Abstract A search for alpha and double beta decays of ytterbium isotopes was performed with an ultra low-background high purity germanium detector at Gran Sasso Underground Laboratory (Italy). A 194.7 g Yb₂(C₂O₄)₃ powder sample was measured for 11.3 days with a total Yb exposure of 1.25 kg×day. Half-life limits for α-decay modes of 168Yb, 170Yb, 171Yb, 172Yb, 173Yb, 174Yb and 176Yb into the first excited states have been obtained between 6×10¹⁴ years and 2×10¹⁶ years. These are the first experimental constraints of these decay modes. Double electron capture of 168Yb and double beta decay of 176Yb into the first excited 2⁺ and 0⁺ states could be excluded with limits between 1×10¹⁴ years to 8×10¹⁶ years. This improves the experimental information on some of the decay modes compared to previous constraints.

1 Introduction

The study of rare nuclear decays is an active field of research with steady improvements utilizing more and more sensitive detectors. Experimental information on rare decays helps understanding nuclear structure, has applications in a variety of fields as nuclear chronometers and is relevant for long-lived backgrounds in other rare events searches. In the case of neutrinoless double beta decay it can even shed light on fundamental concepts beyond the Standard Model of particle physics. Those searches are often targeted to one particular purpose; however, in this work we pursued a more generic approach, investigating many different rare alpha and double beta decays in ytterbium isotopes.

Typically, two fundamentally different detection approaches are used. One where the target isotope is embedded in the detector material (“source = detector”) and one where the target isotope is external to the detector (“source ≠ detector”). Recent examples for the first method are searches for 180W α-decay with the isotopes embedded in scintillating crystals: 116CdWO₄ [1,2], CaWO₄ [3,4], and ZnWO₄ [5]. Limits for α-decays in lead isotopes were set with PbWO₄ detectors [6] and α-decays in 151Eu were investigated with CaF₂(Eu) crystals [7]. A particularly famous example is 209Bi which was long thought to be the heaviest stable isotope. In 2003, the α-decay of 209Bi was discovered with a half-life of 1.9×10¹⁹ years [8], the longest α-decay half-life ever measured. This removed bismuth from the list of elements with at least one stable isotope. In 2011 also the 209Bi α-decay transition to the first excited state was observed [9]. Both experiments were performed with scintillating bolometers based on Bi₄Ge₃O₁₂ (BGO) detectors. A major advantage of the “source=detector” approach is almost 100% detection efficiency as well being able to detect alpha’s and beta’s directly inside bulky large-mass target. The disadvantage is the limitation to certain target elements / isotopes which are suitable for detector manufacturing.

In contrast, the “source≠detector” approach allows to measure virtually all isotopes of interest with well established and high performing detector systems e.g. ionisation chambers or high purity germanium (HPGe) detectors. Ionization chambers for alpha-spectroscopy allow the direct measurement of alpha particles [10] with recent examples of half-life measurements in 147Sm [11] and 190Pt [12]. Precision half-life measurements in the 10¹¹ years range are
achieved but ultimately the sensitivity is limited since the sample thickness cannot be larger than a few microns. With HPGe γ-ray-spectroscopy the detection is limited to decay modes containing γ-rays in the final state. Recent examples for searches of α-decays to excited levels of the daughter nucleus with HPGe γ-ray spectroscopy are in dysprosium (using a Dy2O3 powder sample [13]), in europium (Eu2O3 powder [14]), in platinum (Pt metal [15]) and in osmium (Os metal [16]) isotopes. The best achieved sensitivities are on the level of $2 \times 10^{-24}$ years using low-background HPGe detectors in underground laboratories, optimizing the sample-detector geometry and using purified samples. For a recent review see [17].

In this work we extend the experimental information on rare α-decays in Yb isotopes using an ultra low-background HPGe detector setup in the “source ≠ detector” configuration. Ytterbium contains 7 quasi-stable isotopes ($^{168}\text{Yb}$, $^{170}\text{Yb}$, $^{171}\text{Yb}$, $^{172}\text{Yb}$, $^{173}\text{Yb}$, $^{174}\text{Yb}$ and $^{176}\text{Yb}$) which can undergo α-decay.

