameters simultaneously is the sum of the three terms in the previous display. The efficient influence function of the functional \(\chi\) at the point \(\eta\) is known to take the form

\[
\tilde{\chi}_\eta(X) = Ra(Z)(Y - b(Z)) + b(Z) - \chi(\eta).
\]

By definition this function has two properties. First the derivative of the functional along a path at \(t = 0\) is the inner product of this function with the score function of the path:

\[
\left. \frac{d}{dt} \right|_{t=0} \chi(p_{\eta t}) = P_{\eta} \tilde{\chi}_\eta(X) B_\eta(\alpha, \beta, \phi)(X)
\]

for every path \(t \mapsto p_{\eta t}\) of the above form. Second the function \(\tilde{\chi}_\eta\) is contained in the closed linear span of the set of all score functions. Indeed, in the present case we have, for all \(x\),

\[
(2.5) \quad \tilde{\chi}_\eta(x) = B_\eta \xi_\eta(x) = B^a_\eta a(x) + B^f_\eta (b - \int b dF)(x),
\]

where \(\xi_\eta\) is the least favourable direction given by

\[
\xi_\eta = (0, \xi^b_\eta, \xi^f_\eta) = (0, a, b - \int b dF).
\]

The function \(\xi_\eta\) is the score function for the submodel \(t \mapsto \eta_t\) corresponding to the perturbations in the directions of \((0, a, b - \int f dz)\) on \((a, b, f)\). The latter submodel is called least favourable, since \(t \mapsto p_{\eta t}\) has the smallest information about the functional of interest at \(t = 0\). According to semiparametric theory (e.g. Chapter 25 of [48]) a sequence of estimators \(\hat{\chi}_n = \hat{\chi}_n(X^{(n)})\) is asymptotically efficient for estimating \(\chi(\eta)\) at the true parameter \(\eta_0\) if and only if

\[
(2.6) \quad \hat{\chi}_n = \chi(\eta_0) + \frac{1}{n} \sum_{i=1}^n \tilde{\chi}_{\eta_0}(X_i) + o_{P_{\eta_0}}(n^{-1/2}).
\]

The sequence \(\sqrt{n}(\hat{\chi}_n - \chi(\eta_0))\) is then asymptotically normal with mean zero and variance \(P_{\eta_0} \hat{\chi}^2_{\eta_0}\), which is least possible in a local minimax sense.
For a direction $v = (\alpha, \beta, \phi)$, the information norm corresponding to the score operator (or LAN norm in the language of [9, 30, 10]) equals
\[
\|v\|_T^2 := \mathbb{E}[(B_T v)^2] = \int \left[ \frac{1}{a} \left(1 - \frac{1}{a}\right) \alpha^2 + \frac{b(1-b)}{a} \beta^2 + (\phi - F \phi)^2 \right] dF
\]
\[=: \|\alpha\|^2_a + \|\beta\|^2_b + \|\phi\|^2_f.
\]

It may be noted that the three components of the score operator are orthogonal, which is a consequence of the factorization of the likelihood. The minimal asymptotic variance $\mathbb{E}_T \tilde{\chi}_T^2$ for estimating $\chi(\eta)$ can be written in terms of the information norm as
\[
\|\xi_T\|_T^2 = \mathbb{E}_T (B_T \xi_T)^2 = \mathbb{E}_T \tilde{\chi}_T^2 = \int a_0 b_0 (1 - b_0) dF_0 + \int b_0^2 dF_0 - \chi(\eta_0)^2.
\]

3. Results. We put a prior probability distribution $\Pi$ on the parameter $\eta = (\eta^a, \eta^b, \eta^f)$ or $(\eta^a, \eta^b, F)$, and consider the posterior distribution $\Pi(\cdot | X^{(n)})$ based on the observation $X^{(n)} = (X_1, \ldots, X_n)$. This induces posterior distributions on all measurable functions of $\eta$, including the functional of interest $\chi(\eta)$.

We write $\mathcal{L}_{\Pi}(\sqrt{n}(\chi(\eta) - \tilde{\chi}_n)|X^{(n)})$ for the marginal posterior distribution of $\sqrt{n}(\chi(\eta) - \tilde{\chi}_n)$, where $\tilde{\chi}_n$ is any random sequence satisfying (2.6). We shall be interested in proving that this distribution asymptotically looks like a centered normal distribution with variance $\|\xi_T\|_T^2$. For a precise statement of this approximation, let $d_{BL}$ be the bounded Lipschitz distance on probability distributions on $\mathbb{R}$ (see Chapter 11 of [11]).

Definition 1. Let $X^{(n)} = (X_1, \ldots, X_n)$ be i.i.d. observations with $X_i = (Z_i, R_i, R_i Y_i)$ arising from the density $p_{\eta_0}$ in (2.2), whose distribution we denote by $P_{\eta_0}$. We say that the posterior satisfies the semiparametric Bernstein–von Mises (BvM) if, for $\tilde{\chi}_n$ satisfying (2.6), as $n \to \infty$,
\[
d_{BL}\left(\mathcal{L}_{\Pi}(\sqrt{n}(\chi(\eta) - \tilde{\chi}_n)|X^{(n)}), N(0, \|\xi_T\|_T^2)\right) \to_{P_{\eta_0}} 0.
\]

In the following subsections we present three results for general priors on the parameters $(a, b, F)$, where the first puts a prior on a density of $F$, the second and third use the Dirichlet process prior, and the third also uses an estimator of the propensity score. While the priors become more specific in going from the first to the third result, the conditions for the BvM theorem become increasingly mild. In Section 3.4 we specialize the three results to Gaussian process priors and obtain more concrete results.
3.1. General prior on $a$, $b$ and $f$. In the first result $\Pi$ is a prior on the triple $(a,b,f)$, or equivalently on the triple $\eta = (\eta^a, \eta^b, \eta^f)$ constructed through the parametrization (2.1). Define $\eta_t(\eta)$ to be a perturbation of $\eta = (\eta^a, \eta^b, \eta^f)$ in the least favourable direction as follows:

\begin{equation}
\eta_t(\eta) = (\eta^a, \eta^b - \frac{t}{\sqrt{n}} \xi^b_{\eta_0}, \eta^f - \frac{t}{\sqrt{n}} \xi^f_{\eta_0} - \log \int e^{\eta^f - t \xi^f_{\eta_0}} / \sqrt{n} d\eta).
\end{equation}

**Theorem 1.** Consider an arbitrary prior $\Pi$ on $\eta = (\eta^a, \eta^b, \eta^f)$. Assume that there exist measurable sets $\mathcal{H}_n$ of functions satisfying

\begin{equation}
\sup_{\eta \in \mathcal{H}_n} \|b - b_0\|_{L^2(F_0)} \to 0,
\end{equation}

\begin{equation}
\sup_{\eta \in \mathcal{H}_n} \|f - f_0\|_1 \to 0,
\end{equation}

\begin{equation}
\sup_{\eta \in \mathcal{H}_n} |G_n[b - b_0]| \to 0,
\end{equation}

and also

\begin{equation}
\sup_{\eta \in \mathcal{H}_n} \left|G_n[b - b_0] \int (b - b_0)(f - f_0) d\eta \right| \to 0.
\end{equation}

If for the path $\eta_t(\eta)$ given in (3.1)

\begin{equation}
\prod_{i=1}^n p_{\eta_t(\eta)}(X_i) d\Pi(\eta) / \prod_{i=1}^n p_\eta(X_i) d\Pi(\eta) \to P_0 1,
\end{equation}

then the posterior distribution of $\chi(\eta)$ satisfies the BvM theorem.

Conditions (3.2)–(3.6) permit to control the remainder terms in an expansion of the likelihood. The first four conditions (3.2)–(3.5) require that the posterior concentrates on shrinking neighbourhoods about the true parameters $b_0$ and $f_0$, though not $a_0$, and hence mostly require consistency, whereas the remaining condition (3.6) also requires a $\sqrt{n}$-rate on a certain bias term.

In Theorems 2-3, which put a Dirichlet prior on the distribution $F$ rather than a prior on the density $f$, condition (3.6) disappears and hence this might be interpreted as involving a bias incurred by possibly putting the wrong prior on $F$. The condition, which seems tied to any prior that directly models $f$, may be satisfied for reasonable priors if both $b$ and $f$ are sufficiently
smooth, but in the situation where $f$ has low regularity, even correctly calibrating the smoothness of the prior on $f$ can perform worse than naively using a Dirichlet process. The condition provides another example where an infinite-dimensional prior can induce an undesired bias [13, 29, 24, 10]. This effect becomes more pronounced as the covariate dimension increases and can be problematic in even moderate dimensions.

The uniformity in $b$ required in (3.5) is unpleasant, as it will typically require that the class of $b$ supported by the posterior distribution is not unduly large. The condition is linked to using the likelihood and similar conditions arise in maximum likelihood based estimation procedures, although (3.5) seems significantly weaker, as the uniformity is required only on the essential support of the posterior distribution, which might be much smaller than the full parameter space. The use of estimating equations can avoid uniformity conditions by sample splitting [35]. In the Bayesian framework one might similarly base posterior distributions of different parameters on given subsamples, but this is unnatural so that we do not pursue this route here, although Theorem 3 below is a step in this direction. A sufficient condition for the uniformity in (3.5) is that the class of functions $b$ in the condition is contained in a fixed $F_0$-Donsker class (see Lemma 3.3.5 of [51]). In particular, it suffices that the posterior concentrates on a bounded set in $H^s$ for $s > 1/2$. While this condition is easy to establish for certain priors, such as uniform wavelet priors [17], for the Gaussian process priors considered here we employ relatively complicated arguments using metric entropy bounds.

Condition (3.7) measures the invariance of the prior for the full nuisance parameter under a shift in the least favourable direction $\xi_{\eta_0}$. It is a structural condition on the combination of prior and model, and if not satisfied may destroy the $\sqrt{n}$-rate in the BvM theorem (see [9] or [16] for further discussion). Although we shall verify the condition for some priors of interest below, this condition may impose smoothness conditions on the parameters, and prevent so-called “double robustness”. We shall remove this condition for special priors in Theorem 3 below.

Since $\xi_{\eta_0} = a_0$, Theorem 1 implicitly requires conditions on $a_0$ through (3.7), even though $a$ does not appear in the functional $\chi(\eta)$. Such conditions become explicit for concrete priors below.

**Remark 1.** If the quotient on the left side of (3.7) is asymptotic to $e^{\mu_n t}(1 + o_P(1))$ for some possibly random sequence of real numbers $\mu_n$, then the assertion of the BvM theorem is still true, but the normal approximation $N(0, \|\xi_{\eta_0}\|_F^2)$ must be replaced by $N(\mu_n, \|\xi_{\eta_0}\|_F^2)$. See [10, 30] for further discussion. The same is true for all other results in the following.
Remark 2. If the supremum in (3.5), or similar variables below, is not measurable, then we interpret this statement in terms of outer probability.

3.2. General prior on \(a\) and \(b\) and Dirichlet process prior on \(F\). Intuitively the estimation problem should not depend too much on properties of the distribution of the covariates, as the latter are fully observed and the functional \(\chi(\eta)\) is an integral relative to the covariate distribution \(F\). For \(\sqrt{n}\)-estimation this intuition appears to be correct, which suggests not to assume existence of the covariate density \(f\), and put a prior directly on the distribution \(F\). In the following theorem we shall see that this will remove condition (3.6).

The standard nonparametric prior on the set of probability distributions on a (Polish) sample space is the Dirichlet process prior \([12]\). This distribution is characterized by a base measure \(\nu\), which can be any finite measure on the sample space. It is well known that in the model consisting of sampling \(F\) from the Dirichlet process prior and next sampling observations \(Z_1, \ldots, Z_n\) from \(F\), the posterior distribution of \(F\) given \(Z_1, \ldots, Z_n\) is again a Dirichlet process with updated base measure \(\nu + nF_n\), where \(F_n\) is the empirical distribution of \(Z_1, \ldots, Z_n\). (For full definitions and properties, see the review in Chapter 4 of \([16]\).)

We utilize the Dirichlet process prior on \(F\) together with an independent prior on the remaining parameters \((a, b)\), constructed using the logistic link function, as previously. The Dirichlet process prior does not give probability one to a dominated set of measures \(F\), which means that the posterior distribution of \((a, b, F)\) cannot be derived using Bayes’s formula. However, we can obtain a representation as follows. The parameters and the data are generated through the hierarchical scheme:

- \(F \sim DP(\nu)\) independent from \(\eta = (a, b) \sim \Pi\).
- Given \((F, a, b)\) the covariates \(Z_1, \ldots, Z_n\) are i.i.d. \(F\).
- Given \((F, a, b, Z_1, \ldots, Z_n)\) the pairs \((R_i, Y_i)\) are independent from products of binomial distributions with success probabilities \(1/a(Z_i)\) and \(b(Z_i)\).
- The observations are \(X^{(n)} = (X_1, \ldots, X_n)\) with \(X_i = (Z_i, R_i, R_iY_i)\).

From this scheme it follows that \(F\) and \((R^{(n)}, Y^{(n)})\) are independent given \((Z^{(n)}, a, b)\), and also that \(F\) and \((a, b)\) are conditionally independent given \(X^{(n)}\). We can then conclude that the posterior distribution of \(F\) given \(X^{(n)}\) is the same as the posterior distribution of \(F\) given \(Z^{(n)}\), which is the \(DP(\nu + nF_n)\) distribution. Furthermore, the posterior distribution of \((a, b)\) given \((F, X^{(n)})\) can be derived by Bayes’s rule from the binomial likelihood of \((R^{(n)}, R^{(n)}Y^{(n)})\) given \(Z^{(n)}\), which is dominated. Thus the posterior dis-
Bayesian Causal Inference

The functional of interest \( \eta \) is given by

\[
\Pi((a,b) \in A, F \in B|X^{(n)}) = \int_B \int_A \prod_{i=1}^n p(a,b)(X_i) \, d\Pi(a,b) \, d\Pi(F|Z^{(n)}),
\]

where \( p(a,b) \) is the conditional density of \((R,RY)\) given \( Z \), given by (2.2) with \( f \) deleted or taken equal to 1, and \( \Pi(F \in \cdot | Z^{(n)}) \) is the \( DP(\nu + nF_n) \)-distribution. This formula remains valid if \( \nu = 0 \), which yields the Bayesian bootstrap, see Chapter 4.7 of [16]. This choice is also covered in the following theorem. We suspect that the theorem extends to other exchangeable bootstrap processes, as considered in [27] (see [47], Section 3.7.2).

