The interplay of nuclear effects on the $p_T > 2$ GeV inclusive hadron spectra in $d + Au$ and $Au + Au$ reactions at $\sqrt{s_{NN}} = 17, 200, 5500$ GeV is compared to leading order perturbative QCD calculations for elementary $p + p (p + p)$ collisions. The competition between nuclear shadowing, Cronin effect, and jet energy loss due to medium-induced gluon radiation is predicted to lead to a striking energy dependence of the nuclear suppression/enhancement pattern in $A + A$ reactions. We show that future $d + Au$ data can used to disentangle the initial and final state effects.

Introduction. Tomography is the study of the properties of matter through the attenuation pattern of fast particles that propagate and lose energy as a result of multiple elastic and inelastic scatterings. Recently, this technique has been applied in the field of nuclear physics [1,2] to map out the evolution of the QCD matter density produced in ultra-relativistic heavy ion reaction. It is based on the theoretical advances in understanding QCD multiparticle interactions in non-Abelian media [3,4].

The determination of the opacity of the transient quark-gluon plasma (QGP) produced in such reactions via jet tomography requires theoretical control over the interplay between many competing nuclear effects that modify the high-$p_T$ hadron spectra. These include nuclear modifications to the parton distribution functions (PDFs), referred to as shadowing [5], Cronin effect [6], and jet quenching [7], as well as the energy dependence of the underlying pQCD parton spectra. In this letter we propose an approach to disentangle these effects by comparing high-$p_T$ hadron yields in $p+p (\bar{p}+p)$, $d+A (p+A)$, and $A+A$ reactions over a very wide energy range. In particular, predictions are presented for $d+Au$ and central $Au+Au$ at center of mass energies per nucleon $\sqrt{s_{NN}} = 17, 200, 5500$ GeV typical of the CERN Super Proton Synchrotron (SPS), the Relativistic Heavy Ion Collider (RHIC), and the future Large Hadron Collider (LHC).

We demonstrate that at SPS the puzzling absence of quenching of $\pi^0$ in central $Pb+Pb$ [8] can be understood as due to a larger than previously expected Cronin enhancement [9] dominating over our predicted [4] suppression due to jet energy loss. At RHIC energies, on the other hand, we find that quenching dominates over both Cronin and shadowing effects. Furthermore, the interplay of these effects leads to a surprising approximately constant suppression factor of the Glauber geometry scaled [10] pQCD prediction in the $4 \leq p_T \leq 20$ GeV range. At LHC we predict that the $\pi^0$ suppression factor is substantially larger than at RHIC but also decreases systematically with transverse momentum in the $6 \leq p_T \leq 100$ GeV range due to the higher initial gluon densities expected and the hardening of the underlying initial jet spectra.

Particle spectra in $d + A$ and $A + A$. The scaling of high-$p_T$ hadron production in $d + A$ and $A + A$ is simply controlled by nuclear geometry in the absence of initial and final state interactions. The Glauber multiple collision model [10] can be used to calculate the number of binary nucleon-nucleon collisions at any impact parameter $b$. In $p + A$ the experimental cross section has usually been presented without centrality selection while in $A + A$ reactions hadron multiplicity distributions are generally presented with restricted centrality (impact parameter $b$) cuts. Dynamical nuclear effects for these cases are detectable through the nuclear modification ratio

$$R_{BA}(p_T) = \frac{d\sigma^{dA}_{AB}}{dyd^2p_T} \frac{2A d\sigma^{pp}}{dyd^2p_T} \frac{dN^{AA}(b)}{2A d\sigma^{pp}} = \frac{d\sigma^{dA}_{AA}(b)}{dyd^2p_T} T_{AA}(b) d\sigma^{pp}$$

in $d + A$ and

$$\frac{d\sigma^{dA}_{AA}(b)}{dyd^2p_T} = K \int dx_a dx_b \int d^2k_a d^2k_b g(k_a) g(k_b)$$

where $2A$ and $T_{AA}(b) = \int d^2x_T A(x_T)^2 B(b - x_T)$ in terms of nuclear thickness functions $T_{AA}(r) = \int dz p_A(r,z)$ are the corresponding Glauber scaling factors of $d\sigma^{pp}$. The lowest order pQCD differential cross section for inclusive $A + B \rightarrow h + X$ production that enters Eq. (1) is given by

$$\frac{1}{2A d\sigma^{2}} \frac{d\sigma^{dA}_{AA}(b)}{dyd^2p_T} = \frac{1}{T_{AA}(b)} d\sigma^{dA}_{AA}(b)$$

In Eq. (2) $x_a, x_b$ are the initial momentum fractions carried by the hard-scattered partons with probabilities sampled from the PDFs $f_{a/A}(x_a, Q^2_a)$. The momentum fraction carried away by the leading hadron $z_c = p_h/p_c$ is sampled from the fragmentation functions (FFs)
We use the leading order (LO) Glück-Reya-Vogt (GRV98) parameterization of PDFs [11] and the LO Binniewies-Kniehl-Kramer (BKK) parameterization of the FFs [12].