In addition, $^{176}\text{Yb}$ can undergo double beta decay. The two-neutrino mode ($2νββ$) is a second order standard model process with half-lives in the range of $10^{18}$–$10^{21}$ years. It has been observed in 11 isotopes using the “source=detector” approach. Decays into excited states of the daughter isotope have been observed in $^{150}\text{Nd}$ and $^{100}\text{Mo}$ [18] using the “source ≠ detector” approach and HPGe detectors. The neutrinoless mode ($0νββ$) is subject of intensive research with experiments reaching the tonne-scale in target mass. It has not been observed and would imply lepton number violation, the Majorana nature of neutrinos and help constraining the absolute neutrino mass scale [19].

The opposite processes of double electron capture ($2νee$ and $0νee$) can occur in $^{168}\text{Yb}$. The first compelling evidence of $2νee$ has recently been observed in $^{124}\text{Xe}$ with a half-life of $1.8 \times 10^{22}$ years [20] making it the slowest nuclear decay ever observed. Special cases are $0νee$ modes which nominally have no final state particles other than two x-rays from the two captured electrons. The remaining energy can be released by a Bremsstrahlung photon, carrying the remaining decay energy [21]. Other allowed processes are two Bremsstrahlung photons or an $e^−e^+$ pair in case of sufficiently available energy. However, the latter processes have more complex experimental signatures and are also suppressed by additional vertices. Hence this work focuses on the decay with one Bremsstrahlung photon. The two captures can occur from different electron shells with binding energies $E_{e1}$ and $E_{e2}$, removing energy from the Bremsstrahlung photon $E_γ$. The available energy is $E_γ = Q - E_{\text{level}} - E_{e1} - E_{e2}$ with respect to the Q-value and the energy of the nuclear final state $E_{\text{level}}$. K-shell and L-shell binding energies are about 57.5 keV and 9.7 keV, respectively in erbium [22]. Variations inside the shells are largely within the experimental energy resolution and are neglected. KK-shell captures are most likely, taking a total of 115.0 keV in binding energy. However, KK-shell captures are not allowed for decays into $0^+$ states of the daughter nucleus [21] making KL-shell captures with 67.2 keV binding energy the most likely ones for these cases. Only the most likely capture combinations are considered in this work. For a recent review on neutrinoless double electron capture see [23].

All investigated Yb isotopes and decay modes are listed in Table 1. The natural abundances of the isotopes, the decay daughters, the Q-values, and the investigated excited levels are listed. Decay schemes for all investigated Yb isotopes and transitions are shown in Figs. 1 and 2.

All decay modes require a γ-ray emissions as experimental signature to be detected in the “source ≠ detector” approach. For α-decays, the half-life scales with the available energy by $\log T_{1/2} \propto E^{−1/2}$ according to the Geiger–Nuttall law [24]. We thus limit the search to the lowest excited states for α-decays which are in the range of 60 to 100 keV for all Yb isotopes. For the ββ and $e^−e^+$ modes the half-life scales with the available energy by $T_{1/2} \propto E^{−11}$ and $T_{1/2} \propto E^{−5}$ for the $2ν$ and $0ν$ modes, respectively. Since all double beta decay isotopes have a $0^+$ ground state, the most likely transitions are to a $0^+$ states of the daughter. Spin suppression occurs for larger angular momentum transfers. Hence, we limit the search for double beta decays to the first excited $0^+$ state and all lower lying $2^+$ states.

Calculated half-life estimates for the α-decays are based on the cluster models [25,26], phenomenological fission theory of α-decay [27] and semi-classical WKB approximation [28]. Experimental limits on α-decays to the ground state exist only from a broad search in the 1950s [29] with an experimental half-life sensitivity of $10^{17}$ years assuming 100% isotopic abundance.¹ This work gives the first constraints on α-decays into excited states for all Yb isotopes.

