ABSTRACT
A bright burst, followed by an X-ray tail lasting \( \sim 10 \) ks, was detected during an XMM-Newton observation of the magnetar 1E 1547.0–5408 carried out on 2009 February 3. The burst, also observed by Swift/BAT, had a spectrum well fit by the sum of two blackbodies with temperatures of \( \sim 4 \) keV and 10 keV and a fluence in the 0.3–150 keV energy range of \( \sim 10^{-5} \) erg cm\(^{-2} \). The X-ray tail had a fluence of \( \sim 4 \times 10^{-8} \) erg cm\(^{-2} \). Thanks to the knowledge of the distances and relative optical depths of three dust clouds between us and 1E 1547.0–5408, we show that most of the X-rays in the tail can be explained by dust scattering of the burst emission, except for the first \( \sim 20–30 \) s. We point out that other X-ray tails observed after strong magnetar bursts may contain a non-negligible contribution due to dust scattering.

1 INTRODUCTION
Dust grains in the interstellar medium cause small-angle scattering of soft X-ray photons. Due to this effect, if there is a significant amount of interstellar dust along the line of sight, bright point-like X-ray sources may appear surrounded by diffuse X-rays (the so-called “scattering halo”), as predicted by Overbeck (1965) and first observed by Roll (1983) and Catura (1983). The study of such X-ray halos can provide important information on the properties of the interstellar dust (e.g. Mathis & Lee 1991; Draine 2003; Costantini et al. 2005).

Due to their longer path length, scattered X-rays have a time delay with respect to the unscattered ones. In the case of variable sources, this effect can be used to derive information on the source distance and the spatial distribution of the dust (Trümper & Schönfelder 1973; Predehl et al. 2000; Miralda-Escude 1999). Short duration bursts scattered by thin layers of dust produce dust-scattering rings which appear to expand with time around the central source. Such rings were seen around galactic binary systems (e.g. Heinz et al. 2015, 2016; Vasilopoulos & Petropoulou 2016), magnetars (e.g. Tiengo et al. 2010; Svirski et al. 2011), and gamma-ray bursts (e.g. Vaughan et al. 2004; Tiengo & Mereghetti 2006; Vianello et al. 2007).

The presence of delayed scattered radiation can also affect the time profile and spectrum of the X-rays detected after bright bursts. This must be taken into account when instruments with inadequate angular resolution, which do not permit to disentangle the scattered and unscattered components, are used. For example, it has been suggested that some of the X-ray afterglows of gamma-ray bursts, in particular those showing a long plateau phase, are due to scattering from dust in the host galaxies (Shao & Dai 2007; Shao et al. 2008). Although Shen et al. (2009) showed that the lack of spectral evolution of most afterglows is inconsistent with this hypothesis, a few cases in which at least part of the X-ray emission can be explained by dust scattering have been recently reported (see, e.g., Holland et al. 2010; Evans et al. 2014; Wang et al. 2016).

In this work, we evaluate the effects of dust scattering on the observed properties of the X-ray tails seen after magnetar bursts, using, as a case study, an XMM-Newton observation of 1E 1547.0–5408 in which a burst followed by a decaying tail lasting \( \sim 10 \) ks was detected. 1E 1547.0–5408 is a transient magnetar which showed three outburst episodes (Bernardini et al. 2011) and is surrounded by extended X-ray emission consistent with a dust scattering halo (Olausen et al. 2011). This source is particularly suitable for our investigation since, thanks to previous analysis of three dust scattering rings caused by a much brighter burst, some of the properties of the dust in this direction are already known (Tiengo et al. 2010).
In Section 2 we present the data reduction of the XMM-Newton and Swift observations; in Section 3 we first characterize the properties of the persistent emission and of the burst of 1E 1547.0–5408 and then analyze the time evolution of the radial profiles of the X-ray tails and we fit the tail light curve and spectrum with a dust scattering model. We discuss our results in Section 4 where we also compare this event from 1E 1547.0–5408 with other magnetar bursts and flares followed by extended tails.