A constant $K$-factor and parton $k_T$ broadening function, $g(k) = \exp(\langle k_T^2 \rangle_{pp}/(k_T^2)_{pp}/\pi))$, are included to account phenomenologically for next-to-leading order corrections. In systematic fits [13] to the inclusive hadron production in $p+p(p+p)$ reactions these parameters are fixed from data [6,14]. The $K$-factor drops out in the ratios of $B$ to scaled $p+p$, but the phenomenological $k_T$ broadening in $p+p$ is essential to establish an accurate nuclear geometry scaled baseline. We find that a fixed $\langle k_T^2 \rangle_{pp} = 1.8$ GeV$^2$ reproduces to within 30% the spectral shapes in $p+p(p+p)$ for $p_T > 2$ GeV over the whole energy range of interest.

In $B+A$ reactions isospin effects are accounted for on average in the PDFs for a nucleus with $Z$ protons and $N$ neutrons via $f_{\alpha/p}(x, Q^2) = (Z/A) f_{\alpha/p}(x, Q^2_B) + (N/A) f_{\alpha/n}(x, Q^2_B)$. Nuclear modifications to the PDFs [5] are included through the shadowing function $S(x, Q^2_B)$ from the EKS98 parameterization [15].

The Cronin effect observed in $p+Au$ reactions relative to the Glauber-scaled $p+p$ result [6] is modeled via multiple initial state scatterings of the partons in cold nuclei. For an initial state parton distribution $dN(x,k)/dk$, random elastic scattering induces further $k_T$-broadening as shown for example in [9]. The possibility of hard fluctuations along the projectile path leads to a power law tail of the $k_T$ distribution that enhances $\langle \Delta k_T^2 \rangle_{x}$ beyond the naive Gaussian random walk result $\chi \mu^2$, where $\chi = \langle n \rangle = L/\lambda$ is the cold nuclear opacity in terms of the path length $L$ and the parton mean free path $\lambda$. The screening scale $\mu$ regulates the Rutherford divergence in a cold nucleus. For $\chi \mu^2 \ll k_T^2 \leq Q_{\max}^2$ the Rutherford tail leads to a logarithmic enhancement of the mean square momentum transfer $\langle \Delta k_T^2 \rangle_{x} = \chi \mu^2 \ln(1 + c Q_{\max}^2/\mu^2)$, where $c$ depends on the detailed form of the kinematic cut-off. For a high energy parton with transverse momentum $p_T$ produced in a $p+A$ reaction $Q_{\max}^2 \sim p_T^2$. We therefore model the Cronin effect by using

$$\langle k_T^2 \rangle_{pp} \approx \langle k_T^2 \rangle_{pp} + L_A \frac{\mu^2}{\lambda} \ln(1 + c p_T^2/\mu^2) .$$

in the $k_T$ broadening functions $g(k_\alpha)$ in Eq.(2), taking $L_A = 4/3 R_A$ as the mean nuclear thickness traversed. Fig. 1 shows that the calculation is consistent with the energy dependence $\sqrt{s} = 27.4, 38.8$ GeV [6] observed in $p+W/p+Be$ with transport parameters set as follows: $c/\mu^2 = 0.18/$GeV$^2$, $\lambda = 3.5$ fm and $\mu^2/\lambda = 0.05$ GeV$^2$/fm. These are consistent with $\mu^2/\lambda = 0.064 \pm 0.036$ GeV$^2$/fm extracted from fits to Drell-Yan data [16]. Fig. 1 also shows that the expected Cronin + shadowing effect in $p+W/p+Be$ at RHIC energies is much smaller than at lower energies because the high-$p_T$ pQCD spectra at $\sqrt{s}_{NN} = 200$ GeV are considerably less steep.

The effects of multiple scattering and nuclear shadowing in $d+Au$ and $Au+Au$ without final state interactions at SPS, RHIC, and LHC are shown in Fig. 2 for neutral pions. The numerical results for charged particles are comparable. Variations arise from the different partonic contribution and the correspondingly different shadowing for various hadron species [13]. In our model of the Cronin effect, the enhancement in $Au+Au$ at SPS energies of $\sqrt{s}_{NN} = 17$ GeV may reach a factor $\sim$ 4 at $p_T \approx 4$–5 GeV. This is greater than observed in $Pb+Pb$ reactions and also greater than estimated with the Cronin model of Ref. [8]. Unfortunately, at these low energies the results are extremely sensitive to model assumptions due the very rapid fall-off of the partonic spectra. We note that at least within our model, there is room for hadron suppression due to energy loss even at SPS. At RHIC for $\sqrt{s}_{NN} = 200$ GeV the Cronin enhancement spans the $p_T = 1-8$ GeV range and is seen to peak at $p_T \approx 3$ GeV. Its maximum value in $d+Au$ and $Au+Au$ is 1.3 (1.6) respectively. Similar and even smaller magnitudes of the Cronin effect at RHIC have been discussed in [17]. At higher transverse momenta the effects of isospin and shadowing lead to $R_{BA} \approx 0.8$ at $p_T \approx 20$ GeV. At LHC energies of $\sqrt{s}_{NN} = 5500$ GeV Cronin effect is overwhelmed by shadowing at small $x$ ($p_T < 10$ GeV) and anti-shadowing at larger $x$ when the EKS98 [15] parameterization is used. The net nuclear modification due to Cronin effect and shadowing at LHC is expected to be tiny (≤15%) throughout the $p_T$ range shown.