Predictions for double beta decay half-lives are more difficult, requiring a nuclear matrix element obtained in a specific nuclear model framework. Predictions for excited state transitions are less frequently found in literature compared to ground state transitions. The only data is available for the $^{168}\text{Yb}$ $2νee$ 0$^+_1$ transition at $5.4 \times 10^{33}$ years (corresponding ground state transition at $2.0 \times 10^{35}$ years) [30]. For $^{176}\text{Yb}$, ground state transitions are predicted in [31] ($2ν$: 1.3 $\times 10^{26}$ years) and in [32] ($2ν$: 2.8 $\times 10^{23}$ years, $0ν$ at $m_\beta\beta = 1$ eV: 6.4 $\times 10^{25}$ years). Previous limits on double beta decay modes in $^{168}\text{Yb}$ and $^{176}\text{Yb}$ were established in [33], and are listed in the last column of Table 1.

¹ This generic experimental sensitivity has to be multiplied with the isotopic abundance of the isotope.
Table 1 Isotopes and decay modes investigated in this work. Shown is the Yb isotope, the natural isotopic abundance, the daughter isotope, the decay mode, the level state and energy, the Q-value, the theoretical half-life as discussed in the text and previous experimental constraints.

| Isotope  | Abundance [%] | Daughter  | Q-value [keV] | Mode          | Jπ Level [keV] | Tth1/2 [years] | Texp1/2 previous [years] |

Fig. 1 Decay schemes of Yb isotopes with \(\alpha\)-decay modes as investigated in this work. Data taken from [39]

2 Experimental setup and sample

The experimental setup used for this work is the \(\gamma\)-spectrometry HPGGe detector “GeMPI” [34,35], one of the world’s most sensitive low-background detectors. It is located underground in the Gran Sasso National Laboratories of the I.N.F.N. (Italy) which provides an average shielding of 3600 m w.e. overburden against cosmic muons. The coaxial p-type germanium detector has 405 cm³ active volume and 2.15 kg mass. The energy resolution of the spectrometer is 2.0 keV at the 1332 keV \(^{60}\)Co \(\gamma\)-line. The detector is shielded by 20 cm of low-radioactivity lead with < 133 Bq/kg in the outer layer, 32 Bq/kg in a central layer and < 5 Bq/kg in the inner layer. Inside the lead shield is a 5 cm copper layer. In order to remove radon, the setup is continuously flushed with nitrogen which stems from the gas phase of a liquid nitrogen storage tank. Interlocks for sample insertion and Rn daughter suppression are all enclosed in an air tight aluminum and steel housing (1 mm thick) with butyl rubber gloves (0.8 mm). The detector has a big sample chamber of 250 × 250 × 220 mm.

Various samples containing ytterbium have been investigated for suitability in the rare decay search: \(\text{Yb}_2\text{O}_3\) powder (0.198 kg), \(\text{Yb(NO}_3\text{)}_3\) solution (0.882 kg in 3 liter of weak nitric acid), and \(\text{Yb}_2(\text{C}_2\text{O}_4)_3\) powder (0.195 kg). The latter sample was selected for having the lowest internal background of radioisotopes. This is shown in Table 2. The specific activities were determined via \(\gamma\)-ray spectroscopy in the same dataset that was later used for the main search. The detection efficiencies were obtained using Monte-Carlo simulation in the MaGe framework [36] based on the GEANT4. Limits are set with the Feldman Cousins method [37].
Fig. 2 Decay schemes of Yb isotopes with double beta decay and α-decay modes as investigated in this work. 168Yb has multiple ee decay modes: 2νee is only detectable if the decay goes to one of the excited states. 0νee could also occur radiatively, adding a Bremsstrahlung γ-ray to the final state. The γ-ray energy depends on the atomic shells of two electron captures, sharing the available energy with a combination of XKK or XKL. Angular momentum conservation does not allow the KK capture combination for decays into 0+ states. Data taken from [39].