2 DATA REDUCTION

We analyzed an XMM-Newton observation of 1E 1547.0–5408, with exposure time of ~56 ks, taken on 2009 February 3. This is the same observation used by Tiengo et al. (2010) to study the dust scattering rings produced by a bright burst that occurred on January 22 (Mereghetti et al. 2009). We note that the presence of such rings, at angular distance larger than 3′′ from the central source, does not affect the analysis presented here.

The three cameras of the EPIC instrument, one pn camera (Strüder et al. 2001) and two MOS cameras (Turner et al. 2001), were operated in full-frame mode and with a thick optical blocking filter. We reduced the data with the SAS v.14.0.0 software, selecting single- and double-pixel events (PATTERN≤4) for the pn and single- and multiple-pixel events for the MOS (PATTERN≤12). Because of its high count rate (>6 cts s⁻¹ in the EPIC-pn), the source data were affected by pile-up, therefore we extracted the source spectra and lightcurves from an annular region with inner and outer radii of 5′′ and 40′′, respectively. The background was extracted from a circular region of radius 60′′ free of sources. For the RGS instrument we obtained the source events following the standard procedures described in the SAS thread.

We also used a Swift/BAT observation (Obs.ID: 00341965000) taken almost simultaneously with the XMM-Newton one. Spectra and lightcurves were extracted following the standard data reduction procedures described in the Swift/BAT thread.

The spectral fits were carried out with the XSPEC v.12.8.2 software package, adopting the PHABS model, with the solar abundances of Wilms et al. (2000), for the interstellar absorption. All the errors in the spectral parameters reported below are at the 90% confidence level for a single interesting parameter.

3 DATA ANALYSIS AND RESULTS

During the XMM-Newton observation, 1E 1547.0–5408 emitted several short bursts (Fig. 1). In this work we concentrate on the brightest one, which was followed by a tail of enhanced X-ray emission lasting about 10 ks. In the analysis of the EPIC data, we removed short time intervals corresponding to all the fainter bursts visible during the observation.

We derived the properties of the persistent emission of 1E 1547.0–5408 from the last ~9 ks of the XMM-Newton observation, when the source had the lowest count rate and no bursts were emitted. We extracted the EPIC-pn spectrum, in the energy range 1–10 keV, from this time interval and fitted it with the phenomenological model usually adopted for magnetars in this energy range, i.e. an absorbed blackbody plus power-law model (Mereghetti 2008). We obtained a good fit ($\chi^2$/dof = 139.55/128, see Fig. 2) with the following parameters: column density $N_H=(4.2 \pm 0.3) \times 10^{22}$ cm⁻², blackbody temperature $kT=0.64\pm0.03$ keV, emitting radius $R=(1.8\pm0.2)\cdot d_{\text{sky}}$ km, power-law photon index $\Gamma=1.8\pm0.3$ and normalization $F_{\text{1keV}}=1.0_{-0.5}^{+0.8} \times 10^{-2}$ photons cm⁻² s⁻¹ keV⁻¹. The absorbed and unabsorbed fluxes in the 1–10 keV energy range are $(4.59\pm0.06) \times 10^{-11}$ erg cm⁻² s⁻¹ and $(8.3\pm0.2) \times 10^{-11}$ erg cm⁻² s⁻¹, respectively. These results are consistent with those reported by Bernardini et al. (2011), who did not exclude the time interval of the burst tail from their spectral analysis.

3.1 Burst properties

The initial part of the brightest burst could not be studied with EPIC because the saturation effect due to the high count rate caused a severe loss of photons. Therefore, to derive the burst fluence, we used the Swift/BAT and the RGS data which were not affected by saturation.

The BAT data show that the burst started at $T_b=20:00:39.47$ UT of 2009 February 3. Its light curve, in the energy range 15–150 keV, is shown in Fig. 3; the most energetic part of the burst, with peak intensity of ~1.3 counts s⁻¹, is clearly visible, as well as the X-ray tail with duration of ~2160 s.
keV (Fig. 3), was characterized by a bright peak lasting \( \sim 0.1 \) s, followed by fainter emission lasting about 0.2 s. The burst was also clearly visible in the RGS data, with a start time consistent with the above value, considering the limited time resolution of the two cameras (read-out times of \( \sim 5 \) s and \( \sim 10 \) s).