We turn next to the predicted suppression effects in nucleus-nucleus reactions due to jet quenching [7]. In Eq.(2) this is taken into account in the fragmentation function via the modification of the momentum fraction.
carried away by the leading hadron. If a jet of momentum $p_c$ prior to hadronization looses a fraction $0 \leq \epsilon < 1$ of its energy then $z = p_h/p_c \rightarrow z^* = z/(1 - \epsilon)$. The distribution $P(\epsilon, E)$ of the fractional energy loss of a fast parton with energy $E$ due to multiple gluon emission is computed as in Gyulassy-Levai-Vitev (GLV) [2].

We compute $P(\epsilon, E)$ taking into account the longitudinal Bjorken expansion the plasma (gluon) density $\rho(\tau) = (\tau_0/\tau_0)\rho(\tau_0)$, where $\tau_0\rho_0 = (1/\pi R_0^2) dN^g/dy$ relates to the gluon rapidity density produced in central $A + A$ that fixes the initial opacity. It has been shown that the azimuthally averaged energy loss is insensitive to transverse expansion [18]. The mean number of radiated gluons $\langle N^g(E) \rangle$ remains small due to the plasmon mass cut-off $\omega_{pd} \sim 0.5$ GeV [2]. Therefore, there is a finite $n = 0$ (no radiation) contribution $P_0(\epsilon, E) = e^{-\langle N^g(E) \rangle/\delta(\epsilon)}$. We have checked the sensitivity of the results to reducing the plasmon mass by a factor of two. This was found to lead to $\sim 25\%$ more suppression at $p_T = 5$ GeV and to $< 10\%$ increased suppression at $p_T = 20$ GeV for RHIC energies.

Our main results for central $Au + Au$ including all three nuclear effects (Cronin+Shadowing+Quenching) are presented in Fig. 3. Jet tomography consists of determining the effective initial gluon rapidity density $dN^g/dy$ that best reproduces the quenching pattern of the data [8,19-21]. At SPS the large Cronin enhancement is reduced by a factor of two with $dN^g/dy = 350$ but the data are more consistent with a smaller gluon density $\lesssim 200$. Unfortunately, as emphasized above, at this low energy the results are very sensitive to the details of the model. At RHIC, for $p_T > 2$ GeV jet quenching dominates, but surprisingly the rate of variation with $p_T$ of the Cronin enhancement and jet quenching conspire to yield an approximately constant suppression pattern with magnitude dependent on the initial $dN^g/dy$. At higher $p_T > 20$ GeV the softening of the initial jet spectra due to the EMC modification of the PDFs compensates for the reduced energy loss. This unexpected interplay between the three nuclear effects at RHIC is the main prediction of this letter. At LHC energies the much larger gluon densities $dN^g/dy \sim 2000 - 3500$ are expected to lead to a dramatic variation of quenching with $p_T$ as shown.

In nuclear media of high opacity the mean fractional energy loss $\langle \Delta E/E \rangle$ of moderately hard partons can become on the order of unity. For LHC this may be reflected in the $p_T \leq 10$ GeV region through deviations from the extrapolated high-$p_T$ suppression trend. Hadronic fragments coming from energetic jet would tend to compensate the rapidly increasing quenching (seen in Fig. 3) with decreasing transverse momentum and may restore the hydrodynamic-like participant scaling in the soft regime.

**Conclusions.** In this letter we predicted a characteristic evolution pattern of the magnitude and the $p_T$ dependence of the nuclear modification factor in $d + A$ and $A + A$ reactions as a function of the center of mass energy per nucleon. A systematic approach was used to take into account Cronin effect, nuclear shadowing, as well as jet quenching. Our results suggest that at SPS energies the Cronin enhancement may be larger than expected previously, leaving room for moderate energy loss. At RHIC we predict that the three nuclear effects in central $Au + Au$ lead to a surprising approximately constant suppression pattern of $\pi^0$ with $R_{AA}(p_T) \sim 0.3 - 0.2$.
for $dN^0/dy \sim 800 - 1200$. We emphasize that none of the nuclear effects alone would lead to such a flat $R_{AA}(p_T)$. At LHC shadowing and Cronin effect in the $6 \leq p_T \leq 100$ GeV range were found to be essentially negligible, leading to $\leq 15\%$ correction, while the jet quenching was predicted to be large and with a strong $p_T$ dependence. We emphasize the importance of future $d + Au$ data at RHIC to isolate and test the initial state Cronin and shadowing effects predicted in Fig. 2. While it is still too early to draw conclusions from the preliminary data [20,21] shown in Fig. 3, the combined future analysis of $d + Au$ and $Au + Au$ high-$p_T$ measurements will improve the tomographic determination of the initial gluon densities produced at RHIC.