No evidence for background from the natural decay chains 235U, 238U, and 232Th are observed in the sample. Upper limits are set on the mBq/kg level. Other common radionuclides, such as 40K from natural radioactivity or 137Cs from artificial origins, are also not observed. However, a significant activity of 169Yb, 175Yb, and 176Lu was measured. Short-lived 169Yb (32.0 days) and 175Yb (4.2 days) isotopes are produced by cosmic rays via neutron spallation and through thermal neutron capture on ytterbium isotopes present in its natural abundance. The relatively high observed activities of 22 and 150 mBq/kg for 169Yb and 175Yb, respectively, are due to sample storage above ground, followed by the underground measurement shortly afterwards. The presence of 176Lu (2.6% natural abundance in lutetium, T1/2 = 3.76 × 1010 years) is expected due to similar chemical properties of lutetium and ytterbium which leads to difficulties in chemical separation.

ICP-MS measurements for complementary background estimates were not possible for this sample. The isotopic abundances of Yb isotopes are taken as the natural abundance from literature [39].

For the measurement, 194.7 g of Yb2(C2O4)3 powder was contained in a plastic container and placed directly on the endcap of the ultra low-background HPGe detector. Data was taken for 11.3 days. The full spectrum is shown in Fig. 3 on the left and a zoom into the low energy region is shown on the right. Prominent peaks and the regions of interests are labeled.

Table 2 Radioactive contamination of the 194.7 g Yb2(C2O4)3 powder sample obtained from the same data as described for the main search. The upper limits are given at 90% C.L., and the uncertainties of the measured activities at 68% C.L.

| Chain | Nuclide | Activity [mBq/kg] |
|-------|---------|------------------|
| 238U  | 226Ra   | < 5.0            |
| 235U  | 234Pa   | < 140            |
| 232Th | 228Ra   | < 4.0            |
|       | 228Th   | < 5.0            |
| 40K   |         | < 17             |
| 60Co  |         | < 2              |
| 137Cs |         | < 2              |
| 169Yb |         | 22 ± 5           |
| 175Yb |         | 150 ± 36         |
| 176Lu |         | 15 ± 2           |

3 Analysis

The analysis is a peak search for the de-excitation γ-rays from each decay mode independently. The peak fits are performed in a Bayesian framework using the Bayesian Analysis Toolkit (BAT) [40]. The likelihood L is defined as the product of the Poisson probabilities over each bin i for observing n_i events while expecting λ_i events. λ_i is the sum of the signal S_i and background B_i expectation:

\[
L(p|n) = \prod_i \frac{λ_i(p)^{n_i}}{n_i!} e^{-λ_i(p)}, \quad λ_i(p) = S_i + B_i.
\]  

(1)

Here n denotes the data and p the set of floating parameters.
$S_i$ is the integral of the Gaussian peak shape in bin $i$ given the total signal peak counts $s$

$$S_i = \int_{\Delta E_i} \frac{s}{\sqrt{2\pi} \sigma_E} \cdot \exp\left(-\frac{(E - E_0)^2}{2\sigma_E^2}\right) dE,$$  

(2)

where $\Delta E_i$ is the bin width, $\sigma_E$ the energy resolution, and $E_0$ the $\gamma$-line energy as the mean of the Gaussian. $B_i$ is the background expectation

$$B_i = \int_{\Delta E_i} b + c (E - E_0)$$

$$+ \sum_l \left[ \frac{b_l}{\sqrt{2\pi} \sigma_l} \cdot \exp\left(-\frac{(E - E_l)^2}{2\sigma_l^2}\right) \right] dE,$$  

(3)

which is implemented as a linear function (parameters $b$ and $c$) and $l$ Gaussian background peaks in the fit window, depending on the decay mode.

The signal counts are connected with the half-life $T_{1/2}$ of the decay mode as

$$s = \ln 2 \cdot \frac{1}{T_{1/2}} \cdot \epsilon \cdot N_A \cdot T \cdot m \cdot f \cdot \frac{1}{M},$$  

(4)

where $\epsilon$ is the full energy peak detection efficiency, $N_A$ is Avogadro’s constant, $T$ is the live-time (11.3 days), $m$ is the mass of Yb in the sample (110.4 g), $f$ is the isotopic fraction of the respective Yb isotope, and $M$ is the molar mass of natural Yb (173.05).

