**ABSTRACT**

Although electrophiles are considered as detrimental to cells, accumulating recent evidence indicates that proliferating non-cancerous and particularly cancerous cells utilize these agents for pro-survival and cell cycle promoting signaling. Hence, the redox shift to mild oxidant release must be balanced by multiple defense mechanisms. Our latest findings demonstrate that cell cycle progression, which dictates oxidant level in stress-free conditions, determines **PARP1** transcription. Growth modulating factors regulate CDK4/6-RBs-E2Fs axis. In cells arrested in G1 and G0, RB1-E2F1 and RBL2-E2F4 dimers recruit chromatin remodelers such as HDAC1, SWI/SNF and PRC2 to condense chromatin and turn off transcription. Release of retinoblastoma-based repressive complexes from E2F-dependent gene promoters in response to cell transition to S phase enables transcription of **PARP1**. This enzyme contributes to repair of oxidative DNA damage by supporting several strand break repair pathways and nucleotide or base excision repair pathways, as well as acting as a co-activator of transcription factors such as NRF2 and HIF1a, which control expression of antioxidant enzymes involved in removal of electrophiles and secondary metabolites. Furthermore, **PARP1** is indispensable for transcription of the pro-survival kinases MAP2K6, ERK1/2 and AKT1, and for maintaining MAPK activity by suppressing transcription of the MAPK inhibitor, MPK1. In summary, cell cycle controlled **PARP1** transcription helps cells to adapt to a pro-oxidant redox shift.

1. Pro-oxidant physiology of proliferating cells

Human cells proliferate in a variety of contexts. Controlled cell divisions play a particular function for development of the embryo, while in the adult organism mainly stem and some immune cells retain the ability to proliferate. Cancer cells, as a special type of transformed cells, are capable of unlimited and uncontrolled growth. Regardless of the type of dividing cell, proliferation imposes a requirement for energy and reducing power. Although mitochondrial oxidative phosphorylation is the most efficient source of ATP, it can cause extensive release of \( \text{O}_2^- \), which is dismutated to \( \text{H}_2\text{O}_2 \) either in mitochondria (by SOD2) or in the cytoplasm (by SOD1). Therefore, above some critical threshold value of this oxidant in cell compartments, aerobic glycolysis becomes more favorable than oxidative phosphorylation in order to limit the hazardous waste products resulting from the mitochondrial metabolic pathway [1]. During fatty acid oxidation, \( \text{O}_2^- \) and \( \text{H}_2\text{O}_2 \) can also be produced by xanthine oxidase in peroxisomes, which duplicate and are segregated between progeny cells. Although metabolically unrelated, NADPH oxidases act as a primary source of oxidants in macrophages and some cancer cells [2].

Depending on the cell type, proliferation-inducing agents such as growth factors (platelet-derived, fibroblast, epidermal, insulin-like and transforming growth factor \( \beta \)), cytokines (type I interferons, granulocyte-macrophage colony-stimulating factor), mutant K-ras or small GTPase Rac-1 elevate intracellular \( \text{O}_2^- \) through NADPH oxidase and/or mitochondria [3,4]. Due to pressure induced by an elevated and sustained redox shift to a mild oxidative environment, cells have developed efficient mechanisms of adaptation and functional transformation of „bad” to „good” molecules, which promote cell proliferation and survival at different signaling levels [5].