Define \( \eta_t(\eta) \) to be a perturbation of \( \eta = (\eta^a, \eta^b) \) in the least favourable direction, restricted to the components corresponding to \( a \) and \( b \):

\[
\eta_t(\eta) = (\eta^a, \eta^b - \frac{t}{\sqrt{n}} \xi^b_{\eta_0}).
\]

**Theorem 2.** Consider a prior \( \Pi \) consisting of an arbitrary prior on \( \eta = (\eta^a, \eta^b) \) and an independent Dirichlet prior on \( F \). Assume that there exist measurable sets \( H_{n,a,b} \) of functions \( \eta = (\eta^a, \eta^b) \) satisfying

\[
\Pi(\eta \in H_{n,a,b}|X^{(n)}) \to F_0 1,
\]

\[
\sup_{b=\Psi(\eta^b); \eta \in H_{n,a,b}} \|b - b_0\|_{L^2(F_0)} \to 0,
\]

\[
\sup_{b=\Psi(\eta^b); \eta \in H_{n,a,b}} |G_n[b - b_0]| \to F_0 0.
\]

If for the path \( \eta_t(\eta) \) in (3.9),

\[
\int_{H_{n,a,b}} \prod_{i=1}^n p_{\eta_t(\eta)}(X_i) \, d\Pi(\eta) \int_{H_{n,a,b}} \prod_{i=1}^n p_{\eta}(X_i) \, d\Pi(\eta) \to F_0 1,
\]

then the posterior distribution (3.8) satisfies the BvM theorem.

Formula (3.8) shows that a draw from the posterior distribution of the functional of interest \( \chi(\eta) = \int b \, dF \) is obtained by independently drawing \( b \) from its posterior distribution and \( F \) from the \( DP(\nu + nF_n) \)-distribution, and next forming the integral \( \int b \, dF \). The posterior distribution of \( b \) is constructed from the conditional likelihood of \((R^{(n)}, R^{(n)}Y^{(n)})\) given \( Z^{(n)} \) without the interception of \( F \) or its prior distribution. Instead of a Bayesian-motivated or bootstrap type choice for \( F \), which requires randomization
given $Z^{(n)}$, one could also directly plug in an estimator of $F$ based on $Z^{(n)}$ and randomize only $b$ from its posterior distribution. The empirical distribution $F_n$ is an obvious choice. The proof of Theorem 2 suggests that, under the conditions of the theorem,

$$d_{BL}(LL_n(\sqrt{n}(\eta-\hat{\eta})|X^{(n)}), N(0, \|\xi_{b0}\|_{b0}^2)) \to 0$$

in $P^{a0}$-probability. Compared to the BvM theorem this suggests a normal approximation with the same centering, but a smaller variance, since the variance in the BvM theorem is the sum $\|\xi_{b0}\|_{b0}^2 + \|\xi_{f0}\|_{f0}^2$. The lack of posterior randomization of $F$ thus results in an underestimation of the asymptotic variance. Using credible sets resulting from this ‘posterior’ would give overconfident (wrong) uncertainty quantification. Since our focus is on the Bayesian approach, we do not purse such generalizations further.

3.3. Propensity score-dependent priors. To reduce unnecessary regularity conditions, it can be useful to use a preliminary estimate $\hat{a}_n$ of the inverse propensity score [35, 37, 39]. Such an approach has recently also been advocated in the Bayesian literature in a related setting, where [20] plug an estimator of the propensity score into a Bayesian additive regression tree (BART) prior used in [22] and achieve improved empirical performance. In this section we employ preliminary estimators $\hat{a}_n$ to augment the prior on $b$ with the aim of weakening the conditions required for a semiparametric BvM.

Suppose we have a sequence of estimators $\hat{a}_n$ of the inverse propensity score satisfying

$$\|\hat{a}_n - a_0\|_{L^2(P_0)} = O_P(\rho_n)$$

for some sequence $\rho_n \to 0$. Since the propensity score is just a (binary) regression function of $R$ onto $Z$, standard (adaptive) smoothing estimators satisfy this condition with rate $\rho_n = n^{-\frac{\alpha}{2\alpha+4}}$ if the propensity score is assumed to be contained in $C^\alpha$, which is the minimax rate over this space (note that $\hat{a}_n - a_0 = \hat{a}_n a_0 (1/a_0 - 1/\hat{a}_n)$ will attain at least the rate of an estimator of the propensity score $1/a_0$ itself). Consider the following prior on $b$:

$$b(z) = \Psi(W^b_z + \lambda \hat{a}_n(z)),$$

where $W^b$ is a continuous stochastic process independent of the random variable $\lambda$, which follows a prior $N(0, \sigma_n^2)$ distribution for given variance $\sigma_n^2$ (potentially varying with $n$, but fixed is allowed). We assume that $\hat{a}_n$ is based
on observations that are independent of $X_1, \ldots, X_n$, the observations used in the likelihood to obtain the posterior. Otherwise, the prior (3.15) becomes data-dependent, which significantly complicates the technical analysis.

To improve clarity we only consider the combination of (3.15) with assigning $F$ a Dirichlet process prior, but all results below can be extended to the case where $f$ is assigned an independent prior of the form (3.23) upon making the same extra assumptions as was done previously to ensure the prior does not induce any additional bias through the prior shift condition (3.7).

We may think of $\hat{a}_n$ as a degenerate prior on $a$, and then by the factorization of the likelihood the part of the likelihood involving $a$ cancels from the posterior distribution (3.8) if marginalized to $(b, F)$ (and hence $\chi(\eta)$). Of course the same will happen if we assign an independent prior to $a$. In both cases it is unnecessary to further discuss a prior on $a$.

**Theorem 3.** Given independent estimators $\hat{a}_n$ satisfying (3.14) and $\|\hat{a}_n\|_\infty = O_{P_0}(1)$ consider the prior (3.15) for $b$ with the stochastic process $W^b$ and random variable $\lambda \sim N(0, \sigma_n^2)$ independent, and assign $F$ an independent Dirichlet process prior. Assume that there exist measurable sets $H^b_n$ of functions satisfying, for every $t \in \mathbb{R}$ and some numbers $u_n, \varepsilon_n^b, \rightarrow 0$,

\begin{align}
\Pi(\lambda : |\lambda| \leq u_n \sigma_n^2 \sqrt{n} |X(n)|) \rightarrow P_0 1, \\
\Pi((w, \lambda) : w + (\lambda + tn^{-1/2})\hat{a}_n \in H^b_n|X(n)) \rightarrow P_0 1, \\
\sup_{b=\Psi(\eta^b) : \eta^b \in H^b_n} \|b - b_0\|_{L^2(F_0)} \leq \varepsilon_n^b, \\
\sup_{b=\Psi(\eta^b) : \eta^b \in H^b_n} |\mathcal{G}_n[b - b_0]| \rightarrow P_0 0.
\end{align}

If $n\sigma_n^2 \rightarrow \infty$ and $\sqrt{n} \rho_n \varepsilon_n^b \rightarrow 0$, then the posterior distribution satisfies the semiparametric BvM theorem.

The advantage of this theorem over the preceding theorems is that (3.13) does not appear in its conditions. (The theorem adds (3.16) and (3.17), but these are relatively mild.) As noted above, condition (3.13) requires a certain invariance of the prior of $b$ in the the least favourable direction $\xi^b_{\tau_0} = a_0$, and typically leads to smoothness requirements on $a$. In contrast we show below that Theorem 3 can yield the BvM theorem for propensity scores $1/a$ of arbitrarily low regularity. Thus the theorem is able to achieve what could be named single robustness. Whether “double robustness”, the ability of also handling response functions $b$ of arbitrarily low smoothness, is also achieved remains unclear. Specifically, we have not been able to verify condition (3.19).
for reasonable priors, without assuming that the smoothness of $b$ is above the usual threshold $(d/2$ in $d$ dimensions).

The single robustness is achieved by perturbing the prior process for $b$ in the least favourable direction using the auxiliary variable $\lambda$. Since the least favourable direction $a_0$ is unknown, this is replaced with an estimate $\hat{a}_n$.

Condition (3.16) puts a lower bound on the variability of the perturbation, i.e. on the standard deviation $\sigma_n$ of $\lambda$. An easy method to ascertain this condition is to show that the prior mass of the set $\lambda$ in the left side is exponentially small and next invoke Lemma 3. Specifically, by the univariate Gaussian tail bound the prior mass of $\{\lambda : |\lambda| > u_n \sigma_n \sqrt{n}\}$ is bounded above by $e^{-u_n^2 \sigma_n^2}. If$ the Kullback-Leibler neighbourhood in Lemma 3 has prior probability at least $e^{-n(\varepsilon_n^b)^2}$, then the lemma gives the sufficient condition $u_n^2 \sigma_n^2 \gtrsim (\varepsilon_n^b)^2$ for (3.16), i.e. $\sigma_n \gg \varepsilon_n^b$.

3.4. Gaussian process priors. In this section we specialize Theorems 1–3 to Gaussian process and/or Dirichlet process priors. In all cases the priors on the three parameters $a$, $b$ and $f$ or $F$ are independent. Since $a$ does not appear in $\chi(\eta)$ and the likelihood (2.2) factorizes over $a$, $b$ and $f$, the $a$ terms cancel from the marginal posterior distribution of $\chi(\eta)$. Thus the prior on $a$ is irrelevant, and it is not necessary to consider it.

For simplicity we take the covariate space to be the unit interval $Z = [0, 1]$. We denote a Gaussian process linked to a prior for $b$ or $f$ by $W^i$, where $i \in \{b, f\}$.

There are a great variety of Gaussian process priors, and their success in nonparametric estimation is known to depend on their sample smoothness, as measured through their small ball probability (see [49, 44, 45, 46]). We both derive propositions on general Gaussian processes and consider the special example of the Riemann-Liouville process released at zero. For given $\bar{\beta} > 0$, this is defined by

$$R^\beta_t = \sum_{k=0}^{[\beta]+1} g_k t^k + \int_0^t (t - s)^{\bar{\beta} - 1/2} dB_s, \quad t \in [0, 1],$$

where the $(g_k)$ are i.i.d. standard normal random variables and $B$ is an independent Brownian motion. This process is appropriate for nonparametric modelling of $C^{\bar{\beta}}$-functions. We shall investigate the effect of the smoothness parameter $\bar{\beta}$ on the BvM theorem.

A Gaussian process $W^i$ can typically be viewed as a Borel measurable map in some separable Banach space $(W, \|\cdot\|_W)$, often $C[0,1]$ equipped with the uniform norm $\|\cdot\|_\infty$. Its covariance function determines a so-called reproducing kernel Hilbert space (RKHS) $(H^i, \|\cdot\|_{H^i})$. (For details, see [50].)
The “concentration function” of the \( W \)-valued process \( W^i \) at \( \eta^i_0 \in W \) is defined as, for \( \varepsilon > 0 \),

\[
\phi_{i,\eta^i_0}(\varepsilon) = \inf_{h \in \mathbb{H}^i \mid \|h - \eta^i_0\|_W < \varepsilon} \|h\|^2_{\mathbb{H}^i} - \log P(\|W^i\|_W < \varepsilon).
\]

For standard statistical models, posterior contraction rates for Gaussian process priors are linked to the solution of the equation (see [49])

\[
(3.21) \quad \phi_{i,\eta^i_0}(\varepsilon_n) \sim n(\varepsilon_n)^2.
\]

We in general write \( \varepsilon^i_n, i \in \{b, f\} \), for the respective contraction rates for the two parameters \((b, f)\). Contraction is relative to a distance that depends on the model and the norm of \( W \) (see Section 7).

First consider equipping both \( \eta^b \) and \( \eta^f \) with Gaussian process priors. Given independent mean-zero Gaussian processes \( W^b = (W^b_z : z \in [0, 1]) \) and \( W^f = (W^f_z : z \in [0, 1]) \), consider the prior

\[
(3.22) \quad b(z) = \Psi(W^b_z),
\]

\[
(3.23) \quad f(z) = \frac{e^{W^f_z}}{\int_0^1 e^{W^f_u} du}.
\]

**Proposition 1.** Consider the product Gaussian process prior (3.22)-(3.23) on \( b \) and \( f \). Let \( \varepsilon^b_n \to 0 \) satisfy (3.21) with respect to the norm \( \| \cdot \|_\infty \) for \( i = b \) and suppose \( \sqrt{n}\varepsilon^b_n\varepsilon^f_n \to 0 \), where \( \varepsilon^f_n \to 0 \) is a rate of contraction in \( L^2 \) of the posterior distribution of \( f \) to \( f_0 \). Suppose there exist sequences \( \xi^b_n, \xi^f_n \in \mathbb{H}^b \times \mathbb{H}^f \) and \( \zeta^b_n, \zeta^f_n \to 0 \) such that

\[
(3.24) \quad \|\xi^i_n - \xi^i_{\eta^i_0}\|_\infty \leq \zeta^i_n, \quad \|\xi^i_n\|_{\mathbb{H}^i} \leq \sqrt{n}\zeta^i_n, \quad \sqrt{n}\varepsilon^i_n \zeta^i_n \to 0, \quad i \in \{b, f\}.
\]

Suppose further that there exist measurable sets \( \mathcal{H}^b_n \) of functions such that \( \Pi(\eta^b \in (\mathcal{H}^b_n - t\xi^b_n/\sqrt{n})|X^{(n)}) \to P_1 \) for every \( t \in \mathbb{R} \) and (3.19) holds. Then the posterior distribution satisfies the semiparametric BvM theorem.

The solution to (3.21) for \( i = f \) yields a contraction rate for \( f \) in the Hellinger distance [49], but the proposition requires a rate in \( L^2 \). If the prior is supported on a fixed \( L^\infty \)-ball, for instance suitably conditioned Gaussian process priors [17], then the Hellinger rate automatically implies the same rate in \( L^2 \)-distance. For unbounded priors, such as Riemann-Liouville processes, one may often use regularity properties of the Gaussian process to bootstrap a Hellinger rate to one in \( L^2 \), and thus take \( \varepsilon^b_n \) to be a solution to (3.21) with \( i = f \) (see Proposition 5 of [10]).

For the concrete case of the Riemann-Liouville process the preceding proposition implies the following.
Corollary 1. Suppose \( a_0 \in C^\alpha, \; b_0 \in C^\beta, \; f_0 \in C^\gamma \) and consider the prior \((3.22)-(3.23)\) with Riemann-Liouville processes \((3.20)\) with parameters \(\tilde{\beta}\) and \(\tilde{\gamma}\) on \(b\) and \(f\) respectively. If \(\alpha, \beta > 1/2, \gamma > 0, 1/2 < \tilde{\beta} < \alpha + \beta - 1/2, 0 < \tilde{\gamma} < \gamma + \beta - 1/2\) and

\[
(3.25) \quad \frac{\beta \wedge \tilde{\beta}}{2\beta + 1} + \frac{\gamma \wedge \tilde{\gamma}}{2\gamma + 1} > \frac{1}{2},
\]

then the posterior distribution satisfies the semiparametric BvM theorem.