To estimate the burst fluence, we extracted the BAT and RGS1 and RGS2 spectra of the burst events only, for time intervals of \( \sim 30 \) ms and 10 s, respectively. Since at these time scales the persistent emission contribution is negligible, we studied the burst spectrum in fluence units by assigning an exposure time of 1 s to the RGS and BAT spectra. Despite the low RGS count statistics, both RGS and BAT spectra. Despite the low RGS count statistics, we could constrain the burst spectral shape at low energies. We fitted the spectra simultaneously in the range 0.3–150 keV, with the column density fixed at the value of \( 4 \times 10^{22} \) cm\(^{-2} \) derived for this region.

We fitted the spectra of the burst events only, for time intervals of 3 s and 10 s, respectively. Since at these time scales the persistent emission contribution is negligible, we studied the burst spectrum in fluence units by assigning an exposure time of 1 s to the RGS and BAT spectra. Despite the low RGS count statistics, we could constrain the burst spectral shape at low energies. We fitted the spectra simultaneously in the range 0.3–150 keV, with the column density fixed at the value of \( 4 \times 10^{22} \) cm\(^{-2} \) derived for this region.

t\( (t - T_0) = (0.47 \pm 0.09) e^{-t/(t-T_0)/(2496 \pm 475)} \) cts s\(^{-1} \).

To study the angular distribution of the tail emission and its time evolution, starting from the burst epoch, we built the radial profiles for several, consecutive, time intervals of different durations from the summed pn and MOS images. We subtracted from these profiles the radial profile of the persistent emission, derived from the same time interval used for the spectral analysis. The resulting net radial profiles, shown in Fig. 6, suggest the presence of excess emission at an angular distance which increases with time. The fit of the radial profiles with a King function (as expected from the EPIC PSF) was not acceptable (\( \chi^2 > 2 \)) in all but the first two time intervals, clearly indicating time variability of the profiles, possibly due to the presence of dust-scattering expanding rings. Note that these deviations from a King profile cannot be attributed to pile-up, since the importance of this effect increases with the source count-rate and it should therefore affect the first time intervals rather than the ones found to be inconsistent with the PSF.

We fitted the radial profiles with a Lorentzian function, plus a constant to account for variable diffuse emission on large spatial scales. We fixed the width of the Lorentzian to 10′, corresponding to the value expected for a geometrically-thin ring profile broadened by the EPIC PSF. With this model we found a significant improvement in the quality of the fits for all the radial profiles (\( \chi^2 \sim 1 \); Fig. 6).

The evolution of the centroid of the Lorentzian component as a function of time is shown in the left panel of Fig. 7. We fitted the centroid values with the model expected to describe the angular expansion, \( \theta(t) = K(t - T_0)^{0.5} \), and we found \( K = 0.884 \pm 0.045 \)

\( 10^{-6} \) erg cm\(^{-2} \) (9.9 \( \times 10^{-6} \) erg cm\(^{-2} \)), while in the 4–10 keV range it was \( 1.1 \times 10^{-6} \) erg cm\(^{-2} \) (1.2 \( \times 10^{-6} \) erg cm\(^{-2} \)).
3.3 Dust scattering modelling of the tail light curve

The above results indicate that at least part of the tail emission is consistent with a dust scattering ring which was expanding at the same rate measured by Tiengo et al. (2010) for the inner ring produced by the strong burst of January 22.

As a further check, we computed the light curve expected for the scattered emission in the 4–10 keV band, where the tail is more evident. We adopted the grain model that gave the best fit to the data of Tiengo et al. (2010), i.e. the BARE-GR-B model of Zubko et al. (2004), and the corresponding distances for 1E 1547.0–5408 (3.9 kpc) and for the three dust layers (3.4, 2.6 and 2.2 kpc).

We used the spectral distribution and fluence of the burst derived in section 3.1 and included the effect of the three dust layers with column densities fixed at 1 $\times$ 10$^{22}$, 0.24 $\times$ 10$^{22}$ and 0.27 $\times$ 10$^{22}$ cm$^{-2}$ (Tiengo et al. 2010). We also assumed that the dust layers are geometrically thin and that the burst was instantaneous.