2. Cell cycle progression regulates PARP1 transcription

Poly-ADP-ribose polymerase 1 (PARP1) is a multitasking enzyme that regulates many intracellular processes, including DNA repair, metabolism, signaling and transcription, by direct interaction with other proteins and DNA, involving their ADP-ribosylation and auto-ADP-ribosylation of PARP1. The data acquired and published in the EMBL-EBI Expression Atlas indicate high PARP1 abundance in proliferating cancerous and non-cancerous cells (e.g. macrophages) [6]. In search for the link between PARP1 transcription and cell cycle progression, we recently revealed that cell arrest in G1 or exit to G0 lead to PARP1 repression by retinoblastoma-based multiprotein complexes, which are also known to repress transcription of EZF-dependent genes encoding proteins responsible for cell transition to S phase [7]. The mode of growth inhibition determines the composition of the repressive complex at the PARP1 promoter, giving priority to E2F1-RB1 dimers under G1 arrest in cancer, as well as in CD34 + hematopoietic progenitor/stem cells treated with cyclin-dependent kinases 4 and 6 (CDK4/6) pharmacological inhibitors or depleted of nucleotides by mimosine. E2F4-RBL2-based complexes were found to be prevalent in differentiated cells (Fig. 1). Since PARP1 is involved in cell protection against oxidants, one may think that PARP1 repression in response to proliferation arrest may sensitize cells to agents that challenge redox homeostasis. Some ongoing and recruiting clinical trials have been testing FDA approved CDK4/6 inhibitors Palbociclib (IBRANCE®) and Ribociclib (LEE011, Kisqali) in combination with drugs such as doxorubicin, carboplatin and paclitaxel, which trigger acute redox imbalance [8].

Furthermore, PARP1 enhances cell proliferation. Hormone-activated cyclin-dependent kinase 2 (CDK2) phosphorolyses and activates PARP1, thereby facilitating H1 displacement and transcription of the majority of hormone-responsive genes in breast cancer [9]. In urinary bladder carcinoma cells, PARP1 regulates cyclin E expression, cell cycle re-entry and G1/S progression [10]. Thus, high levels of PARP1 in cancer cells promote cell cycle progression, which is associated with an increased level of oxidants, thereby maintaining PARP1 transcription and creating a self-promoting cycle.

3. PARP1 co-activates expression of proteins that enzymatically decompose oxidants and remove secondary metabolites

The primary role in antioxidant defense and in cell adaptation to excessive oxidant or electrophile production is fulfilled by enzymatic antioxidant defense, which comprises direct scavengers of electrophiles, but also enzymes that detoxify the secondary metabolites. Many such enzymes are under transcriptional control of nuclear factor erythroid 2 (NFE2)-related factor 2 (NRF2), a basic leucine zipper (bZIP) protein, which dissociates from its repressor Keap1 and translocates to nucleus in response to a physiological shift in redox homeostasis towards oxidative production. NRF2 requires PARP1 for full transcriptional activity, because PARP1 facilitates interaction of NRF2 and NRF2-partner (small MAF protein; MAFG) with the antioxidant response element (ARE) (Fig. 2) [11]. An inhibitory effect of PARP1 knockdowns was found in breast cancer cells and proliferating mouse fibroblasts. Although in normal cells NRF2 suppresses tumor promotion and progression, this pathway is constitutively activated in various cancers by mutation and transcriptional repression of Keap-1, accumulation of Keap-1-NRF2 disruptors, transcriptional and post-translational NRF2 induction. In view of NRF2 targets, this transcription factor provides chemoresistance and, like PARP1, has become a target for anticancer interventions [12].

Another oxidant-counteracting mechanism that involves PARP1 is represented by its interaction with the transcription factor hypoxia-inducible factor 1-alpha (HIF1α), which undergoes activation during hypoxia and hypoxia-triggered redox imbalance [13,14]. PARP1 co-activates HIF1α-dependent transcription of genes, which promotes cell survival. In murine embryonic fibroblasts, PARP1 caused accumulation of HIF1α via upregulation of NO and oxidant production in cells treated with deferoxamine [15]. In addition to PARP1, HIF1α binds EP300/CBP acetylase(s) for full transcriptional activity. A similar observation was made for nuclear factor kappa B (NF-κB), activation of which required synergistic interaction with PARP1 and EP300/CBP. However, for HIF1α mutual dependence between these two types of co-activators has not been documented yet.