The corollary suggests that modelling the density \(f\) using a Gaussian process prior works well under smoothness conditions on \(f\). If \(\bar{\beta} = \beta\) and \(\bar{\gamma} = \gamma\), so that the prior processes select the correct smoothness, the conditions in the corollary reduce to \(\alpha, \beta > 1/2\) and \(\beta/(2\beta + 1) + \gamma/(2\gamma + 1) > 1/2\). This requires smoothness \(\gamma > 1/(4\beta)\) for \(f\), although it is known that no smoothness of \(f\) is required to estimate the functional \(\chi(\eta)\). For \(d\)-dimensional covariates, the equivalent condition is \(\gamma > d^2/(4\beta)\), which is problematic for even moderate dimensions. The prior for the parameter \(f\) can therefore have a significant impact and must be carefully chosen.

This can be avoided by modelling not the density \(f\), but the corresponding distribution \(F\), with a Dirichlet process prior.

Proposition 2. Consider the Gaussian process prior \((3.22)\) on \(b\) and an independent Dirichlet process prior on \(F\). Let \(\varepsilon_n^b \to 0\) satisfy \((3.21)\) with respect to the norm \(\|\cdot\|_\infty\). Suppose there exist sequences \(\xi_n \in \mathbb{H}^b\) and \(\zeta_n^b \to 0\) such that

\[
\|\xi_n^b - \xi_n^b\|_\infty \leq \xi_n^b, \quad \|\xi_n^b\|_{\mathbb{H}^b} \leq \sqrt{n}\zeta_n^b, \quad \sqrt{n}\varepsilon_n^b \xi_n^b \to 0.
\]

Suppose further that there exist measurable sets \(\mathcal{H}_n^b\) of functions \(\eta_n^b\) such that \(\Pi(\eta_n^b \in (\mathcal{H}_n^b - t\xi_n^b)/\sqrt{n})|X^{(n)}) \to P_0 1\) for every \(t \in \mathbb{R}\) and \((3.19)\) holds. Then the posterior distribution satisfies the semiparametric BvM theorem.

Corollary 2. Suppose \(a_0 \in C^\alpha, b_0 \in C^\beta,\) and consider the prior \((3.22)\) with Riemann-Liouville process \((3.20)\) with parameter \(\tilde{\beta}\) on \(b\) combined with an independent Dirichlet process prior on \(F\). If \(\alpha, \beta > 1/2\) and \(1/2 < \tilde{\beta} < \alpha + \beta - 1/2\), then the posterior distribution satisfies the semiparametric BvM theorem.

For \(\alpha, \beta > 1/2\), the parameter \(\tilde{\beta}\) can always be chosen to satisfy the remaining condition in the corollary. The values \(\alpha, \beta > 1/2\) are one particular pair satisfying \((2.4)\). However, when using product priors, it does not seem
possible to use extra smoothness in one parameter to offset low regularity in the other, as in (2.4).

To remedy this we consider the propensity-score dependent prior (3.15) with $W^b$ equal to the Riemann-Liouville process.

**Corollary 3.** Suppose $a_0 \in C^\alpha$ and $b_0 \in C^\beta$. Let $\hat{a}_n$ be an independent estimator satisfying $\|\hat{a}_n\|_\infty = O_P(n^{1/2})$ and (3.14) for some $\rho_n \to 0$. Consider the prior (3.15) for $b$, where $W^b$ is the Riemann-Liouville process (3.20) with parameter $\bar{\beta}$ and $(n/\log n)^{-\beta/(2\beta+1)} \ll \sigma_n \lesssim 1$. Let $F$ have an independent Dirichlet process prior. If $\beta \wedge \bar{\beta} > 1/2$ and $\sqrt{n}\rho_n(n/\log n)^{-\beta/(2\beta+1)} \to 0$, then the posterior distribution satisfies the semiparametric BvM.

If $\bar{\beta} = \beta$ and $\rho_n = (\log n)^{\alpha}n^{-\alpha/(2\alpha+1)}$ is the minimax rate of estimation, possibly up to a logarithmic factor, then the above conditions reduce to $\beta > 1/2$ and (2.4). If $\beta$ is near the lower limit 1/2, then the latter condition requires that $\alpha$ be bigger than nearly 1/2 as well, but if $\beta$ is large, then the latter condition will be satisfied for $\alpha$ close to zero. Thus the estimation method is able to exploit extra smoothness in $b_0$ to offset lower regularity in $a_0$, in particular if $0 < \alpha \leq 1/2$, unlike the standard product Gaussian process priors, where we required both $\alpha, \beta > 1/2$. Because it is still needed that $\beta > 1/2$ the preceding corollary does not give full “double robustness”, in also taking advantage of extra regularity in $a_0$ if $0 < \beta \leq 1/2$. The technical reason is requirement (3.5), which is present in all our theorems, and used in the proofs to establish the LAN expansion of the model. Whether this is a fundamental limitation of the Bayesian approach or a purely technical artefact is unclear.

**4. Discussion.** A key technical difficulty for establishing semiparametric BvM results is controlling the ratio (3.7) or (3.13). While one can use the Cameron-Martin theorem for Gaussian priors, such results are typically more involved outside the Gaussian setting. The hyper parameter $\lambda$ in the prior (3.15) removes this obstacle, allowing results for a much wider class of priors. For instance, one may select $W^b$ in (3.15) to be a truncated prior or sieve prior, without having to treat (3.13) directly for those priors.

Such a prior construction generalizes to other models and functionals. Consider a model $P = (P_\eta : \eta \in \mathcal{H})$ and a parameter $\chi(\eta)$. For a prior of the form $\eta = W + \lambda \hat{\xi}_n$, where $W$ is a continuous stochastic process, $\lambda \sim N(0, \sigma^2_n)$ and $\hat{\xi}_n$ is an estimate of the least favourable direction $\xi_{\eta_0}$ of $\chi$ at $\eta_0$ in the model $P$, similar results to the above should hold. We emphasize, however, that such a prior is designed for semiparametric estimation of the specific
functional χ and will not perform any better for any other functional. It is thus suitable for estimating a functional of interest in the presence of a high or infinite-dimensional nuisance parameter that can have a significant impact, as in the model we study here.

5. Proofs.

5.1. Proof of Theorem 1: density prior.

Proof of Theorem 1. The total variation distance between the posterior distributions based on the prior Π and the prior Π_n(·) := Π(· ∩ ℋ_n)/Π(ℋ_n), which is Π conditioned to ℋ_n, is bounded above by 2Π(ℋ_n^c|X(n)) (e.g. page 142 of [48]). Since this tends to zero in probability by assumption and the total variation topology is stronger than the weak topology, it suffices to show the desired result for the conditioned prior Π_n instead of Π.

Let \( \hat{\chi}_n = \chi(\eta_0) + \mathbb{P}_n \chi_{\eta_0} \), so that it satisfies (2.6) with the remainder term identically zero. The posterior Laplace transform of the variable \( \sqrt{n}(\chi(\eta) - \hat{\chi}_n) \) is given by, for any \( t \in \mathbb{R} \),

\[
I_n(t) = \mathbb{E}^{\Pi_n}[e^{t\sqrt{n}(\chi(\eta) - \hat{\chi}_n)}|X^{(n)}]
\]

\[
= \frac{\int_{\mathcal{H}_n} e^{t\sqrt{n}(bf-b_0f_0)dz - tf_n(\eta) + tf_n(\eta_0) - tf_n(\eta_0)} e^{t\ell_n(\eta)} d\Pi(\eta)}{\int_{\mathcal{H}_n} e^{t\ell_n(\eta)} d\Pi(\eta)},
\]

for any \( \eta \), in particular for the path \( \eta_t = \eta_t(\eta) \) defined in (3.1). We shall show that \( I_n(t) \) tends in probability to \( \exp(t^2\|\xi_{\eta_0}\|^2/\eta_0) \), which is the Laplace transform of a \( N(0, \|\xi_{\eta_0}\|^2) \) distribution, for every \( t \in \mathbb{R} \). Since convergence of Laplace transforms in probability implies convergence in distribution in probability (see Lemma 11), this would complete the proof.

In view of assumption (3.7) it certainly suffices to show that the exponent of the first exponential in the numerator of (5.1) tends to \( t^2\|\xi_{\eta_0}\|^2/\eta_0 \) in probability, uniformly in \( \eta \in \mathcal{H}_n \). This entails an expansion of the likelihood \( \ell_n(\eta) - \ell_n(\eta_t) \) along the submodel \( \eta_t \). This submodel consists of perturbations in the directions of \( b \) and \( f \). Since the likelihood factorizes in these parameters, whence the log likelihood is additive, the expansion can be performed separately in the perturbations in the two parameters and the results added. In a slight abuse of notation, we write \( \eta_t^b = (\eta^a, \eta^b_0, \eta^b_t) \) and \( \eta_t^f = (\eta^a, \eta^f_0, \eta^f_t) \) for the path (3.1) with the perturbations with \( f \) and \( b \) held fixed, respectively, and leave off the argument \( \eta \) of \( \eta_t = \eta_t(\eta) \). For \( \chi^b_{\eta} = B^b_{\eta}b \) and \( \chi^f_{\eta} = B^f_{\eta}(b - \chi(\eta)) = b - \chi(\eta) \) the components of the efficient influence function in the \( b \) and \( f \) directions, respectively (see (2.5)), we shall show
that, uniformly in \( \eta \in \mathcal{H}_n \),

\[
\ell_n^b(\eta) - \ell_n^b(\eta^b) = tG_n[\tilde{\chi}_n^b] + t\sqrt{n} \int (b_0 - b) f_0 \, dz + \frac{t^2}{2} \| \xi_{\eta^b}^b \|_{b_0}^2 + o_P(1),
\]

(5.2)

\[
\ell_n^f(\eta) - \ell_n^f(\eta^f) = tG_n[\tilde{\chi}_n^f] + t\sqrt{n} \int b_0(f_0 - f) \, dz + \frac{t^2}{2} \| \xi_{\eta^f}^f \|_{f_0}^2 + o_P(1).
\]

(5.3)

Adding these results yields

\[
t\sqrt{n} \int (b - b_0)(f - f_0) \, dz - tG_n[\eta] + \ell_n(\eta) - \ell_n(\eta^b)
\]

\[
= t\sqrt{n} \int (b - b_0)(f - f_0) \, dz + \frac{t^2}{2} \| \xi_{\eta^b}^b \|_{b_0}^2 + o_P(1).
\]

By assumption (3.6) the first term on the right side tends to zero uniformly over \( \mathcal{H}_n \). The left side is the exponent in the right of (5.1) and the proof is complete. We finish by proving (5.2) and (5.3).

b term (5.2): We can decompose

\[
\ell_n^b(\eta) - \ell_n^b(\eta^b) = tG_n[\tilde{\chi}_n^b] + \sqrt{n}G_n[\log p_{\eta^b} - \log p_{\eta^b}] + nP_{\eta^b}[\log p_{\eta^b} - \log p_{\eta^b}].
\]

(5.4)

We shall show that the second term on the right tends to zero in probability, while the third term tends to the quadratic \( t^2a_0^2/2 \), where \( a_0 = \xi_{\eta^b}^b \).

The definition \( \eta_u := (\eta^a, \eta_u^b, \eta_u^f) \) with \( \eta_u^b = \eta^b - tu\xi_{\eta^b}^b / \sqrt{n} \), for \( u \in [0, 1] \), gives a path from \( \eta_{u=0} = \eta \) (not \( \eta^b \)) to \( \eta_{u=1} = \eta_{u=1}^b \), so that \( \log p_{\eta^b} - \log p_{\eta^b} = g(0) - g(1) \), for \( g(u) = \log p_{\eta^b} \). We shall replace this difference in both terms on the right of (5.4) by the Taylor expansion \( g(0) - g(1) = -g'(0)\frac{g''(0)}{2} - \theta \), where \( \theta \leq \| g'' \|_\infty \). The expansion will be uniform in \( \eta \in \mathcal{H}_n \), although the dependence of \( g \) and \( \theta \) on \( \eta \) is not indicated in the notation.

By explicit calculations the derivatives of \( g \) can be seen to be

\[
g'(u) = -\frac{t}{\sqrt{n}} B_{\eta^b} a_0 = -\frac{t}{\sqrt{n}} r(y - \Psi(\eta_u^b)) a_0,
\]

\[
g''(u) = -\frac{t^2}{n} r \Psi'(\eta_u^b) a_0^2, \quad g'''(u) = \frac{t^3}{n^{3/2}} r \Psi''(\eta_u^b) a_0^3,
\]

where we have omitted the function arguments \( (r, y, z) \). Since \( |\theta| \leq \| g'' \|_\infty \lesssim n^{-3/2} \) it follows that both \( \sqrt{n}G_n[\eta] \) and \( nP_{\eta^b} \) tend to zero in probability, uniformly in \( \eta \in \mathcal{H}_n \). Since \( B_{\eta^b} a_0 = \tilde{\chi}_n^b \),

\[
g'(0) = -\frac{t}{\sqrt{n}} B_{\eta^b} a_0 = -\frac{t}{\sqrt{n}} \tilde{\chi}_n^b + \frac{t}{\sqrt{n}} r(b - b_0) a_0,
\]

\[
g''(0) = -\frac{t^2}{n} r \Psi'(\eta^b) a_0^2 = -\frac{t^2}{n} r \Psi'(\eta^b) a_0^2 - \frac{t^2}{n} r(b(1 - b) - b_0(1 - b_0)) a_0^2
\]
for $b = \Psi(\eta^b)$, since $\Psi' = \Psi(1 - \Psi)$.

By assumption (3.5) and Lemma 8 we have that $G_n^b[r(b - b_0)a_0] \to 0$, in probability, uniformly in $\{b = \Psi(\eta^b) : \eta \in \mathcal{H}_n\}$, whence $\sqrt{n}G_ng'(0) = -tG_n^b[\chi^{b_0}] + o_P(1)$, uniformly in $\eta \in \mathcal{H}_n$. By the same assumption and lemma, $G_n^b[r(b - b_0)(b_0 - b_0)a_0^2] \to 0$ in probability, whence $\sqrt{n}G_ng''(0) = O_P(n^{-1/2}) \to 0$ in probability. We conclude that the second term on the right in (5.4) tends to zero in probability, uniformly in $\eta \in \mathcal{H}_n$.

Since $\Psi'(\eta^b_0) = 0(b_1 - b_0)$ and $\int b_0(1 - b_0)a_0 dF_0 = \|\xi_{\eta_0}^b\|^2_{a_0}$,

$$-nP_{\eta_0}g'(0) = t\sqrt{n} \int (b_0 - b) dF_0,$$

$$-nP_{\eta_0}g''(0) - t^2\|\xi_{\eta_0}^b\|^2_{b_0} = t^2P_{\eta_0} \int (b(1 - b) - b_0(1 - b_0))a_0^2$$

$$\lesssim P_{\eta_0} \|b - b_0\|_{L^1(F_0)} ||a_0||_{\infty}.$$ 

Therefore $nP_{\eta_0}[-g'(0) - g''(0)/2]$ is equal to $t\sqrt{n} \int (b_0 - b) dF_0 + t^2\|\xi_{\eta_0}^b\|^2_{b_0}/2 + o_P(1)$. The third term on the right of (5.4) is equivalent to the same expression. This concludes the proof of (5.2).

