(Dated: January 21, 2022)

The prevalence of Milnor attractors has recently been reported in a class of high-dimensional dynamical systems. We study how this prevalence depends on the number of degrees of freedom by using a globally coupled map and show that the basin fraction of Milnor attractors increases drastically around 5-10 degrees of freedom, saturating for higher numbers of degrees of freedom. It is argued that this dominance of Milnor attractors in the basin arises from a combinatorial explosion of the basin boundaries. In addition, the dominance is also found in a system without permutation symmetry, i.e., a coupled dynamical system of non-identical elements. Possible relevance to the magic number $7 \pm 2$ in psychology is discussed.

PACS numbers: 05.45 Jn, 87.19 La, 05.45 Ra

In recent studies of dynamical systems with many degrees of freedom, the prevalence of Milnor attractors has been recognized\cite{1, 2}. The Milnor attractors are defined as follows: an arbitrary small perturbation to an orbit at a Milnor attractor can kick the orbit away from it to a different attractor, even though a finite measure of initial conditions is attracted to the attractor by temporal evolution\cite{3, 4, 5}. In other words, the basin of the attractor touches the attractor itself somewhere. An orbit is often attracted to a Milnor attractor, but can be kicked away from it by infinitesimal perturbation.

It should be noted that Milnor attractors can exist in low dimensional dynamical systems like a two-dimensional map as well. When changing the parameter of a dynamical system, the basin boundary of an attractor may move until, for a specific value of the parameter, the basin boundary touches the attractor. If, for this parameter value, the attractor has a positive measure of initial conditions forming the basin of attraction, it becomes a Milnor attractor. It is naively expected that the above situation occurs only for very specific parameter values (e.g., at a bifurcation point), and that the Milnor attractors may not exist for an open set of parameter values.

In recent studies of a class of dynamical systems, however, Milnor attractors are found to be sometime prevalent, occurring not only for specific isolated parameter values, but for continuous ranges of parameter values. Furthermore, the measure of the initial conditions that belong to the basin of these Milnor attractors is a relatively large proportion of the phase space. Indeed, for some parameter ranges, almost all randomly chosen initial conditions fall onto Milnor attractors\cite{1, 2}.

Such dominance of Milnor attractors is often found in high-dimensional dynamical systems, for example, globally coupled maps with 10 degrees of freedom or so, and within a range of parameter values where many attractors coexist. The question we address in the present Letter is why can there be so many Milnor attractors in a “high-dimensional” dynamical system, and how many elements are sufficient for constituting such ‘high’ dimensionality. With the help of numerical results obtained from simulations of globally coupled maps, we will show that the dominance starts to be common at 5 ~ 10 degrees of freedom. We propose a possible origin for this dominance of Milnor attractors, by noting a combinatorial explosion of saddle points (or more generally basin boundary points). We will also show that the prevalence of Milnor attractors is observed even in a system without symmetry, i.e., in a coupled dynamical system of non-identical elements. Finally we briefly discuss the possible relevance of our results to the magic number $7 \pm 2$ discussed in psychology.

As a prototype example to study this problem we use a globally coupled map\cite{3}

$$x_{n+1}(i) = (1 - \epsilon)f(x_n(i)) + \frac{\epsilon}{N} \sum_j f(x_n(j)), \quad (1)$$

where $n$ is the discrete time and $i$ the index for its elements ($i = 1, 2, \cdots, N = \text{dimension of the system}$). For the elements we choose $f(x) = 1 - ax^2$, since the model has thoroughly been investigated as a prototype model for high-dimensional dynamical systems. The coupling parameter $\epsilon$ is fixed at 0.1, since for this value the typical behaviors of the above GCM that are relevant here can be observed by changing only $a$.

In the present model, each attractor can be coded by the so-called clustering condition, that is to say, by the way how the $N$ elements of the system partition into mutually synchronized clusters, i.e., a set of elements in which $x_n(i) = x_n(j)$\cite{1}. Each attractor is coded by the number of clusters $k$ and the number of elements $N_k$ in each cluster with the clustering condition given by $(N_1, N_2, \cdots, N_k)\cite{1}$. Indeed, for a GCM with $N = 10\cite{1}$, that many initial conditions are attracted to a Milnor attractor. Here, in order to discuss the dependence of the size of the basin fraction of the Milnor attractors on the number of degrees of freedom, we have computed the
The increase of the number of attractors cannot explain the increase of the average basin fraction of Milnor attractors. In Fig.3, the increase of the basin for Milnor attractors is plotted as a function of the parameter interval $1.55 < a < 1.72$. In Fig.2, this average is plotted as a function of the number of degrees of freedom $N$. The increase of the average basin fraction of Milnor attractors with $N$ is clearly visible for $N \approx (5 \sim 10)$, while it levels off for $N > 10$.