Promoters of some antioxidant enzymes such as catalase, SOD1 or SOD2 carry the binding motif for NF-κB, but the role of PARP1 in transcription activation of these genes has not been confirmed. Instead,
expressed in a particular cell type, shifts up or down the intracellular level of oxidants. Ha-RAS isoform promotes O2 oxidative metabolism and FOXO-dependent repression of catalase. Growth factors and oxidants switch on ERK signaling via RAS, which, depending on the isoform blocks dephosphorylation of tyrosine and threonine residues of MAPKs, which undergo activation upon acute cell exposure to H2O2.

MAP2K6 links PARP1 with transcription of anti-apoptotic genes indirectly by starting the phosphorylation cascade MAP2K6-p38-MSK1/2-CREB. The last component of this axis controls transcription of HO-1 and PGC-1 transcription. PARP1 contributes to antioxidant cell defense by enhancing transcription of enzymatic scavengers of electrophiles and secondary metabolites. Under normal oxygen conditions, PARP1 determines intracellular redox homeostasis by intensifying nuclear factor erythroid 2 (NFE2L2)-related factor 2 (NRF2)-dependent transcription of enzymatic redox-balancing enzymes (NADPH quinone oxidoreductase 1, NQO1; heme oxygenase-1, HO-1; aldo-keto reductase family 1, member C1, AKR1C1; superoxide dismutase 1, SOD1), as well as phase II detoxifying enzymes (glutathione S-transferase, GST; UDP-glucuronosyltransferase, UGT; catalytic and modifier subunits of glutamate cysteine ligase, GCLC and GCLM respectively) and drug transporters (multidrug resistance-associated proteins, MRPs). In the absence of PARP1, transcription of the above-mentioned genes is restricted as NRF2 moderately associates with small MAF proteins (in this case with MAFG) and the antioxidant response element (ARE), which is localized within the promoter of NRF2 target genes. When abundant, PARP1 enhances the interaction among NRF2, MAFG and ARE, thereby acting as a co-activator of NRF2-dependent gene transcription. PARP1 also functions actively in cell adaptive responses to match O2 supply under hypoxia by supporting hypoxia-inducible factor 1-alpha (HIF1α) at different signaling levels. This protein, together with PARP1, acts as a key modulator of the transcription response in cells that experience a low O2 level. Under normal oxygen condition, factor inhibiting HIF1α (FIH1; asparaginyl hydroxylase) and propyl hydroxylase domain-containing enzymes (PHDs) hydroxylate HIF1α, thereby preventing transcription factor interaction with EP300/CREB coactivators and marking HIF1α for proteosomal degradation by E3 ubiquitin ligase, the von Hippel-Lindau (pVHL) complex. Low O2 concentration inhibits hydroxylases and stabilizes HIF1α. PARP1 forms complex and co-activates HIF1α in a PARP1 enzymatic activity-dependent manner, therefore enabling expression of genes controlled by hypoxia response element (HRE)-positive promoters. This group comprises antioxidant defense enzymes such as heme oxygenase-1 (HO-1), glutathione peroxidase 8 (GPX8), ER oxidoreductin 1 (ERO1) and glucose transporter 1 (GLUT1), the activity of which helps to maintain glutathione homeostasis.