For term (5.3): We use the same decomposition (5.4), but with $b$ replaced by $f$. Define the path $\eta_u := (\eta^a, \eta^b, \eta^f)$ with $\eta^f_u = \eta^f - tu\xi_{\eta_0}^f/\sqrt{n} + \log c_u$, for $c_u^{-1} = \int e^{\eta^f - tu\xi_{\eta_0}^f/\sqrt{n}} d\xi_{\eta_0}^f$ the norming constant and $u \in [0,1]$. Then

$$f_u = e^{\eta^f}$$

is a one-dimensional exponential family in $u$ with score function $f_u' / f_u = -(t/\sqrt{n})(\xi_{\eta_0}^f - F_u\xi_{\eta_0}^f)$ (note that $c_u' / c_u = (t/\sqrt{n}) \int \xi_{\eta_0}^f f_u$).

By explicit computation (or exponential family identities), we see that the function $g(u) = \log p_{\eta_u}$ possesses derivatives

$$g'(u) = -\frac{t}{\sqrt{n}}(\xi_{\eta_0}^f - F_u\xi_{\eta_0}^f), \\
g''(u) = -\frac{t^2}{n} \int (\xi_{\eta_0}^f - F_u\xi_{\eta_0}^f)^2 dF_u, \\
g'''(u) = \frac{t^3}{n^{3/2}} \int (\xi_{\eta_0}^f - F_u\xi_{\eta_0}^f)^3 dF_u.$$ 

The third derivative is bounded by a multiple of $n^{-3/2}$, uniformly in $u$ and $f$.

Since $g''(u)$ is a constant and the empirical process centered, $\sqrt{n}G_n g''(0) = 0$, while $\sqrt{n}G_n g'(0) = -tG_n \xi_{\eta_0}^f$. Next $nP_{\eta_0}g'(0) = -t\sqrt{n}(F_0 - F)\xi_{\eta_0}^f$, while

$$nP_{\eta_0}g''(0) = -t^2 \int (\xi_{\eta_0}^f - F \xi_{\eta_0}^f)^2 dF = -t^2 \int (\xi_{\eta_0}^f - F_0 \xi_{\eta_0}^f)^2 dF_0 + o(1).$$

uniformly in $\{f : \eta \in \mathcal{H}_n\}$ by assumption (3.4). Inserting these approximations together with the Taylor expansion $\log p_{\eta} - \log p_{\eta^f} = -g'(0) - g''(0)/2 + O(n^{-3/2})$ in (5.4), with $b$ replaced by $f$, yields (5.3).
5.2. Proof of Theorem 2: Dirichlet process prior.

Proof of Theorem 2. We follow the same approach as in Theorem 1, firstly localizing the posterior to the set $\mathcal{H}_{a,b}$ and then evaluating the localized posterior Laplace transform (5.1) asymptotically.

In what follows, we write $\eta = (\eta^a, \eta^b)$ and let $\eta_t$ be as in (3.9), dropping the component $f$ and argument $\eta^f$. In view of (3.8) and the factorization of the likelihood over $a$ and $b$, the Laplace transform (5.1) equals

$$I_n(t) = \int \int_{\mathcal{H}_{a,b}} e^{t\sqrt{n} (b \log F - b \log F_0 - t b \log |\eta_t| + t b \log (\eta^b_t - \eta^b_t) \int_{\mathcal{H}_{a,b}} e^{t_b(\eta^b)} d\Pi(\eta^b) d\Pi(\eta^a)}-\n\n\int_{\mathcal{H}_{a,b}} e^{t_b(\eta^b)} d\Pi(\eta^b) d\Pi(\eta^a)\n\n= \int \int_{\mathcal{H}_{a,b}} e^{t\sqrt{n} (b \log F - b \log F_0 - t b \log |\eta_t| + t b \log (\eta^b_t - \eta^b_t) \int_{\mathcal{H}_{a,b}} e^{t_b(\eta^b)} d\Pi(\eta^b) d\Pi(\eta^a)}-\n\n\int_{\mathcal{H}_{a,b}} e^{t_b(\eta^b)} d\Pi(\eta^b) d\Pi(\eta^a)\n\n\times e^{-\mathbb{E}_{\mathcal{H}_{a,b}} \left[ \int_{\mathcal{H}_{a,b}} \log |\eta_t| \right] + \frac{t^2}{2} \|\xi_{n0}^b\|^2 + \mathcal{O}(t)}
$$

using the expansion for $\log |\eta^b_t - \eta^b_t|$ given in (5.2) and where $\tilde{\chi}_{n0}^f = \chi_{n0} - \chi_{n0}^b = b_0 - \chi(\eta_0)$. Note that the integral in the denominator is a constant relative to $\eta$ and $F$, since all variables are integrated out. By Fubini’s theorem, the double integral without the normalizing constant equals

$$\int_{\mathcal{H}_{a,b}} e^{t_b(\eta_t)} \int e^{t\sqrt{n} (b \log F - b \log F_0)} d\Pi(\eta_t) d\Pi(\eta).$$

Let $F_n = n^{-1} \sum_{i=1}^n \delta_{Z_i}$ denote the empirical distribution of the covariates. By assumption (3.12) we certainly have that $\sup\{ |(F_n - F_0)b| : b = \Psi(\eta^b), \eta \in \mathcal{H}_{a,b} \}$ tends to zero in probability. Therefore Lemma 1 yields that for every $t$ in a neighbourhood of zero, the preceding display of equals

$$e^{t \mathcal{O}(1)} \int_{\mathcal{H}_{a,b}} e^{t_b(\eta_t)} \int e^{t\sqrt{n} (b \log F - b \log F_0)} e^{t^2 \|b - F_0b_0\|^2_{L^2(F_0)}} d\Pi(\eta).$$

Since $\|b - b_0\|_{L^2(F_0)} \to 0$ uniformly on $\mathcal{H}_{a,b}$ and $\sqrt{n} \int b \log (F_n - F_0) = \mathbb{E}[\mathbb{E}_n[b_0] + \mathcal{O}(1)]$ by assumption (3.12), the previous display equals

$$e^{t \mathbb{E}[b_0] + \frac{t^2}{2} \|b_0 - F_0b_0\|^2_{L^2(F_0)} + \mathcal{O}(1)} \int_{\mathcal{H}_{a,b}} e^{t_b(\eta_t)} d\Pi(\eta).$$

We insert this in the expression for $I_n(t)$, combine the two exponential terms using that $\tilde{\chi}_{n0}^f = b_0 - \chi(\eta_0)$ and $\|b_0 - F_0b_0\|_{L^2(F_0)} = \|\xi_{n0}^f\|_{F_0}$, and invoke assumption (3.13), to see that $I_n(t)$ tends to $e^{t^2 \|\xi_{n0}^f\|^2_{F_0}/2}$ in probability. The theorem then follows by the convergence of Laplace transforms, as in Theorem 1. \hfill \Box
The preceding proof makes use of the following lemma, which can be considered a BvM theorem for the Laplace transform of the Dirichlet posterior process. A proof of the lemma can be found in [28].

Let \( F_n \) be the empirical distribution of an i.i.d. sample \( Z_1, \ldots, Z_n \) from a distribution \( F_0 \) on a Polish sample space \((\mathcal{Z}, \mathcal{C})\), and given \( Z_1, \ldots, Z_n \) let \( F_n \) be the distribution of a draw from the Dirichlet process with base measure \( \nu + nF_n \). Thus \( \nu \) is a finite measure on \((\mathcal{Z}, \mathcal{C})\), and \( F_n|Z_1, \ldots, Z_n \sim DP(\nu + n\overline{F}_n) \) is the posterior distribution obtained when equipping the distribution of the observations \( Z_1, Z_2, \ldots, Z_n \) with a Dirichlet process prior with base measure \( \nu \). The case that \( \nu = 0 \) is allowed.

**Lemma 1.** Suppose \( \mathcal{G}_n \) are separable classes of measurable functions such that \( \sup_{g \in \mathcal{G}_n} |F_ng - F_0g| \to 0 \) in probability and have envelope functions \( G_n \) satisfying \( \nu G_n = O(1) \) and \( F_0G_n^{2+\delta} = O(1) \) for some \( \delta > 0 \). Then for every \( t \) in a sufficiently small neighbourhood of 0, in probability,

\[
\sup_{g \in \mathcal{G}_n} \mathbb{E}\left[ e^{\sqrt{n}(F_ng - F_0g)} \mid Z_1, \ldots, Z_n \right] - e^{\sqrt{2}F_0(g - F_0g)^2/2} \to 0.
\]

**5.3. Proof of Theorem 3: propensity score-dependent prior.**

**Proof of Theorem 3.** For the propensity-score dependent prior \( (3.15) \) the posterior distribution for \( \sqrt{n}(\chi(\eta) - \hat{\chi}_n) \) is dependent both on the data \( X^{(n)} \) and the estimator \( \hat{a}_n \), and hence the bounded Lipschitz distance between this posterior distribution and the approximating normal distribution in Definition 1 is a function \( H(X^{(n)}, \hat{a}_n) \) of this pair of stochastic variables. By the assumed stochastic independence of \( X^{(n)} \) and \( \hat{a}_n \), the expectation of this distance can be disintegrated as \( \mathbb{E}H(X^{(n)}, \hat{a}_n) = \int \mathbb{E}H(X^{(n)}, a) dP\hat{a}_n(a) \), where the expectation inside the integral is relative to \( X^{(n)} \) only and concerns the “ordinary” posterior distribution relative to the prior \( (3.15) \) with \( \hat{a}_n \) set equal to the deterministic function \( a \), i.e. the posterior distribution for the prior of the form \( \Psi(w + \lambda a) \) on \( b \), for a fixed function \( a \) and \((w, \lambda)\) following their prior. Since the bounded Lipschitz distance is bounded, \( \mathbb{E}H(X^{(n)}, \hat{a}_n) \) certainly tends to zero if for every \( \eta > 0 \) there exist sets \( A_n \) with \( \Pr(\hat{a}_n \in A_n) > 1 - \eta \) such that \( \mathbb{E}H(X^{(n)}, a) \to 0 \), uniformly in \( a \in A_n \).

In view of \( (3.17) \) there exist sets \( A_n \) with \( \Pr(\hat{a}_n \in A_n) \to 1 \) and \( E\Pi((w, \lambda) : w + (\lambda + \eta)^{-1/2})a \in \mathcal{H}_n \mid X^{(n)} \to 1 \), uniformly in \( a \in A_n \) (e.g. the sets of all \( a \) where these expectations are bounded below by \( 1 - \nu_n \) for a sequence \( \nu_n \to 0 \) sufficiently slowly). Since we assume that \( \|\hat{a}_n\|_\infty = O_P(1) \) and \( (3.14) \), we can further reduce these sets to \( A_n = \{ a \in A_n : \|a\|_\infty \leq M, \|a - a_0\|_{L^2(F_0)} \leq M\rho_n \} \), and then show that \( \mathbb{E}H(X^{(n)}, a) \to 0 \) uniformly in \( a \in A_n \) for (ev-
ery) fixed $M > 0$. Thus in the remainder of the proof we fix $\hat{a}_n$ to be a deterministic sequence $a_n$ in $A_n$.

We verify the conditions of Theorem 2. By (3.16)–(3.19), conditions (3.10)–(3.13) are met by $\mathcal{H}_n^{a,b} = \{ \eta : \eta^b = w + \lambda a_n, (w, \lambda) \in B_n \}$, for

$$B_n = \{(w, \lambda) : w + \lambda a_n \in \mathcal{H}_n^b, |\lambda| \leq 2u_n\sigma_n^2\sqrt{n}\}.$$ 

It therefore remains only to control the change of measure (3.13). We need only consider the $b$ part of the integrals, as the $a$ part cancels. Because the assumptions become ‘more true’ if $u_n$ is replaced by a bigger sequence and $n\sigma_n^2 \to \infty$, we may assume that $u_n \to 0$ and $u_n n\sigma_n^2 \to \infty$.

For the $b$ term, (3.13) equals

$$\left.\frac{\int_{B_n} e^{\ell_n(w + \lambda a_n - t a_0 / \sqrt{n})} \phi_{\sigma_n}(\lambda) \, d\lambda \, d\Pi(w)}{\int_{B_n} e^{\ell_n(w + \lambda a_n)} \phi_{\sigma_n}(\lambda) \, d\lambda \, d\Pi(w)}\right|.$$ 

where $\phi_{\sigma}$ denotes the probability density function of a $N(0, \sigma^2)$ random variable. By Lemma 2, applied with $A_n = \{ w + \lambda a_n : (w, \lambda) \in B_n \}$, $\xi_n = a_n$, $\xi_0 = a_0$, $\zeta_n = M\rho_n$, $w_n$ the constant $M$ in the definition of $A_n$ and $\varepsilon_n = e_n$, for $(w, \lambda) \in B_n$

$$\sup_{(w, \lambda) \in B_n} \left| \ell_n(w + \lambda a_n - \frac{t}{\sqrt{n}} a_0) - \ell_n(w + \frac{t}{\sqrt{n}} a_n) \right| = o_{P_0}(1).$$

Furthermore, for $|\lambda| \leq 2u_n\sigma_n^2\sqrt{n}$, we have for the log likelihood ratio of two normal densities

$$\left| \log \frac{\phi_{\sigma_n}(\lambda)}{\phi_{\sigma_n}(\lambda - t / \sqrt{n})} \right| \leq \frac{|t\lambda|}{\sqrt{n}\sigma_n^2} + \frac{t^2}{2n\sigma_n^2} \to 0.$$ 

Consequently, the numerator of (5.5) equals

$$e^{o_{P_0}(1)} \int_{B_n} e^{\ell_n(w + (\lambda - t / \sqrt{n}) a_n)} \phi_{\sigma_n}(\lambda - t / \sqrt{n}) \, d\lambda \, d\Pi(w).$$ 

By the change of variables $\lambda - t / \sqrt{n} \sim \lambda'$ the ratio (5.5) therefore equals, for $B_{n,t} = \{(w, \lambda) : (w, \lambda) \in B_n \}$,

$$e^{o_{P_0}(1)} \int_{B_{n,t}} e^{\ell_n(w + \lambda a_n)} \phi_{\sigma_n}(\lambda') \, d\lambda' \, d\Pi(w) = e^{o_{P_0}(1)} \frac{\Pi(B_{n,t} | X^{(n)})}{\Pi(B_n | X^{(n)})} = 1 - o_{P_0}(1).$$

Since $\Pi(B_n | X^{(n)}) = 1 - o_{P_0}(1)$, it remains to show that $\Pi(B_{n,t} | X^{(n)}) = 1 - o_{P_0}(1)$.