A prior probability is assigned to each free parameter. The prior distribution for the inverse half-life $(T_{1/2})^{-1}$ and the linear background parameters is flat. For energy resolution, peak position and detection efficiencies, the priors are Gaussian distributions centered around the mean values of these parameters and a width of the parameter uncertainty. This naturally includes the systematic uncertainty into the fit result.

The uncertainty of the peak positions are set to 0.1 keV. The energy scale and resolution is obtained from standard calibration spectra with an estimated uncertainty of 5%. The full energy peak detection efficiencies are determined with Monte-Carlo simulations in the MaGe framework [36], based on Geant4. The decays were generated independently for each decay mode using Decay0 [38]. The number of simulated decays was chosen so that the statistical uncertainty in the simulation is subdominant to the estimated systematic uncertainty. A total of 10% uncertainty is estimated for the detection efficiencies and used as prior input. Systematic uncertainties on the measured sample mass and the isotopic fraction in the sample are small with respect to the uncertainty of the detection efficiency and are neglected.

Background $\gamma$-lines above 1\% emission probability from the $^{238}\text{U}$ and $^{232}\text{Th}$ decay chains are included in the fit windows. Also included are $\gamma$-lines from the $^{176}\text{Lu}$ and $^{169}\text{Yb}$ isotopes in the target powder where applicable. For these searches this affects only the low energy region through $63.1$ keV (4.3\%, $^{169}\text{Yb}$), $63.2$ keV (3.6\%, $^{176}\text{Lu}$), $63.3$ keV (2.7\%, $^{234}\text{Th}$), $64.9$ keV (1.2\%, $^{176}\text{Lu}$), $84.4$ keV (1.2\%, $^{238}\text{Th}$), $88.3$ keV (14.5\%, $^{176}\text{Lu}$), $92.4$ keV (2.1\%, $^{234}\text{Th}$), $92.8$ keV (2.1\%, $^{234}\text{Th}$), $93.6$ keV (2.6\%, $^{169}\text{Yb}$), $99.5$ keV (1.3\%, $^{228}\text{Ac}$), and $129.1$ keV (2.4\%, $^{228}\text{Ac}$) $\gamma$-rays, with emission probability and isotope in parenthesis. The $88.3$ keV $\gamma$-line from $^{176}\text{Lu}$ originates from the same final state in $^{176}\text{Hf}$ as the $^{176}\text{Yb} 2\nu\beta\beta 2^+_{\text{e+}}$ transition, making this decay mode signal indistinguishable from background. Hence, no discovery is possible in this case. Nevertheless, peak counts and thus a half-life can be constrained with a limit. Similarly, for the $^{173}\text{Yb}$ $\alpha$-decay, the $64.6$ keV signal $\gamma$-line is too close to background $\gamma$-lines to be resolved. Also here only a half-life exclusion below a certain value is possible.

The posterior probability distribution is calculated from the likelihood and prior probabilities with BAT. It is then marginalized for $(T_{1/2})^{-1}$. The best fit values for all decay modes is consistent with zero signal counts and the 0.9 quantile of the distribution is used to set 90\% credibility limits.

The results are shown for all investigated decay modes in Table 3. Also shown are the $\gamma$-line energies, the full energy

Fig. 3 Measured HPGe spectrum of the 194.7 g Yb$_2$(C$_2$O$_4$)$_3$ powder sample obtained in 11.3 days. Left: full spectrum normalized to counts per day. Right: zoom in to the low energy region in original DAQ binning. Prominent background peaks and regions of interest are highlighted.
peak detection efficiency and the resolution for the $\gamma$-lines used in the analyses. For the $^{168}\text{Yb}$ $2\nu\nu\gamma$, $0\nu\text{KK}$ $2^+_1$, $0\nu\text{KK} 2^+_2$, and $0\nu\text{KL}$ $0^+_1$ decay modes, multiple $\gamma$-lines are used, each having its own fit window, likelihood, and free parameters but sharing the same half-life parameter in Eq. 4.