Now we discuss how the dominance of Milnor attractors appears. In a system with identical elements, due to the symmetry, there are at least $M(N_1, \cdots, N_k) = \prod_{i=1}^{N_k} \prod\overset{\text{overset}{N_i}}{N_i} \prod_{i \neq j} N_j$ attractors for each clustering condition, where $m_\ell$ is the number of clusters with the same value $N_j$. Then, combinotorial increase in the number of attractors can be expected when many of the clustering conditions are allowed as attractors. However, the increase of the number of attractors cannot explain the increase of the basin for Milnor attractors. In Fig.3, we have plotted the number of attractors and the basin fraction of Milnor attractors for $N = 10$. As can clearly be seen, the dominance of the Milnor attractors is not necessarily observed when the number of attractors is high. Rather, the fraction of Milnor attractors gets large even when many attractors start to disappear with the increase of $a$.

For the parameter region where many attractors start to disappear, there remain basin boundary points separating such (collapsed) attractors and the remaining attractors. To explain the prevalence of Milnor attractors, we discuss how the distance between an attractor and the remaining attractors that are concluded to exist by the symmetry argument are also counted. The basin fraction of Milnor attractors obtained in the same way as in Fig.1 is also by dotted line with $\times$.
boundary does not change with $N$.

On the other hand, consider a boundary given by some condition for $(x_1, \cdots, x_N)$. In the present system with global (all-to-all) couplings, many of permutational change of $x_i$ in the condition give also basin boundaries. Here the condition for the basin is typically related with some attractor (or a ruin of collapsed attractor) that has clustering $(N_1, \cdots, N_k)$. Then there are $M(N_1, \cdots, N_k)$ partitions by boundaries equivalent by permutations. The number of regions partitioned by the boundaries increases combinatorially with $N$. Roughly speaking, it increases in the order of $(N - 1)!$, when the boundary has a variety of clusterings (i.e., large $M$). Recalling that the distance between an attractor and the basin boundary remain at the same order for the partition of the order of $2^N$, the distance should decrease if $(N - 1)!$ is larger than $2^N$. Since the former increases remarkably faster for $N > 5$ than the latter, the distance should decrease drastically for $N > 5$. Since this argument is applied for any basin boundary condition with a complex clustering having combinatorially large $M(N_1, \cdots, N_k)$, the distance between an attractor and such basin boundary may often go drastically small. For a certain parameter regime (1.64 < $a$ < 1.68 in the present case), basin boundaries with such partitions are dominant, and the above argument is applied to most attractors. Although this explanation may be rather rough, it gives a hint as to why Milnor attractors are so dominant when $N$ is larger than 5 ~ 10.

Since the above discussion is based mainly on simple combinatorial arguments, what we need is instability in orbits leading to many attractors, and global (all-to-all) couplings to allow for permutations of elements. Then, the dominance of Milnor attractors for $N \gtrsim (5 ~ 10)$ may be rather common in globally coupled dynamical systems. To check this possibility, we have also made numerical simulations for Josephson junction series arrays that are globally coupled through a resistive shunting load and driven by an rf bias current, given by

$$i_{\bar{m}} = g\dot{x}_m + g\dot{x}_j + g\sigma/N \sum_{j=1}^{N} \phi_{m} - x_m + \frac{1}{N} \sum_{j} f_j(x_j).$$

By using the parameter values adopted in [10], we have computed the basin volumes for Milnor attractors, at the partially ordered phase where a variety of attractors with many clusters coexist. Again, the basin volumes are close to 0 for $N \leq 4$, and increase at 5 < $N < 10$. It is also interesting that pulse-coupled oscillators with global coupling also show the prevalence of Milnor attractors for $N \geq 5$ [8].

So far reports on the prevalence of Milnor attractors have been limited to a system with symmetry. For example, in the GCM (1), the permutation symmetry arising from employing identical elements leads to a combinatorial explosion in the number of attractors as mentioned. Then, one may wonder whether the prevalence of Milnor attractors is possible only for such highly symmetric systems, especially because some Milnor attractors are known to disappear when introducing tiny asymmetries [11]. We have therefore studied a GCM with inhomogeneous parameters [12], given by $x_{n+1}(i) = (1 - \epsilon)f_i(x_n(i)) + \frac{1}{N} \sum f_j(x_n(j))$. with $f_i(x) = 1 - a_i x^2$, and $a_i = a_0 + a_w \frac{i - 1}{N - 1}$.