In Fig. 8 we compare the computed lightcurve (red line) with the observed data. Clearly, we cannot reproduce the data with the above column density values. Instead, we found that a $\sim$ 3.5 times higher column density in the three dust layers is required to describe the tail lightcurve after the first $\sim$ 20 s (blue line in Fig. 8).

3.4 Spectral analysis of the tail

The results described above indicate that the angular distribution and the light curve of the X-ray tail, at least for times greater than $\sim T_0+20$ s, are consistent with those expected for dust scattering. Here we investigate whether also the spectral properties of the tail emission are consistent with this hypothesis.

We created an XSPEC table model with the spectra expected for the scattered emission. We computed it for a range of distances of 1E 1547.0–5408 (from 0.1 to 10 kpc) and using again the BARE-GR-B dust model. For each value of the source distance, the relative distances of the three dust layers are determined by the measured rates of expansion of the rings (Tiengo et al. 2010). We assumed that the optical depths of the two closer dust layers are 24% and 27% of that of the layer responsible for the inner ring. We fixed the burst spectrum and its fluence as done above for the light curve computation. Therefore, the table model has only two parameters: source distance and column density of the farthest dust layer, N$_{H1}$.

We fitted the pn spectrum of the tail extracted in the time interval from $T_0 + 20$ s to $T_0 + 4$ ks. The limit of 4 ks was chosen because, for longer exposure times, the signal-to-noise ratio of the spectrum is too low. The contribution of the persistent emission was included in the fit, with parameters fixed at the best-fit blackbody plus powerlaw model described above.

Since the source distance was poorly constrained, we fixed it at 3.9 kpc and found a very good fit ($\chi^2$/dof = 62.79/67) with N$_{H1}$ = (4.0 $\pm$ 0.4) $\times$ 10$^{22}$ cm$^{-2}$ (see Table 1 and Fig. 9). The total column density in the three dust layers, N$_{H1}$ $\times$ (1 + 0.24 + 0.27) = (6.0 $\pm$ 0.6) $\times$ 10$^{22}$ cm$^{-2}$ is about a 40% larger than that derived

\[\chi^2 = \sum \frac{(y_i - \bar{y}_i)^2}{\sigma_i^2} \]

\[\text{dof} = \text{degrees of freedom} = \text{number of data points} - \text{number of parameters} \]

\[N_{H1} = \text{column density of the farthest dust layer} \]

\[\text{Column density of the farthest dust layer, N}_{H1} = (4.0 \pm 0.4) \times 10^{22} \text{ cm}^{-2} \]

\[N_{H1} \times (1 + 0.24 + 0.27) = (6.0 \pm 0.6) \times 10^{22} \text{ cm}^{-2} \]

\[\text{The farthest dust layer is responsible for the smallest of the three rings of Tiengo et al. (2010) ("inner" ring, in the following). This model includes polycyclic aromatic hydrocarbons (PHA), silicate grains and bare graphite grains with the abundances of B-type stars.} \]
from the fit of the persistent emission ($N_{HI} = 4.2 \times 10^{22} \text{ cm}^{-2}$). Fixing $N_{HI} = 2.78 \times 10^{22} \text{ cm}^{-2}$, to avoid exceeding the total absorption of the persistent emission, requires an additional blackbody to fit the spectrum. Its parameters are $kT = 1.2 \text{ keV}$ and emitting radius of $R = 167^{+167}_{-95} \text{ m}$. Such a thermal component can be attributed to the emission from a small region on the NS surface that has been heated by the energy released in the burst. Although the current data yield relatively large errors on the best fit parameters, we note that by completely neglecting the dust scattering, one would obtain different results. In fact, if we assume that there is no dust scattering contribution in the tail, it is still possible to obtain a good fit ($\chi^2/dof = 49.97/66$) by adding to the persistent emission a blackbody with a slightly higher temperature $kT = 1.8^{+0.3}_{-0.2} \text{ keV}$, emitting radius $R = 135^{+32}_{-36} \text{ m}$, and flux of $(7.1 \pm 1.0) \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$ (4–10 keV unabsorbed, see Table 1).