The set $B_{n,t}$ is the intersection of the sets in assumptions (3.17) (with $\hat{a}_n = a_n$) and (3.16), except that the restriction on $\lambda$ in $B_{n,t}$ is $|\lambda + t / \sqrt{n}| \leq 2u_n\sqrt{n}\sigma_n^2$, whereas in (3.16) the restriction is $|\lambda| \leq u_n\sqrt{n}\sigma_n^2$. Since $t / \sqrt{n} \ll u_n\sqrt{n}\sigma_n^2$ by construction, the latter restriction implies the former, and hence $\Pi(B_{n,t} | X^{(n)}) = 1 - o_{P_0}(1)$ by assumption. \hfill $\Box$
5.4. Proofs for Section 3.4: Gaussian process priors.

Proof of Proposition 1. We verify the conditions of Theorem 1. Since the likelihood factorizes and we have a product prior on $b$ and $f$, the posterior is also a product measure. By Lemma 13 with norm $\| \cdot \|_\infty$, the posterior distribution of $b$ contracts about $b_0$ at rate $\varepsilon_n^b$ in $L^2$, while the posterior of $f$ contracts to $f_0$ in $L^2$ at rate $\varepsilon_n^f$, by assumption. For $\mathcal{H}_n^b$ the sets as in the statement of the proposition, define

$$\mathcal{H}_n = \{(\eta^a, \eta^b, \eta^f) : \eta^b \in \mathcal{H}_n^b, \| \Psi(\eta^b) - b_0 \|_{L^2} \leq \varepsilon_n^b, \| \int e^{\eta^f} \frac{d\eta^f}{dz} - f_0 \|_{L^2} \leq \varepsilon_n^f\}.$$ 

Then $\Pi(\mathcal{H}_n | X^{(n)}) \to \Pi_0$ as $n \to \infty$, by assumption. Furthermore, for any $\eta \in \mathcal{H}_n$, by the Cauchy-Schwarz inequality and the assumption that $f_0$ is bounded away from zero, $|\sqrt{n} \int (b - b_0)(f - f_0)dz| \leq \sqrt{n} \| b - b_0 \|_{L^2(\mathcal{H}_n)} \| f - f_0 \|_{L^2} \leq \sqrt{n} \varepsilon_n^b \varepsilon_n^f$, which tends to zero by assumption. It follows that $\mathcal{H}_n$ satisfies conditions (3.2)–(3.6) of Theorem 1.

It remains to verify (3.7), which by the prior independence of $b$ and $f$ factorizes in a $b$-term and an $f$-term. The $f$-term consists of a prior change of measure for the exponentiated Gaussian process prior, which is exactly the situation considered in [10]. Since $h(f, f_0) \lesssim \| f - f_0 \|_{L^2}$, one may localize the posterior to a Hellinger neighbourhood of radius $\varepsilon_n^f$ as in Proposition 3 of [10]. The result then follows from [10], under the same conditions.

We consider the change of measure (3.7) in the $b$ direction in detail. Following [9], we first approximate the perturbation $\eta^b_n$ by an element in the RKHS $\mathbb{H}^b$ and then apply the Cameron-Martin theorem. Let $\xi_n^b \in \mathbb{H}^b$ satisfy (3.24), and set $\eta_{n,t} = \eta_{n,t}(\eta^b) = \eta^b - t\xi_n^b/\sqrt{n}$. By the Cameron-Martin theorem (see Lemma 10), the distribution $\Pi_{n,t}$ of $\eta_{n,t}$ if $\eta^b$ is distributed according to the prior $\Pi$ has Radon-Nikodym density

$$\frac{d\Pi_{n,t}(\eta^b)}{d\Pi} = e^{-U_n(\eta^b)/\sqrt{n} - t^2 \| \xi_n^b \|_{\mathbb{H}^b}^2/(2n)},$$

where $U_n(\eta^b)$ is a centered Gaussian variable with variance $\| \xi_n^b \|_{\mathbb{H}^b}^2$ if $\eta^b \sim \Pi$, and $\| \cdot \|_{\mathbb{H}^b}$ is the RKHS norm of the Gaussian process $\eta^b$. By the univariate Gaussian tail bound,

$$\Pi(\eta^b : |U_n(\eta^b)| > M \sqrt{n} \varepsilon_n^b \| \xi_n^b \|_{\mathbb{H}^b}) \leq 2e^{-M^2n(\varepsilon_n^b)^2/2}. $$

Consequently, by Lemma 3 the posterior measure of the set in the display tends to 0 in probability, for large enough $M$. Hence the sets

$$B_n = \{\eta^b : |U_n(\eta^b)| \leq M \sqrt{n} \varepsilon_n^b \| \xi_n^b \|_{\mathbb{H}^b}\} \cap \mathcal{H}_n^b.$$
also satisfy \( \Pi(B_n|X^{(n)}) \to 1 \) in probability. On the sets \( B_n \), in view of (3.24),

\[
(5.7) \quad \left| \log \frac{d\Pi_{n,t}(\eta^b)}{d\Pi(\eta^b)} \right| \leq M|t|\sqrt{n}e_n^b\zeta_n + \frac{t^2}{2}(\zeta_n^b)^2 \to 0. 
\]

Furthermore, by Lemma 2 applied with \( A_n = B_n \), \( \xi_0 = \xi_{n0}^b \), \( \epsilon_n = \epsilon_n^b \), \( \zeta_n = \zeta_n^b \) and \( w_n \) a sufficiently large fixed constant, we have

\[
\sup_{\eta^b \in B_n} |\ell_n^b(\eta_{n,t}) - \ell_n^b(\eta_n^b)| = o_{P_0}(1). 
\]

(Note that condition (5.8) holds by assumption (3.19) and Lemma 7.) By the last display followed by the change of integration variable \( \eta^b - t\xi_n^b/\sqrt{n} \sim v \),

\[
\frac{\int_{B_n} e^{\ell_n^b(\eta_n^b)} d\Pi(\eta^b)}{\int_{B_n} e^{\ell_n^b(\eta_n^b)} d\Pi(\eta^b)} = \frac{\int_{B_n} e^{\ell_n^b(\eta_{n,t})} d\Pi(\eta^b)}{\int_{B_n} e^{\ell_n^b(\eta_{n,t})} d\Pi(\eta^b)} e^{o_{P_0}(1)} = \frac{\int_{B_{n,t}} e^{\ell_n^b(v)} d\Pi_{n,t}(v)}{\int_{B_n} e^{\ell_n^b(\eta_{n,t})} d\Pi(\eta^b)} e^{o_{P_0}(1)},
\]

where \( B_{n,t} = B_n - t\xi_n^b/\sqrt{n} \). By (5.7) we can next replace \( \Pi_{n,t} \) in the numerator by \( \Pi \) at the cost of another multiplicative \( 1 + o_{P_0}(1) \) term. This turns the quotient into the ratio \( \Pi(B_{n,t}|X^{(n)})/\Pi(B_n|X^{(n)}) \). We have already shown that \( \Pi(B_n|X^{(n)}) = 1 - o_{P_0}(1) \), so it suffices to show the same result holds true for the numerator. Now

\[
B_{n,t}^c = \{ v : v + t\xi_n^b/\sqrt{n} \notin \mathcal{H}_n^b \} \cup \{ v : \|\Psi(v + t\xi_n^b/\sqrt{n}) - b_0\|_{L^2(F_0)} > \epsilon_n^b \} \\
\quad \quad \cup \{ v : |U_n(v + t\xi_n^b/\sqrt{n})| > M\sqrt{n}\epsilon_n^b\|\xi_n^b\|_{L^2} \}.
\]

The posterior probability of the first set tends to zero in probability by assumption. Since \( \|\Psi(\eta^b + t\xi_n^b/\sqrt{n}) - \Psi(\eta^b)\|_{L^2(F_0)} \lesssimuentes \|\xi_n^b/\sqrt{n}\|_{L^2(F_0)} \lesssim 1/\sqrt{n} \),

the second set is contained in \( \{ \eta^b : \|\Psi(\eta^b) - b_0\|_{L^2(F_0)} > \epsilon_n^b - C/\sqrt{n} \} \),

which has posterior probability \( o_{P_0}(1) \) by Lemma 13, possibly after replacing \( \epsilon_n^b \) by a multiple of itself. For the third set, we use that \( U_n(\eta^b + t\xi_n^b/\sqrt{n}) \sim N(-t\|\xi_n^b\|_{L^2}^2/\sqrt{n}, \|\xi_n^b\|_{L^2}^2) \) if \( \eta^b \) is distributed according to the prior, by Lemma 10. Since the mean \( t\|\xi_n^b\|_{L^2}^2/\sqrt{n} \) of this variable is negligible relative to its standard deviation, \( \Pi(|U_n(\eta^b + t\xi_n^b/\sqrt{n})| > M\sqrt{n}\epsilon_n^b\|\xi_n^b\|_{L^2}) \)

differs not substantially from the left side of (5.6), whence it is also exponentially small, so that again Lemma 3 applies to see that the posterior probability tends to zero.

\[\square\]

**Proof of Proposition 2.** The proof follows by verifying the conditions of Theorem 2. This follows as in Proposition 1, with fewer conditions. 

\[\square\]
PROOF OF COROLLARY 1. We verify the conditions of Proposition 1. Using the form of the concentration function in Theorem 4 of Castillo [8], we see that (3.21) is satisfied for

$$\varepsilon^b_n = n^{-\beta/2+1} (\log n)^\kappa, \quad \varepsilon^f_n = n^{-\kappa/2+1} (\log n)^{\kappa'},$$

where $\kappa$ is function of $(\beta, \bar{\beta})$ and $\kappa'$ is the same function of $(\gamma, \bar{\gamma})$, given explicitly in [8]. This yields a posterior contraction rate $\varepsilon^f_n$ for $f$ in Hellinger distance by Lemma 15. Since a Riemann-Liouville process with parameter $\bar{\gamma}$ takes values in $C^\delta$ for all $\delta < \bar{\gamma}$ [26], and the same property holds when adding a polynomial part in (3.20), we can apply Proposition 5 of [10] to deduce that $\varepsilon^f_n$ is also a contraction rate for $f$ in $L^2$. By (3.25) the given sequences satisfy $\sqrt{n}c_n^b \varepsilon^f_n \to 0$. Condition (3.19) is verified in Lemma 4, under the assumption that $\beta \wedge \bar{\beta} > 1/2$.

It thus remains only to establish (3.24), the approximation by elements of the RKHS, which for the Riemann-Liouville process is the Sobolev space $H^{\beta+1/2}$. From the computations in Theorem 4 of [8], one gets that for $\xi^b_n = a_0 \in C^\alpha$, as $\xi^b_n \to 0$,

$$\inf_{\xi: \|\xi-a_0\|_{C^\alpha} \leq \xi^b_n} \|\xi\|_{L^{2\beta}} \lesssim (\xi^b_n)^{-\frac{\beta-\alpha+1/2}{\alpha}}. $$

If follows that (3.24) is satisfied if we can choose $\xi^b_n$ so that the right side of the display is bounded above by $\sqrt{n}c_n^b$ and $\sqrt{\varepsilon^b_n} \xi^b_n \to 0$. If $\bar{\beta} \leq \alpha - 1/2$, simply set $\xi^b_n = \xi_n^b$ and $\xi^b_n = n^{-1/2} \|\xi_n^b\|_{C^\alpha}$. If $\bar{\beta} > \alpha - 1/2$, take $\xi^b_n = n^{-\beta/2+1}$, so that $\sqrt{\varepsilon^b_n} \xi^b_n \to 0$ for $\beta \wedge \bar{\beta} > 1/2 + \bar{\beta} - \alpha$. A careful analysis of all cases shows that these inequalities, together with the requirement $\beta \wedge \bar{\beta} > 1/2$, are equivalent to $\alpha, \beta > 1/2$ and $1/2 < \bar{\beta} < \alpha + \beta - 1/2$.

The same argument for $f$, with $\xi^f_n = b_0 - \chi(\eta_0) \in C^\beta$, gives the requirement that $\gamma \wedge \bar{\gamma} > [1/2 + \bar{\gamma} - \beta] \vee 0$. Analyzing the different cases then yields that this is equivalent to $\beta > 1/2$, $\gamma > 0$ and $0 < \bar{\gamma} < \gamma + \bar{\beta} - 1/2$.

PROOF OF COROLLARY 2. The proof follows by verifying the conditions of Proposition 2. This follows as in the more complicated Corollary 1. 

PROOF OF COROLLARY 3. We verify the conditions of Theorem 3, where we replace $\hat{a}_n$ by a deterministic sequence with $\|a_n\|_{L^2} = O(1)$ as explained in the proof of Theorem 3. The contraction rate $\varepsilon^a_n$ is established in Lemma 14 and is slower than $(n/\log n)^{-(\beta\wedge 2\beta)/(2\beta+1)}$. Together with Lemma 5, this verifies conditions (3.17)–(3.19). To verify (3.16), we use the Gaussian tail inequality to see that $\Pi(\|\lambda\| \geq u_n \sigma_n \sqrt{n}) \leq 2e^{-u_n^2 \sigma_n^2 n/2}$. This is bounded above.
by $e^{-Ln(e_n^b)}$ for $u_n \to 0$ sufficiently slowly, since $\varepsilon_n^b = o(\sigma_n)$ by assumption. Lemma 3 now implies (3.16).