In Fig.4, we have plotted the basin fraction for Milnor attractors with the change of the parameter $a_0$ while fixing $a_w = 0.1$, for $N = 3, 4, \cdots, 10$. Although the fraction is smaller than in the homogeneous case, Milnor attractors are again observed and found to dominate the basin volume for some parameter region. As in the symmetric case, the basin fraction of Milnor attractors increases around $N \approx (5 ~ 10)$.

Note that even though complete synchronization between two elements is lost, clusterings as with regards to the phase relationships can exist [13]. For example, there are two groups when considering the oscillations of phases as large-small-large... and small-large-small..., that are preserved in time for many attractors. Similarly, it is natural to expect an explosion in the number of the basin boundaries for some parameter regime. Accordingly the argument on the dominance of Milnor attractors for a homogeneous GCM can be applied here to some degree as well.
The term magic number $7 \pm 2$ was originally coined in psychology [13], when it was found that the number of chunks (items) that is memorized in short term memory is limited to $7 \pm 2$. (See [15] for a pioneering study to relate this number with chaos.) To memorize $k$ chunks of information including their order (e.g., a phone number of $k$ digits) within a dynamical system, let us assign each memorized state to an attractor of a $k$-dimensional dynamical system, as is generally adopted in neural network studies. In this $k$ dimensional phase space, a combinatorial variety of attractors has to be presumed in order to assure a sufficient variety of memories. Depending on the initial condition (given by inputs), an orbit has to be separated to different attractors. Then, a combinatorial explosion of basin boundaries is generally expected with the increase of $k$, if the neural dynamics in concern are globally coupled (as often adopted in neural networks). Then, following the argument in the present paper, Milnor attractors may be dominant for $k > (5 \sim 10)$. (Recall that the number does not strongly depend on the choice of models, since it is given by the combinatorial argument.) Since the state represented by a Milnor attractor is kicked out by tiny perturbations, robust memory may not be possible for information that contains more than $7 \pm 2$ chunks. Although this explanation is a rough sketch, it can possibly be applied to other systems that adopt attractors as memory [19].

In dynamical systems, it is well known that the dimensional cutoff $\geq 3$ plays an important role for the existence of chaos. It is interesting then to investigate whether there are certain higher dimensions that similarly form dimensional boundaries beyond which the behavior of a dynamical system changes qualitatively. The present study may shed new light on this possibility. Also, it is interesting to note that in Hamiltonian dynamical systems, agreement with thermodynamic behavior is often observed only for degrees of freedom higher than $5 \sim 10$ [21]. Considering the combinatorial complexity woven by all the possible Arnold webs (that hence may be termed “Arnold spaghetti”), the entire phase space volume that expands only exponentially with the number of degrees of freedom may be covered by webs, resulting in uniformly chaotic behavior. If this argument holds, the degrees of freedom required for thermodynamic behavior can also be discussed along the line of the present Letter.

I would like to thank F. Willeboordse for critical reading of the manuscript. This work is partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture of Japan.

[7] For some cases it is also necessary to establish whether an attractor belongs to a period-2 band in the logistic map, since for some parameter region, the period-2 band motion remains even though the motion itself is chaotic [6].

[8] In the estimate here, ‘attractors’ with an escape rate of more than 50% are not counted as Milnor attractors in order to avoid possible inclusion of transient states. Even if they are included, however, there is only a small increase in the basin fraction. Note that in spite of the ‘severe’ criterion adopted here, Milnor attractors are dominant. See also [1].

[9] In this class of models, we have found that the fraction of Milnor attractors is larger for odd $N$ than for even $N$. Note that two clusters with equal cluster numbers and anti-phase oscillations generally have less chaotic instability. A globally coupled map with an even number of elements allows for equal partition into two clusters. This gives a plausible explanation for the smaller instability for even $N$ system.

[16] This does not necessarily imply that Milnor attractors are irrelevant to cognitive processes. Milnor attractors, for example, may be useful for chaotic search processes [1]. Searches with chaos iterating over attractor ruins has been discussed in [17, 18] with an experimental support on the olfactory bulb [19].

[19] Of course, the present argument should mainly be applied to systems with all-to-all couplings, or to highly connected network systems. If the connections are hierarchically ordered, the number of memory items can be increased. The often adopted module structure is relevant for this purpose.