4 DISCUSSION

In this work we studied a long-lasting X-ray tail emitted from the magnetar 1E 1547.0–5408 after a bright short burst on 2009 February 3. The burst consisted of a bright peak lasting about 0.1 s, with fluence, derived with a joint spectral analysis of Swift/BAT and XMM-Newton/RGS data, of $\sim 10^{-5} \text{ erg cm}^{-2}$ (0.3–150 keV). The X-ray tail was characterized by a steep initial decay, with a duration of about 20 s, followed by a slower decrease, lasting at least 8 ks and with a fluence of $\sim 4 \times 10^{-6} \text{ erg cm}^{-2}$. We found evidence for an angular expansion of the X-ray emission during the tail and, thanks to the previous knowledge of the properties of the dust clouds in the direction of 1E 1547.0–5408 (Tiengo et al. 2010), we showed that the part of the tail starting $\sim 20–30$ s after the burst can be entirely explained by dust-scattering.

The total column density derived from our fit of the X-ray tail
with a dust scattering model ($N_H = 6 \times 10^{22}$ cm$^{-2}$) is slightly larger than that obtained in the spectral analysis of the persistent emission of 1E 1547.5–5408 ($N_H = 4.2 \times 10^{22}$ cm$^{-2}$). Such an apparent discrepancy is likely related to the fact that the gas-to-dust ratio is not uniform in the Galaxy, while the normalisation of the adopted dust model (number of grains per H atom) is based on an average value. In particular, the comparison between the $N_H$ derived from X-ray spectra and the reddening in stars behind nearby molecular clouds indicates, as in our results, an excess of dust with respect to gas in dense clouds (see, e.g., Vuong et al. 2003; Hasenberg et al. 2016). On the other hand, if also unscattered emission from 1E 1547.0–5408 contributes to the tail, a lower column density of dust is required (see Table 1). Note, however, that such a contribution must be small because, although the tail spectrum is compatible with thermal emission from a fraction of the NS surface, the spatial analysis described in Sect. 3.2 shows that most of the tail emission is produced by dust scattering.

The steep part of the X-ray tail at $t < T_0 + 20$ s cannot be reproduced by the dust scattering model used to describe it at later times. In principle, it could be explained by invoking the presence of a dense dust layer very close (less than a few pc) to the source, possibly related to the supernova remnant associated with

- c Average flux in the 0.3–10 keV range (unabsorbed).
1E 1547.0–5408 (Gelfand & Gaensler 2007). However, it is more likely that the first part of the X-ray tail is dominated by unscattered emission, which comes directly from 1E 1547.0–5408. This emission could originate, for example, in a region of the NS surface which has been heated by the burst or in a trapped fireball in the star magnetosphere (Thompson & Duncan 1993). Unfortunately, the small number of counts did not allow us to confirm this with a significant detection of pulsations in the first 20–30 s.

To put our results in the context of other similar events, we compiled in Table 2 the properties of several bursts followed by X-ray tails detected in 1E 1547.0–5408 and in other magnetars. We included, for comparison, also the three giant flares from SGR 0526–66, SGR 1806–20, and SGR 1900+14, although they involved a much larger energy budget (see Mereghetti 2008 and references therein). Based on the best available spectral and timing information reported in the literature, we estimated for each event the fluence of the tail and that of the associated initial burst and, using the distances given in Table 2, we derived the energies plotted in Fig. 10. Note that some of these estimates have relatively large uncertainties due to the poorly constrained spectra and/or instrumental saturation effects (in some cases, only lower limits could be established).

For the burst of 1E 1547.0–5408 we plotted two values in Fig. 10 one in which we consider the whole energy of the tail and one in which we exclude the part attributed to dust scattering. For the latter we only considered the fluence of the first part of the tail, estimated by its EPIC-pn spectrum. The fluence of the short burst corresponds to a total energy release of \(2 \times 10^{38} \text{erg cm}^{-2}\). Therefore, this was a relatively strong burst, although not as energetic as the brighter events seen from this source on 2009 January 22 (Mereghetti et al. 2009; Savchenko et al. 2010).