The half-life limits are strongly dependent on the isotopic abundance and the detection efficiency. For $\alpha$-decays into excited states, the lower limits range from $6 \times 10^{14}$ years to $2 \times 10^{16}$ years. For double beta decay modes, half-lives up to $8 \times 10^{16}$ years could be excluded.

### 4 Discussion and conclusion

A general search for rare nuclear decays was performed in ytterbium isotopes using an ultra low-background HPGe $\gamma$-spectroscopy setup and a 194.7 g $\text{Yb}_2(\text{C}_2\text{O}_4)_3$ powder sample. The search included $\alpha$-decays, double beta decays and double electron captures into excited states of the daughter isotopes. No signal was found and 90% credibility limits were set using a Bayesian analysis. These results are the first constraints on the $\alpha$-decay modes. Existing constraints on double beta decay and double electron capture mode could be confirmed and partially improved. The achieved sensitivity, however, is still far away from theoretical predictions (Table 1).

General improvements for this measurement can be achieved through background reduction and increased mass and measurement time. The natural radionuclide content of the sample was already very low. No significant contribution from the natural decay chains $^{235}\text{U}$, $^{238}\text{U}$, and $^{232}\text{Th}$, nor from $^{40}\text{K}$, $^{60}\text{Co}$, and $^{22}\text{Cs}$ were detected. Some radioactivity of $^{169}\text{Yb}$, $^{175}\text{Yb}$, and $^{176}\text{Lu}$ was observed. However, it did not strongly interfere with the measurement. The $\text{Yb}_2(\text{C}_2\text{O}_4)_3$ sample in this work contained a significantly lower contamination of $^{176}\text{Lu}$ (15 mBq/kg) compared to the $\text{Yb}_2\text{O}_3$ sample used in a previous search [33] (420 mBq/kg). This allowed for a lower background in searches of decay modes with $\gamma$-ray emissions below 300 keV. The precise control of the $^{176}\text{Lu}$ contamination is also the only way to probe the $^{176}\text{Yb} 2\nu\beta\beta 2^+_1$ transition which shares the same de-excitation $\gamma$-ray. Further purification can be achieved through liquid-liquid extraction of inorganic ytterbium compounds followed by their transformation to metallo-organic $\text{Yb}_2(\text{C}_2\text{O}_4)_3$. A factor of 10 reduction of $^{40}\text{K}$, U/Th-chain backgrounds has been demonstrated in $\text{CeO}_2$, $\text{Gd}_2\text{O}_3$, and $\text{Nd}_2\text{O}_3$, as described in [41]. Mitigation of cosmogenically produced short-lived $^{169}\text{Yb}$ and $^{175}\text{Yb}$ isotopes can be achieved by underground storage for multiple half-lives of a few months. The mea-
measurement time of 11 days could be significantly improved in future measurements. A 3 years measurement would increase the sensitivity by about an order of magnitude.

To approach the predicted half-lives, a drastic improvement of detection efficiencies is necessary. Realistically, this can only be achieved by applying the “source = detector” approach, where target isotopes are embedded into the detector material. Crystals, such as Yb$_2$SiO$_5$, operated as scintillators, as bolometers, or as a combination of both could be used. This would especially benefit the low energy region where multiple orders of magnitude improvement in detection efficiency can be achieved. Alphas would be detected directly, making ground state transitions accessible. Pulse-shape discrimination of alpha and electron recoil interaction would allow a practically background-free search for $\alpha$-decays modes.

Ultimately, enrichment of specific ytterbium isotopes could gain another one or two orders of magnitude improvement in sensitivity for a focused search in a certain ytterbium isotope. However, this procedure is expensive (level of $1000/mg$) and only feasible for relatively small target masses.

Acknowledgements These results have been obtained as a by-product of internal radioactive contamination studies for Yb$_2$(C$_2$O$_4$)$_3$ compounds in connection with the LENS (Low Energy Neutrino Search) experiment [42].