5.5. Technical results. The following lemma controls changes in the likelihood under perturbations of $\eta^b$.

**Lemma 2.** For bounded functions $\xi_n$ and $\xi_0$, $t \in \mathbb{R}$, a set $A_n$ of measurable functions, some $w_n > 0$ and $\varepsilon_n, \zeta_n \to 0$, suppose that

$$
\|\xi_n\|_\infty \leq w_n, \quad \|\xi_n - \xi_0\|_{L^2(F_0)} \leq \zeta_n, \quad \sup_{\eta^b \in A_n} \|\Psi(\eta^b) - \Psi(\eta_0^b)\|_{L^2(F_0)} \leq \varepsilon_n.
$$

If $n^{-1/2}w_n \to 0$, $\sqrt{n}\zeta_n\varepsilon_n \to 0$ and, for $b_0 = \Psi(\eta_0^b)$,

$$
(1 + w_n) \sup_{b = \Psi(\eta^b): \eta^b \in A_n} |G_n[b - b_0]| = o_{P_0}(1),
$$

then

$$
\sup_{\eta^b \in A_n} \left| \ell_n^b(\eta^b - \frac{t}{\sqrt{n}}\xi_n) - \ell_n^b(\eta^b - \frac{t}{\sqrt{n}}\xi_0) \right| = o_{P_0}(1).
$$

**Proof.** The part $\ell_n^b$ of the full log-likelihood (2.3) involving only the terms $b = \Psi(\eta^b)$ equals

$$
\ell_n^b(\eta^b) = \sum_{i=1}^{n} \left[ R_i Y_i \log \frac{e^{\eta^b(Z_i)}}{1 + e^{\eta^b(Z_i)}} + R_i (1 - Y_i) \log \frac{1}{1 + e^{\eta^b(Z_i)}} \right],
$$

where $\varphi(\eta) = \log(1 + e^{\eta})$. We apply this with $\eta^b$ equal to $\eta_{n,t} := \eta^b - t\xi_n/\sqrt{n}$ and $\eta_t := \eta_t^b - t\xi_0/\sqrt{n}$, take the difference and Taylor expand $\varphi(\eta_{n,t})$ and $\varphi(\eta_t)$ about $\eta^b$ to third order. Since $\varphi' = \Psi$, $\varphi'' = \Psi(1 - \Psi)$ and $\varphi''' = \Psi(1 - \Psi)(1 - 2\Psi)$, we have that $\varphi'(\eta^b) = b$ and $\varphi''(\eta^b) = b(1 - b)$ and the third derivative is uniformly bounded. Consequently,

$$
\ell_n^b(\eta_{n,t}) - \ell_n^b(\eta_t) = nP_n \left[ r\varphi(\eta_{n,t} - \eta_t) - r(\varphi(\eta_{n,t}) - \varphi(\eta_t)) \right]
$$

$$
= nP_n \left[ r(y - b)(\eta_{n,t} - \eta_t) \right] - \frac{n}{2} P_n \left[ rb(1 - b) ((\eta_{n,t} - \eta_t)^2 - (\eta_t - \eta_t)^2) \right] + R,
$$

where

$$
|R| \lesssim nP_n \left[ r|\eta_{n,t} - \eta_t|^3 + r|\eta_t - \eta_t|^3 \right] \lesssim \frac{w_n + 1}{\sqrt{n}} P_n (|\xi_n|^2 + |\xi_0|^2).
$$
The last expression is $O_{P_b}((w_n + 1)/\sqrt{n})$ and tends to zero by assumption. The first term on the right of the preceding display can be rewritten as

$$tG_n[r(y - b_0)(\xi_0 - \xi_n)] + tG_n[r(b_0 - b)(\xi_0 - \xi_n)] + t\sqrt{n}P_{\eta_0}[r(y - b)(\xi_0 - \xi_n)].$$

Here the first term tends to zero in probability, since $\xi_n \to \xi_0$ in $L^2(F_0)$, the second tends to zero uniformly in $b \in B_n := \{b = \Psi(\eta^b) : \eta^b \in A_n\}$ by assumption (5.8) and Lemma 6 applied with $\varphi = r(\xi_0 - \xi_n)$, which satisfies $\|\varphi\|_\infty = O(1 + w_n)$. By the Cauchy-Schwarz inequality the third term is bounded above in absolute value by $|t||1/a_0||\sqrt{n}\|b_0 - b_0\|_{L^2(F_0)}\|\xi_n - \xi_0\|_{L^2(F_0)} \lesssim \sqrt{n}\varepsilon_n\zeta_n$, which also tends to zero by assumption. The second, quadratic term of the expansion $\ell^b_n(\eta_n, t) - \ell^b_n(\eta_t)$ can be rewritten as

$$-\frac{t^2}{2}(\mathbb{P}_n - P_{\eta_0})[rb(1 - b)(\xi_n^2 - \xi_0^2)] - \frac{t^2}{2}P_{\eta_0}[rb(1 - b)(\xi_n^2 - \xi_0^2)].$$

The second term is bounded above in absolute value by $t^2P_{\eta_0}|\xi_n^2 - \xi_0^2| \to 0$, as $\xi_n \to \xi_0$ in $L^2(F_0)$. The first term tends to zero, uniformly in $b \in B_n$ by (5.8) and Lemma 8 applied with the classes of functions $\{r\}$, $B_n$ and $\{\xi_n^2 - \xi_0^2\}$ and the continuous function $(r, b, a) \mapsto rb(1 - b)a$.

**Lemma 3** (Lemma 1 of [15]). If $B_n$ are measurable sets such that $\Pi(\eta \in B_n)/\Pi(\eta : K \vee V(p_{\eta_0}, p_\eta) \leq \varepsilon_n^2) = o(e^{-2n\varepsilon_n^2})$, then $P_{\eta_0}\Pi(\eta \in B_n|X^{(n)}) \to 0$.

Since all contraction rates in the paper are established using the testing approach of Ghosal et al. [14], establishing a contraction rate $\varepsilon_n$ automatically involves proving a lower bound of the form $\Pi(B_{KL}(\eta_0, \varepsilon_n)) \geq e^{-Cn\varepsilon_n^2}$. The condition of the lemma is therefore satisfied if $\Pi(\eta \in B_n) \leq e^{-Ln\varepsilon_n^2}$ for sufficiently large $L$.

In the case of a product prior on the parameters $(a, b, f)$ and sets $B_n$ that refer to only one of the parameters $a, b, f$, both the numerator and denominator in the condition of the lemma factorize. Consequently, one may use the rate obtained from lower bounding the small-ball probability for that parameter, rather than the worst rate $\max(\varepsilon_n^a, \varepsilon_n^b, \varepsilon_n^f)$. For instance if we consider the product prior (3.22)-(3.23) and $B_n$ involves only conditions concerning $b$, then we use the rate $\varepsilon_n^b$ in Lemma 3.

These two remarks will be used throughout without further mention.

**Lemma 4.** Let $\Pi$ be the Gaussian process prior $\Psi(R^\beta)$ on $b$, for $R^\beta$ the Riemann-Liouville process given in (3.20). If $b_0 \in C^\beta$ and $\beta \wedge \bar{\beta} > 1/2$, then there exist sets $\mathcal{H}_n \subset C[0, 1]$ such that $\Pi(\eta^b \in \mathcal{H}_n - t\xi_n^b/\sqrt{n}|X^{(n)}) \to P_{\eta_0}$ for every $t \in \mathbb{R}$ and every $\xi_n^b$ satisfying (3.24), and such that (3.19) holds.
PROOF. We shall show that the posterior distribution concentrates on a set of small bracketing entropy, which will allow us to verify (3.19) by a standard maximal inequality for the empirical process.

The Riemann-Liouville process $R^\beta$ can be viewed as a Gaussian random element in the Sobolev space $H^s$ for $s < \beta$ and its RKHS is equal to $H^{\beta+1/2}$ by Theorem 4.2 of [49]. For $H^s_\beta$ the unit ball of $H^s$ and 1/2 < $s < \beta$ to be specified below, we define

\[
\mathcal{H}^b_n = \{ \gamma_n H^s_1 + M \sqrt{n} \varepsilon_n H^s_1 \} \bigcap \{ \eta^b : \| \Psi(\eta^b) - b_0 \|_{L^2(F_0)} \leq \varepsilon_n \},
\]

where $M$ is a large constant to be determined and

\[
(5.9) \quad \gamma_n = n^{-2(\beta+1/2-\beta \wedge \beta)(\beta-s)} (\log n)^{-2s-2} n^{-2s/2}, \quad \varepsilon_n^b \asymp n^{-2s/2}(\log n)^{\kappa}. \tag{5.9}
\]

The rate $\varepsilon_n^b$ is the contraction rate of the posterior distribution of $b$. This is given by (3.21) with $i = b$, in view of Lemma 13, and shown to take the form as in the display in [8] (see his Theorem 4), where the exponent $\kappa$ of the logarithmic factor depends in a complicated manner on $(\beta, \beta)$, but will not be of concern here. It follows that the second set in the definition of $\mathcal{H}^b_n$ has posterior mass tending to one in probability, provided the proportionality constant in $\varepsilon_n^b$ is chosen large enough.

By the Borell-Sudakov inequality (e.g. Theorem 5.1 in [50]), the prior probability of the complement of the first part of $\mathcal{H}^b_n$ satisfies

\[
\Pi[R^\beta \notin \gamma_n H^s_1 + M \sqrt{n} \varepsilon_n H^s_1] \leq 1 - \Phi \left[ \Phi^{-1} \left( \Pi(\| R^\beta \|_{H^s} \leq \gamma_n) \right) + M \sqrt{n} \varepsilon_n^b \right].
\]

Reasoning as in Theorem 4.3.36 of [18], we see that $\log N(H^{\beta+1/2}, \| \cdot \|_{H^s}, \varepsilon) \leq K(\beta, s) \varepsilon^{-1/(\beta+1/2-s)}$ for small $\varepsilon > 0$. Therefore, by Theorem 1.2 of Li and Linde [25], the small ball exponent $-\log \Pi(\| R^\beta \|_{H^s} \leq \gamma)$ is bounded above by a multiple of $\gamma^{-1/(\beta-s)}$ for small $\gamma$. Substituting this in the preceding display and using the bounds $\Phi^{-1}(y) \geq -\sqrt{2 \log(1/y)}$ for $0 < y < 1$, and $1 - \Phi(x) \leq e^{-x^2/2}$ for $x > 0$, we see that the right side of the display is smaller than $e^{-\ln(\varepsilon_n^b)^2}$, where $L$ can be made large by choosing $M$ large enough. It then follows from Lemma 3 that the posterior probability of the first set in the definition of $\mathcal{H}^b_n$ also tends to 1 in probability.

For $t \in \mathbb{R}$ and $\xi_n^b$ satisfying (3.24), since $\| \xi_n^b \|_{H^{\beta+1/2}} \leq \sqrt{\varepsilon_n} \xi_n^b$ and $\| \Psi(\eta^b) - \Psi(\eta^b - t \xi_n^b / \sqrt{n}) \|_{L^2(F_0)} \leq |t| \| \xi_n^b \|_\infty / \sqrt{n}$,

\[
\mathcal{H}^b_n - t \xi_n^b / \sqrt{n} \supset \{ \gamma_n H^s_1 + (M \sqrt{n} \varepsilon_n \mathbf{1} - |t| \xi_n^b) H^s_1 \bigcup \{ \eta^b : \| \Psi(\eta^b) - b_0 \|_{L^2(F_0)} \leq \varepsilon_n - |t| (\| \xi_n^b \|_\infty + \xi_n^b) / \sqrt{n} \}.
\]
Since $\sqrt{n} \varepsilon_n^b \to \infty$ and $\zeta_n^b \to 0$, this set hardly differs from the set $\mathcal{H}_n^b$. Its posterior probability is seen to tend to 1 in probability by the same arguments as for $\mathcal{H}_n^b$, possibly after replacing $\varepsilon_n^b$ with a multiple of itself.

Finally we show (3.19), which is that the supremum of the empirical process indexed by the class of functions $\mathcal{F}_n := \{ \Psi(\eta^b) : \eta^b \in \mathcal{H}_n^b \}$ tends to zero. By Theorem 2.14.2 of [51] applied with the constant function 1 as envelope function,

$$P_0 \sup_{f \in \mathcal{F}_n} |G_n f| \lesssim \int_0^\delta \sqrt{1 + \log N_0(\mathcal{F}_n, L^2(P_0), \tau)} d\tau + \varepsilon_n^b \sqrt{1 + \log N_0(\mathcal{F}_n, L^2(P_0), \delta)},$$

for any $\delta > 0$ such that $\sqrt{n} \delta > \sqrt{1 + \log N_0(\mathcal{F}_n, L^2(P_0), \delta)}$ (so that $\sqrt{n} a(\delta)$ as defined in Theorem 2.14.2 is bigger than the envelope 1). It therefore remains to bound the above bracketing entropy and pick $\delta = \delta_n \to 0$ such that all the terms converge to zero.

Because $\Psi$ is monotone and Lipschitz, a set of $\tau$-brackets in $L^2(P_0)$ for $\mathcal{H}_n^b$, transforms into a set of $\tau$-brackets in $L^2(P_0)$ for $\mathcal{F}_n$. Furthermore, separate sets of brackets for the two constituents of the set $\gamma_n H_1^b + M \sqrt{n} \varepsilon_n^b H_1^{b+1/2}$ can be combined into brackets for the sum space. By [7] (or see [52], Section 2.7.2),

$$\log N_0(\mathcal{H}_n^b, L^2(P_0), 2\tau) \leq \log N(\gamma_n H_1^b, \| \cdot \|_\infty, \tau)
+ \log N(M \sqrt{n} \varepsilon_n^b H_1^{b+1/2}, \| \cdot \|_\infty, \tau)
\lesssim (\gamma_n / \tau)^{1/s} + (\sqrt{n} \varepsilon_n^b / \tau)^{1/(b+1/2)}.$$

The first term dominates if $\tau \lesssim \delta_n := n^{-\beta + 1/2 - \beta / s + \beta + \kappa / (2\beta + 1)} (\log n)^{-\kappa / (2\beta + 1)} \to 0$. For $\delta_n > 0$ such that $\delta_n / \delta_n \to 0$, we therefore have

$$P_0 \sup_{f \in \mathcal{F}_n} |G_n f| \lesssim \frac{1}{\sqrt{n}} \int_0^\delta \tau^{-\frac{s}{2}} d\tau + (\sqrt{n} \varepsilon_n^b)^{\frac{1}{2\beta + 1}} \int_0^\delta \tau^{-\frac{1}{2\beta + 1}} d\tau + \varepsilon_n^b \left[ \sqrt{n} \varepsilon_n^b \right]^{2\beta + 1},$$

provided $\sqrt{n} \delta_n \gtrsim (\sqrt{n} \varepsilon_n^b / \delta_n)^{1/(2\beta + 1)}$. The first integral on the right tends to zero, since $\gamma_n, \delta_n \to 0$ and $s > 1/2$. Thus we must choose $\delta_n$ so that

$$\delta_n \gg \delta_n,$$

$$\delta_n \ll \delta_{II} := (\sqrt{n} \varepsilon_n^b)^{-1/(2\beta)} = n^{-\beta / (2\beta + 1)} (\log n)^{-\kappa / (2\beta)},$$

$$\delta_n \gg \delta_{IV} := (\varepsilon_n^b)^{2\beta + 1} \sqrt{n} \varepsilon_n^b = n^{\beta + 1/2 - 2\beta / (2\beta + 1)} (\log n)^{2\kappa (\beta + 1)},$$

$$\delta_n \gg \delta_{III} := n^{-2\beta / (2\beta + 1)} (\log n)^{2\kappa (\beta + 1)}.$$
The middle two restrictions arise from the second integral and the last term on the right side of the preceding display, and the fourth is a strengthening of the restriction $\sqrt{n}\delta_n \gtrsim (\sqrt{n}\varepsilon_n^b/\delta_n)^{1/(2\beta+1)}$. Necessary and sufficient conditions for the four requirements are: (i) $\delta_n = o(\delta_{II})$, (ii) $\delta_{II} = o(\delta_{II})$ and (iii) $\delta_{IV} = o(\delta_{II})$. Substituting in the values of $\delta_n, \delta_{II}, \delta_{III}, \delta_{IV}$, using that $1/2 < s < \beta$ and rearranging, we find the necessary and sufficient conditions: (i) $\beta > 1/2$, (ii) $\beta > 1/2$ and (iii) $\beta \wedge \beta > 1/2$. Thus under the condition $\beta \wedge \beta > 1/2$, we can find a choice of $\delta_n$ such that all requirements are met.