From Fig. 10 it is clear that magnetar bursts span a large range of intensities, with several events with “intermediate” energy outputs, which bridge the “standard” bursts with the much rarer giant flares. Although there is an overall correlation between the burst and tail energetics, especially when also the giant and intermediate flares are considered, the data show a large dispersion. The energy in the tail can be either a fraction of that of the burst or exceed it. The latter case seems to require an additional energy supply released on a longer timescale after the burst, but the analysis of 1E 1547.0–5408 reported here shows that, in some cases, the tail energy might be overestimated if assuming an intrinsic NS emission only.

### 4.1 Implications for the burst of 2009 January 22

Tiengo et al. (2010) studied three bright dust scattering rings around 1E 1547.0–5408. Their angular expansion rate measured with XMM-Newton and Swift, clearly indicates that they were produced by one (or possibly more) of the very luminous bursts seen by INTEGRAL in the time interval from 6:43 to 6:51 UT of 2009 January 22 (Mereghetti et al. 2009). Unfortunately, the fluence of these bursts in the soft X-ray band (0.5–10 keV) was not measured directly, since they were observed only in the hard X-ray range and, furthermore, the two brightest ones saturated the instruments. For this reason, Tiengo et al. (2010) could only estimate the combined information of the two factors which determine the flux of the scattered radiation, i.e. the dust optical depth and the fluence of the burst.

This degeneracy can now be removed because, for the burst of February 3 analyzed in this work, both the unscattered and scattered X-ray fluences have been measured: if the tail after T0+20 s is entirely due to dust scattering, a column density \(N_{\text{H1}} = 4 \times 10^{22} \text{cm}^{-2}\) is required for the farthest of the three dust clouds. This is four times larger than the value assumed by Tiengo et al. (2010) and implies that the January 22 burst emitted \(2.5 \times 10^{39} \text{erg cm}^{-2}\) in the 1–100 keV range, for a thermal bremsstrahlung spectrum with temperature \(kT = 30 \text{keV}\). These values are a factor of 4 smaller than those reported in Tiengo et al. (2010).

### 5 Conclusions

We have shown that most of the long lasting X-ray emission detected after a burst of the magnetar 1E 1547.0–5408 can be explained as radiation scattered by interstellar dust. In fact, based on previous observations of expanding rings after a brighter event, there is solid evidence for the presence of a significant amount of dust concentrated in three clouds along the line of sight of this source. The effect of this dust on fainter bursts, such as the one analyzed here, is certainly less spectacular, but it cannot be neglected. Indeed, by ignoring it, one would attribute the whole X-ray tail, lasting about 10 ks and with a fluence of \(\sim 4 \times 10^{-8} \text{erg cm}^{-2}\), to enhanced emission coming directly from 1E 1547.0–5408 and related to the burst.

Can a similar scenario apply also to other X-ray tails observed after the bursts of different magnetars? Most of these sources are located in the Galactic plane, at distances of several kiloparsecs, and have absorption values similar to, and in a few cases larger than, that of 1E 1547.0–5408. Undoubtedly, their radiation is subject to absorption. To test this hypothesis, one would need to observe the tail of a bright magnetar well before the burst so as to measure the intrinsic X-ray fluence, correct it for the interstellar absorption, and compare it with the tail energy. This is clearly a challenging task, but it seems that with future missions it will probably be possible to do this.
when pulsations are observed, while the interpretation of unpowered emission, often showing a hard to soft spectral evolution which suggests a cooling region on the NS, is subject to more uncertainties. Often the quality of the data is insufficient to disentangle the contribution of dust scattering from that of the intrinsic emission in the observed X-ray tails. Unfortunately, a quantitative assessment of this effect, as we did for 1E 1547.0–5408, can be done only when bright bursts are observed and timely follow-ups with good imaging and sensitivity are carried out to study the X-ray halo evolution.

ACKNOWLEDGEMENTS

This work has been partially supported through financial contribution from PRIN INAF 2014. The results are based on observations obtained with XMM-Newton, an ESA science mission with instruments and contributions directly funded by ESA Member States and NASA, and on data obtained from the HEASARC archive. PE acknowledges funding in the framework of the NWO Vidi award A.2320.0076. EC acknowledges support from a VIDI grant from the Netherlands Organisation for Scientific Research (NWO). We thank Daniele Viganò who developed part of the software used in this work.