**Lemma 5.** Let the prior $\Pi$ on $b$ be the distribution of $\Psi(R^3_\beta + \lambda a_n)$ with $R^\beta$ the Riemann-Liouville process (3.20), independent of $\lambda \sim N(0, \sigma_n^2)$ and $a_n$ a sequence of functions with $\|a_n\|_\infty = O(1)$. If $b_0 \in C^\beta$ and $\beta \wedge \beta > 1/2$, then there exist sets $\mathcal{H}_n^b \subset C[0, 1]$ such that $\Pi((w, \lambda): w + (\lambda + tn^{-1/2})a_n \in \mathcal{H}_n^b | X(n)) \to \delta_{01}$ for every $t \in \mathbb{R}$, and such that (3.19) holds.

**Proof.** Since the proof of this result is very similar to that of Lemma 4, we present only an outline. For $1/2 < s < \beta$, define the set $\mathcal{H}_n^b = \{w + \lambda a_n: (w, \lambda) \in \mathcal{W}_n\}$, for

$$\mathcal{W}_n = \{(w, \lambda): w \in \gamma_n H_1^{\frac{s}{\beta} + 1/2}, |\lambda| \leq M\sigma_n \sqrt{\varepsilon_n^b}\} \cap \{(w, \lambda): \|\Psi(w + \lambda a_n) - b_0\|_{L^2(P_0)} \leq \varepsilon_n^b\},$$

where $\varepsilon_n^b$ and $\gamma_n$ are defined in (5.9) in the proof of Lemma 4. The first set in the intersection that defines $\mathcal{W}_n$ is seen to have posterior probability tending to one by the same argument as in Lemma 4, combined with the univariate Gaussian tail inequality $\Pi(|\lambda| \geq M\sigma_n \sqrt{\varepsilon_n^b}) \leq 2e^{-1/2Mn(\varepsilon_n^b)^2}$. The posterior probability of the second set in the intersection tends to one in probability by Lemma 14. The posterior probability of the set $\mathcal{W}_n$ shifted in its second coordinate is seen to tend to 1 in the same manner. These results are true uniformly in $\|a_n\|_\infty \leq M$.

To verify (3.19) we apply the bracketing maximal inequality, Theorem 2.14.2 of [51], as in the proof of Lemma 4. Presently we need to control the $L^2(P_0)$-bracketing entropy of the sets $\mathcal{F}_n = \{\Psi(w + \lambda a_n) - b_0: (w, \lambda) \in \mathcal{W}_n\}$. Since

$$N(\mathcal{F}_n, L^2(P_0), 3\tau) \leq N(\gamma_n H_1^{\frac{s}{\beta} + 1/2}, \|: \|_\infty, \tau) \cdot \left(\sqrt{\gamma_n H_1^{\frac{s}{\beta} + 1/2}, \|: \|_{\infty, \tau}\right) \cdot \left(\sqrt{\gamma_n H_1^{\frac{s}{\beta} + 1/2}, \|: \|_{\infty, \tau}\right) \times N(\gamma_n H_1^{\frac{s}{\beta} + 1/2}, \|: \|_{\infty, \tau}),$$

and the last term is of strictly smaller order than the second, we recover the right-hand side of (5.10) and hence the proof can be completed as in Lemma 4. □
6. Auxiliary results.

6.1. Empirical process results. In this subsection we collect some novel results on empirical processes, which are useful to simplify otherwise long lists of technical conditions for the main results. We denote by \( P_n \) and \( G_n = \sqrt{n}(P_n - P_0) \) the empirical measure and process of a sample of i.i.d. observations \( X_1, \ldots, X_n \) with law \( P_0 \) in a sample space \((\mathcal{X}, \mathcal{A})\). For the interpretation of outer expectation and probability, these are understood to be defined as the coordinate projections on a product probability space.

**Lemma 6.** For any set \( \mathcal{H} \) of measurable functions \( h : \mathcal{X} \to \mathbb{R} \) and bounded measurable function \( \varphi : \mathcal{X} \to [0,1] \),

\[
\mathbb{E}^* \sup_{h \in \mathcal{H}} |G_n[\varphi h]| \leq 4\|\varphi\|_\infty \mathbb{E}^* \sup_{h \in \mathcal{H}} |G_n[h]| + \sqrt{P_0(\varphi - P_0\varphi)^2} \sup_{h \in \mathcal{H}} |P_0 h|.
\]

**Proof.** Since \( G_n[\varphi h] = G_n[\varphi(h - P_0 h)] + P_0 h G_n \varphi \), and the expectation of \( \sup_{h} |P_0 h| |G_n[\varphi]| \) is bounded above by the second term on the right of the lemma, it suffices to bound \( \mathbb{E}^* \sup_{h} |G_n[\varphi(h - P_0 h)]| \) by the first term on the right of the lemma. The latter term does not change if every \( h \) is replaced by \( h - P_0 h \). Therefore, it suffices to prove the lemma under the assumption that \( P_0 h = 0 \), for every \( h \).

Let \( \varepsilon_1, \ldots, \varepsilon_n \) be i.i.d. Rademacher random variables independent of the observations, defined on an additional factor of the underlying probability space that carries the observations. By the symmetrization inequality Lemma 2.3.6 of [51],

\[
\mathbb{E}^* \sup_{h} \left| \sum_{i=1}^{n} (\varphi(X_i)h(X_i) - P_0[\varphi h]) \right| \leq 2\|\varphi\|_\infty \mathbb{E}^* \sup_{h} \left| \sum_{i=1}^{n} \varepsilon_i \varphi(X_i)h(X_i) \right|.
\]

By the contraction principle, Proposition A.1.10 of [51], this inequality remains true if the variables \( \varphi(X_i)/\|\varphi\|_\infty \) in the right side are removed. Since \( P_0 h = 0 \) for every \( h \), the resulting expression is bounded above by \( 4\|\varphi\|_\infty \mathbb{E}^* \sup_{h} \left| \sum_{i=1}^{n} h(X_i) \right| \), by the other part of the symmetrization inequality Lemma 2.3.6 of [51]. Dividing everything through by \( \sqrt{n} \) completes the proof.

**Lemma 7.** If \( \mathcal{H}_n \) are classes of measurable functions with uniformly square-integrable envelope functions, then \( \sup_{h \in \mathcal{H}_n} |G_n[h]| \to 0 \) in outer probability if and only if the convergence is in outer mean.

**Proof.** Convergence in outer mean always implies convergence in outer probability. It suffices to show the converse in this special case. By the
Hoffmann-Jørgensen inequality for moments applied to the stochastic processes \( n^{-1/2}(h(X_i) - P_0h) \) (see the second inequality in Proposition A.1.5 of [51]), this follows if \( E^* \max_{i \leq n} \sup_h |h(X_i) - P_0h| = o(\sqrt{n}) \). If \( H_n \) are measurable square-integrable envelope functions, then clearly \( \sup_h |P_0h| \leq P_0H_n = O(1) \), while \( \max_{i \leq n} \sup_h |h(X_i)| \leq \max_{i \leq n} H_n(X_i) \). For every \( \epsilon > 0 \), the latter variable is bounded above by \( \epsilon \sqrt{n} + \sum_{i=1}^n H_n(X_i)1\{H_n(X_i) > \epsilon / n \} \). The expectation of the second term is bounded above by \( \sqrt{n} \epsilon^{-1} P_0 H_n^2 H_n > \epsilon / n = o(\sqrt{n}) \), by the assumed uniform integrability of the envelope functions \( H_n \).

Since this is true for any \( \epsilon > 0 \), the desired result follows.

**Lemma 8.** For \( i = 1, 2, \ldots, k \), let \( \mathcal{H}_{n,i} \) be classes of measurable functions that are separable as subsets of \( L^1(P_0) \), have uniformly integrable envelope functions \( (n = 1, 2, \ldots) \), and are such that \( \sup_{h \in \mathcal{H}_{n,i}} |(P_n - P_0)[h]| \to 0 \) in outer probability. Let \( \phi : \mathbb{R}^k \to \mathbb{R} \) be continuous. If the classes of functions \( \phi(\mathcal{H}_n) := \{\phi(h_1, \ldots, h_k) : h_i \in \mathcal{H}_{n,i}\} \) have uniformly integrable envelope functions, then \( E^* \sup_{h \in \phi(\mathcal{H}_n)} |(P_n - P_0)[h]| \to 0 \).

**Proof.** Because the classes \( \mathcal{H}_{n,i} \) are separable as subsets of \( L^1(P_0) \), they admit by a result of Talagrand (see Theorem 2.3.16 in [51]) pointwise separable modifications \( \mathcal{H}_{n,i} \) relative to the \( L^1(P_0) \)-norm. Arguing as in the proof of Theorem 2.10.6 of [51] (or Theorem 2.10.1 in the second edition of this reference), we see that it suffices to prove the theorem for these separable versions. Thus we may assume that the classes \( \mathcal{H}_{n,i} \) are appropriately measurable.

By the preceding lemma and the assumed uniform integrability of the envelope functions, the convergence in probability \( \sup_{h \in \mathcal{H}_{n,i}} |(P_n - P)[h]| \to 0 \) can be strengthened to convergence in outer mean. Then, by the (de)symmetrization inequality, Lemma 2.3.6 of [51], for independent Rademacher variables \( \epsilon_1, \ldots, \epsilon_n \),

\[
E^* \sup_{h \in \mathcal{H}_{n,i}} \left| \frac{1}{n} \sum_{i=1}^n \epsilon_i (h(X_i) - P_0h) \right| \leq 2E^* \sup_{h \in \mathcal{H}_{n,i}} |(P_n - P_0)[h]| \to 0.
\]

Because \( E \sup_{h} |n^{-1} \sum_{i=1}^n \epsilon_i P_0h| \leq E |n^{-1} \sum_{i=1}^n \epsilon_i| \sup_{h} |P_0h| \) tends to zero in mean by the law of large numbers, we also obtain convergence to zero of the left side without the terms \( P_0h \). Next by the multiplier inequalities, Lemma 2.9.1 of [51], we see that, for any \( n_0 \in \mathbb{N} \) and i.i.d. standard normal variables \( \xi_1, \ldots, \xi_n \) independent from \( X_1, \ldots, X_n \),

\[
E^* \sup_{h \in \mathcal{H}_{n,i}} \left| \frac{1}{n} \sum_{i=1}^n \xi_i h(X_i) \right| \leq \frac{n_0 P_0 H_{n,i}}{n} E \max_{i \leq n} |\xi_i| + \max_{0 \leq k \leq n} E^* \sup_{h \in \mathcal{H}_{n,i}} \left| \frac{1}{k} \sum_{i=n_0}^k \xi_i h(X_i) \right|.
\]
By Jensen’s inequality the last term on the right does not decrease if the sum on the right starts at \( i = 1 \) rather than \( i = n_0 \). Then by the preceding the limsup as \( n \to \infty \) is arbitrarily close to zero if \( n_0 \) is large enough. For fixed \( n_0 \) the first term on the right tends to zero as \( n \to \infty \). We conclude that the left side tends to zero as \( n \to \infty \). Given \( X_1, \ldots, X_n \) the process \( n^{-1/2} \sum_{i=1}^{n} \xi_i h(X_i) \) is mean-zero Gaussian, with natural pseudo-metric given by the \( L^2(\mathbb{P}_n) \)-norm. By Sudakov’s inequality (e.g. Proposition A.2.5 of \([51]\))

\[
\frac{1}{\sqrt{n}} \sup_{\varepsilon > 0} \varepsilon \sqrt{\log N(\mathcal{H}_{n,i}, L^2(\mathbb{P}_n), \varepsilon)} \leq 3\mathbb{E}_\xi \sup_{h \in \mathcal{H}_{n,i}} \left| \frac{1}{n} \sum_{i=1}^{n} \xi_i h(X_i) \right|.
\]

Taking the outer expectation across this inequality, we see that the left side tends to zero in outer expectation and hence \( n^{-1} \log N(\mathcal{H}_{n,i}, L^2(\mathbb{P}_n), \varepsilon) \) tends to zero in outer probability, for every \( \varepsilon > 0 \).

Let \( H_{n,1}, \ldots, H_{n,k} \) and \( F_n \) be integrable envelopes for the classes of functions \( H_{n,1}, \ldots, H_{n,k} \) and \( F_n := \phi(\mathcal{H}_n) \), respectively, and set \( H_n = H_{n,1} \lor \cdots \lor H_{n,k} \). Furthermore, for \( M \in (0, \infty) \) define \( F_{n,M} \) to be the class of functions \( f : H_{n,1} \leq M \), when \( f \) ranges over \( F_n \). Then

\[
\sup_{f \in F_n} \left| (\mathbb{P}_n - \mathbb{P}_0)(f) \right| \leq (\mathbb{P}_n + \mathbb{P}_0)F_n 1_{[H_n > M]} + \sup_{f \in F_{n,M}} \left| (\mathbb{P}_n - \mathbb{P}_0)(f) \right|.
\]

The expectation of the first term on the right converges to 0 as \( M \to \infty \) by the assumed uniform integrability of \( F_n \) and \( H_n \). We shall show that the second term tends to zero in outer mean, for every fixed \( M \). By Lemma 9 below, applied to the function \( \phi : [-M, M]^k \to \mathbb{R} \) and \( \| \cdot \| \) the \( L^1 \)-norm on \( \mathbb{R}^k \), there exists for every \( \varepsilon > 0 \) a \( \delta > 0 \), depending only on \( \varepsilon, \phi \) and \( M \), such that for any pairs \( (g_i, h_i) \in H_{n,i} \), the inequality

\[
\mathbb{P}_n |g_i - h_i| 1_{[H_{n,i} \leq M]} \leq \delta \frac{1}{k}, \quad i = 1, \ldots, k
\]

implies that

\[
\mathbb{P}_n |\phi(g_1, \ldots, g_k) - \phi(h_1, \ldots, h_k)| 1_{H_n \leq M} \leq \varepsilon.
\]

We conclude that

\[
N(F_{n,M}, L^1(\mathbb{P}_n), \varepsilon) \leq \prod_{i=1}^{k} N(\mathcal{H}_{n,i}, L^1(\mathbb{P}_n), \frac{\delta}{k}).
\]

Take the logarithm and divide by \( n \) to see that \( n^{-1} \log N(F_{n,M}, L^1(\mathbb{P}_n), \varepsilon) \) tends to zero in outer probability, in view of the preceding paragraph. This is true for every \( \varepsilon > 0 \) and \( M > 0 \).
If $\mathcal{F}_{n,M}'$ is a minimal $\epsilon$-net over $\mathcal{F}_{n,M}$ for the $L^1(\mathbb{P}_n)$-norm and fixed observations, then
\[
\mathbb{E}_* \sup_{f \in \mathcal{F}_{n,M}} \left| \frac{1}{n} \sum_{i=1}^{n} \epsilon_i f(X_i) \right| \leq \mathbb{E}_* \sup_{f \in \mathcal{F}_{n,M}} \left| \frac{1}{n} \sum_{i=1}^{n} \epsilon_i f(X_i) \right| + \epsilon.
\]
For fixed observations the process $n^{-1/2} \sum_{i=1}^{n} \epsilon_i f(X_i)$ is subgaussian relative to the $L^2(\mathbb{P}_n)$-norm. For $f \in \mathcal{F}_{n,M}$ these norms are bounded above by $M$. Therefore, by the subgaussian maximal inequality the the preceding display is bounded above by a multiple of
\[
\sqrt{\frac{1}{n}} \sqrt{1 + \log N(\mathcal{F}_{n,M}, L^1(\mathbb{P}_n), \epsilon) M + \epsilon}.
\]
Since this tends to $\epsilon$ in outer probability, for any $\epsilon > 0$, the left side of the preceding display tends to zero in outer probability. Since this is bounded above by $M$, it follows that its expectation also tends to zero and hence in view of the symmetrization inequality, Lemma 2.3.6 of [51],
\[
\mathbb{E}_* \sup_{f \in \mathcal{F}_{n,M}} \left| \frac{1}{n} \sum_{i=1}^{n} (f(X_i) - P_0f) \right| \leq 2 \mathbb{E}_* \sup_{f \in \mathcal{F}_{n,M}} \left| \frac{1}{n} \sum_{i=1}^{n} \epsilon_i f(X_i) \right| \to 0.
\]
This concludes the proof.

The assumption that the classes $\mathcal{H}_{n,i}$ are separable as subsets of $L^1(P_0)$ is made only to ensure enough measurability. The proof of the preceding lemma is based on a combination of the proof of the converse of the Glivenko-Cantelli theorem and the preservation result [47]. The lemma extends a known result for Glivenko-Cantelli classes to sequences of classes that depend on $n$.

The following lemma is proved in [47]. Let $\| \cdot \|$ be any norm on $\mathbb{R}^k$.

**Lemma 9.** Suppose that $K \subset \mathbb{R}^k$ is compact and $\phi : K \to \mathbb{R}$ is continuous. Then for every $\epsilon > 0$ there exists $\delta > 0$ such that for all $n$ and for all $a_1, \ldots, a_n, b_1, \ldots, b_n \in K$, the inequality $n^{-1} \sum_{i=1}^{n} \|a_i - b_i\| < \delta$ implies that $n^{-1} \sum_{i=1}^{n} |\phi(a_i) - \phi(b_i)| < \epsilon$.

6.2. Miscellaneous results. In this section we state slightly different versions of otherwise known results.

**Lemma 10 (Cameron-Martin).** If $W$ is a Gaussian random variable in a separable Banach space with RKHS $\mathbb{H}$, then for $\xi \in \mathbb{H}$ the distribution
$P^W-\xi$ of $W-\xi$ is absolutely continuous with respect to the distribution of $P^W$ with Radon-Nikodym derivative of the form

$$\frac{dP^W-\xi}{dP^W}(W) = e^{U(W,\xi)-\|\xi\|_2^2},$$

for a measurable map $w \mapsto U(w,\xi)$ such that $U(W-g,\xi) \sim N(\langle g,\xi \rangle, \|\xi\|_2^2)$, for any $g,\xi \in \mathbb{H}$.

**Proof.** For the statement with $g = 0$, giving the representation of the Radon-Nikodym density and the distributional result $U(W,\xi) \sim N(0, \|\xi\|_2^2)$ for $\xi \in \mathbb{H}$, see e.g. Section 3 of [50]. For $g \neq 0$, we first note that by this known case applied with $g$ instead of $\xi$, a change of measure gives that $Pr(U(W-g,\xi) \in B) = \mathbb{E}[\{U(W,\xi) \in B\}e^{U(W,g)-\|g\|_2^2/2}]$. Therefore $\mathbb{E}_e^{U(W-g,\xi)} = \mathbb{E}_e^{e^{U(W,\xi)+U(W,g)-\|g\|_2^2/2}}$, which can be computed to be $e^{t^2\|\xi\|_2^2+\langle g,\xi \rangle}$ from the joint multivariate distribution of the variables $U(W,\xi')$ for $\xi' \in \mathbb{H}$, which follows from the Cramér-Wold device and the given normal distribution of $U(W,\xi')$, for every $\xi'$.

**Lemma 11** (Laplace transform). Let $T \subset \mathbb{R}$ contain both a strictly increasing and a strictly decreasing sequence of numbers with limit 0.

(i) If $Y_n$ are random variables with $\mathbb{E}e^{tY_n} \to e^{t^2\sigma^2/2}$ for every $t \in T$, then $Y_n$ tends in distribution to $N(0, \sigma^2)$.

(ii) If $(Y_n, Z_n)$ are random vectors with $\mathbb{E}(e^{tY_n}|Z_n) \to e^{t^2\sigma^2/2}$ in probability for every $t \in T$, then $d_{BL}(\mathcal{L}(Y_n|Z_n), N(0, \sigma^2)) \to 0$ in probability.

(iii) If the convergence in the preceding assumption is in the almost sure sense, then the conclusion is also true in the almost sure sense.

**Proof.** (i) Let $a < 0$ and $b > 0$ be contained in $T$. Because $\mathbb{E}e^{tY_n}$ is bounded in $n$ for both $t = a$ and $t = b$, the sequence $Y_n$ is tight by Markov’s inequality. For every $t \in T$ strictly between $a$ and $b$, some power bigger than 1 of the variables $e^{tY_n}$ are bounded in $L^1$, and hence the sequence $e^{tY_n}$ is uniformly integrable. Consequently, if $Y$ is a weak limit point of $Y_n$, then $\mathbb{E}e^{tY}$ tends to $\mathbb{E}e^{tY}$ along the same subsequence for every $t \in (a,b) \cap T$. In view of the assumption of the lemma, it follows that $\mathbb{E}e^{tY} = e^{t^2\sigma^2/2}$. The set $(a,b) \cap T$ is infinite by assumption. Finiteness of $\mathbb{E}e^{tY}$ on this set implies that the function $z \mapsto \mathbb{E}e^{zY}$ is analytic in an open strip containing the real axis. By analytic continuation it is equal to $e^{z^2\sigma^2/2}$, whence $\mathbb{E}e^{izY} = e^{-z^2\sigma^2/2}$ for every $t \in \mathbb{R}$.

(ii) It suffices to show that every subsequence of $\{n\}$ has a further subsequence with $d_{BL}(\mathcal{L}(Y_n|Z_n), N(0, \sigma^2)) \to 0$ almost surely. From the assumption we know that every subsequence has a further subsequence with
\[ E(e^{\mathcal{Y}_n | Z_n}) \rightarrow e^{\mu^2/2} \text{ almost surely.} \]

For a countable set of \( t \), we can construct a single subsequence with this property for every \( t \) by a diagonalization scheme. Part (i) gives that \( d_{BL}(\mathcal{L}(\mathcal{Y}_n | Z_n), N(0, \sigma^2)) \rightarrow 0 \) almost surely along this subsequence.

(iii) This is immediate from (i).

7. Contraction rates. A first step in proving the semiparametric BvM is localizing the posterior near the true parameter by establishing a contraction rate. In this section we achieve this for the Gaussian priors in Section 3.4, mainly by combining the results of [14, 49] in our setting.

In the case of a product prior on different components of \((a, b, f)\), the posterior is a product measure, since the likelihood (2.2) factorizes. It then suffices to consider contraction in each component separately, and when considering the posterior distribution of one component, the other component(s) can be fixed to their true values, without loss of generality.

In particular, when considering an independent prior on the \( b \) component, we can set the parameters \( a \) and \( f \) to \( a_0 \) and \( f_0 \) and incorporate these into the dominating measure. Thus we use the restricted likelihood with parametrization \( \eta^b = \Psi^{-1}(b) \) given by

\[
p_{\eta^b}(x) = \Psi(\eta^b(z))^{ry}(1 - \Psi(\eta^b(z)))^{r(1-y)}
\]

with respect to the dominating measure

\[
d\nu(z, r, y) = (1/a_0(z))^{-r}(1 - 1/a_0(z))^{1-r} d\mu(r, y) dF_0(z),
\]

where \( \mu \) is counting measure on \( \{\{0, 0\}, \{1, 0\}, \{1, 1\}\} \).

The first result is an analogue of Lemma 3.2 of [49]; the proof is similar and omitted.

**Lemma 12.** For any measurable functions \( v^b, w^b : [0, 1] \rightarrow \mathbb{R} \) and \( q \geq 1 \),

- \( \|p_{v^b} - p_{w^b}\|_{L^q(\nu)} = \|\Psi(v^b) - \Psi(w^b)\|_{L^q(F_0/a_0)} \leq \|v^b - w^b\|_{L^2(F_0)}, \)
- \( K(p_{v^b}, p_{w^b}) \leq \|v^b - w^b\|_{L^2(F_0)}, \)
- \( V(p_{v^b}, p_{w^b}) \leq \|v^b - w^b\|_{L^2(F_0)}. \)

**Lemma 13.** Consider the Gaussian process prior (3.22) for \( b \). If \( \varepsilon^b_n \) satisfies (3.21) for \( i = b \) and concentration function with norm \( \| \cdot \|_{L^2(F_0)} \), then the posterior distribution for \( b \) concentrates about \( b_0 \) in \( L^2(F_0) \) at rate \( \varepsilon^b_n \).

**Proof.** Since the densities \( p_{w^b} \) are uniformly bounded, the \( L^2(\nu) \)-norm of the densities is bounded above by a multiple of the Hellinger distance.
We can thus apply Theorem 2.1 of [14] with $d$ equal to the $L^2(\nu)$-norm. Using Lemma 12 and arguing as in Theorem 3.2 of [49] gives contraction of the density in $L^2(\nu)$. Using the first result in Lemma 12, this equals the $L^2(F_0/a_0)$-norm, which is equivalent to the $L^2(F_0)$-norm if $1/a_0$ is bounded away from zero.

Next consider the propensity score-dependent prior (3.15) using the external estimator $\hat{a}_n$. As explained in the first paragraph of the proof of Theorem 3 it suffices to have the contraction rate with $\hat{a}_n$ set equal to a deterministic sequence of functions satisfying the known restrictions of $\hat{a}_n$. Only boundedness of the latter functions is needed.

**Lemma 14.** Consider the prior $\Psi(W^b + \lambda a_n)$ for $b$ with $W^b$ a centered Gaussian process independent of $\lambda \sim N(0, \sigma_n^2)$ and $a_n$ a sequence of functions with $\|a_n\|_\infty = O(1)$. If $\varepsilon_n^b$ satisfies (3.21) for $i = b$ and concentration function with norm $\|\cdot\|_{L^2(F_0)}$ and $\sigma_n = O(1)$, then the posterior for $b$ concentrates about $b_0$ in $L^2(F_0)$ at rate $\varepsilon_n^b$.

**Proof.** Since the densities $p_{w+\lambda a_n}$ are uniformly bounded, the $L^2(\nu)$-norm of the densities is bounded above by a multiple of the Hellinger distance. We can thus apply a triangular version of Theorem 2.1 of [14] (which is contained in [15]) with $d$ equal to the $L^2(\nu)$-norm.

Because $\|w + \lambda a_n - \eta_0^b\|_\infty \leq \|w - \eta_0^b\|_\infty + |\lambda|\|a_n\|_\infty$ and $\|a_n\|_\infty$ is bounded by assumption, Lemma 12 gives the existence of a constant $c$ such that

$$\{(w, \lambda) : \|w - \eta_0^b\|_\infty \leq c\varepsilon_n, |\lambda| \leq c\varepsilon_n\} \subset \{(w, \lambda) : (K \vee V)(p_{\eta_0^b}, p_{w+\lambda a_n}) \leq \varepsilon_n^2\}.$$ 

By the prior independence of $W^b$ and $\lambda$, the prior probability of the set on the left is lower bounded by $\Pi(\|W^b - \eta_0^b\|_\infty \leq c\varepsilon_n)\Pi(|\lambda| \leq c\varepsilon_n)$. For $\varepsilon_n = \varepsilon_n^b$ satisfying (3.21), the first term is lower bounded by $e^{-C_1 n\varepsilon_n^2}$ in view of Theorem 2.1 of [49]. The second term is bounded below by a multiple of $(\varepsilon_n/\sigma_n) \wedge 1 \geq \varepsilon_n$, for $\sigma_n = O(1)$. This verifies (2.4) of Theorem 2.1 of [14].

Let $B_n$ denote the sets constructed in Theorem 2.1 of [49] for the Gaussian process $W^b$ and set, for some large enough $M > 0$,

$$\mathcal{P}_n = \{p_{w+\lambda a_n} : w \in B_n, |\lambda| \leq M\sigma_n \sqrt{n\varepsilon_n}\}.$$ 

Property (2.3) of Theorem 2.1 of [49] gives that $\Pi(B_n^c) \leq e^{-C n\varepsilon_n^2}$. Combined with the univariate Gaussian tail inequality for $\lambda$ and a union bound, this yields that $\Pi(\mathcal{P}_n^c) \leq e^{-C n\varepsilon_n^2}$. By the first assertion of Lemma 12 and the
triangle inequality, \( \| p_w + \lambda_{an} - p_{\bar{w} + \bar{\lambda}_n} \|_{L^2(\nu)} \lesssim \| w - \bar{w} \|_{L^2(F_0)} + |\lambda - \bar{\lambda}| \| a_n \|_\infty \). It follows that, for some \( c_1 > 0 \),

\[
N(P_n, \| \cdot \|_{L^2(\nu), \varepsilon_n}) \leq N(B_{a_0}, \| \cdot \|_\infty, \varepsilon_n/2) N([0, 2M\sigma_n\sqrt{n}\varepsilon_n], |\cdot|, c_1\varepsilon_n). \]

Property (2.2) of Theorem 2.1 of [49] gives that the logarithm of the first term on the right side is bounded by a multiple of \( n\varepsilon_n^2 \). The logarithmic of the second term grows at most logarithmically in \( n \). Combined these imply that \( \log N(P_n, \| \cdot \|_{L^2(\nu), \varepsilon_n}) \lesssim n\varepsilon_n^2 \). This concludes the proof of the verification of (2.2)-(2.4) in Theorem 2.1 of [14], which establishes posterior contraction in \( L^2(\nu) \). Using the first result in Lemma 12, this equals the \( L^2(F_0/a_0) \)-norm, which is equivalent to the \( L^2(F_0) \)-norm since \( 1/a_0 \) is assumed to be bounded away from zero.

**Lemma 15 (Theorem 3.1 of [49]).** Consider the exponentiated Gaussian process prior (3.23) for \( f \). If \( \varepsilon_n \) satisfies (3.21) for \( i = f \) and concentration function with norm \( \| \cdot \|_\infty \), then the posterior for \( f \) concentrates about \( f_0 \) in Hellinger distance at rate \( \varepsilon_n^f \).

**Acknowledgements:** The first author would like to thank Richard Nickl for helpful conversations on symmetrization. Much of this work was done while Kolyan Ray was a postdoc at Leiden University.