PARP1 contributes to regulation of redox-related signaling pathways. PARP1 regulates both positively and negatively transcription of numerous enzymes involved in the transmitting signals to and from oxidant-releasing intracellular systems or extracellular sources. Expression of MAP2K6 and ERK1 are, like PARP1, controlled by cell cycle progression and RB-based repressive complexes. In proliferating cells, PARP1 is indispensable for their transcription, because it mediates EP300 recruitment to their promoters. Although Akt and ERK2 are not directly repressed by RBs, PARP1 maintains their expression. All these kinases were shown to protect proliferating cells facing mild or physiological increases in the electrophile abundance from death. In the Akt pathway, PI3 acts as a redox sensor and after activation phosphorylates Akt, which in turn activates mTOR kinase. This enzyme stimulates cell proliferation via the SGK1-FOXO3 pathway, which represses transcription of CDK inhibitors. Moreover, mTOR phosphorylates and inactivates BAD, thus blocking the release of cytochrome c from mitochondria. Akt contributes to H2O2 accumulation by stimulating oxidative metabolism and FOXO-dependent repression of catalase. Growth factors and oxidants switch on ERK signaling via RAS, which, depending on the isoform expressed in a particular cell type, shifts up or down the intracellular level of oxidants. Ha-RAS isoform promotes O2 accumulation by activating NADPH oxidase, while the Ki-RAS pathway upregulates transcription of SOD2. There are numerous ERK targets, which implicate this enzyme in cell proliferation: carbamoyl phosphate synthetase (CPS II, source of pyrimidine nucleotides), MSK1/2 (chromatin remodeling and induction of cell cycle-related gene transcription), RNA polymerase I (transcription of the ribosomal RNA genes), CDK inhibitors or MYC (transcription of cyclin D1). ERK protects cells from death by repressing pro-apoptotic BIM and stabilizing anti-apoptotic MCL-1 protein. PARP1-MAP2K6 functional cross-talk at the genomic level is not limited to upregulation of kinase transcription. MAP2K6 links PARP1 with transcription of anti-apoptotic genes indirectly by starting the phosphorylation cascade MAP2K6-p38-MSK1/2-CREB. The last component of this axis controls transcription of HO-1 and PGC-1α; the latter promotes mitochondrial biogenesis. Furthermore, PARP1 regulates activity of MAPKs independently of their promoters by regulating transcription of JNK, ER1/2 and the p38 inhibitor MKP1. Downregulation of MKP1 expression by PARP1 blocks dephosphorylation of tyrosine and threonine residues of MAPKs, which undergo activation upon acute cell exposure to H2O2.
ADP-ribose polymers recruit XRCC1, then the remaining SSBR machinery comprising DNA polymerase (DNAP) and DNA ligase III, which also can be PARylated by PARP1. PARP1 de

DNAP breaks (SSBs), which again involve PARP1 in the BER machinery at a later repair step. DNA nick-induced poly-ADP-ribosylation facilitates PARP1 interaction with OGG1 glycosylase, which requires PARP1 for proper and efficient functioning. AP endonuclease (APE1) binds to apurynic sites and produces single-strand breaks resulting from direct oxidant action also need PARP1 activity to be repaired. Poly-ADP-ribose polymers recruit XRCC1, then the remaining SSBR machinery comprising DNA polymerase (DNAP) and DNA ligase III, which also can be PARylated by PARP1. PARP1 deficiency in growth-arrested cells substantially impairs both pathways. Of note, inhibition of OGG1 in combination with G1-blockade leads to further accumulation of single strand breaks.

PARP1 level negatively correlates with mitochondrial SOD in cancer cells (EMBL-EBI Expression Atlas), where SOD2 overexpression causes a growth inhibitory effect by shifting the $O_2^-/H_2O_2$ balance towards $H_2O_2$ accumulation [16]. If PARP1 is involved in SOD2 repression, this enzyme could be capable of defining the intracellular repertoire of growth promoting or inhibiting oxidants. Furthermore, low SOD2 level is known to stabilize HIF1α [17].

### 4. PARP1 regulates redox-sensitive signaling pathways

The roles that small species of oxidizing nature play in cellular signaling are becoming increasingly appreciated. Redox-sensitive pathways allow cells to adapt to mild oxidant/antioxidant imbalance and promote survival by linking redox shifts to post-translational modifications of proteins and to their interactorome [5,18]. According to our and previous findings, PARP1 regulates transcription of numerous genes encoding redox sensors and mediators transmitting signals upstream or downstream of electrophile sources (Fig. 3). Redox-sensitive MAP kinase signaling serves as a good example of the PARP1-MAPK-ROS-cell survival axis since PARP1 couples transcription of MAP2K6, ERK1/2 and AKT1 with the cell cycle progression, thereby assuring active transcription of kinases that have a pro-survival function under mild redox imbalance [19-26]. Furthermore, oxidative stress-induced PARP1 activation represses transcription of MPK1, a known MAPK inhibitor [27]. Although in this particular case JNK and p38 were shown to act as pro-death kinases, the beneficial or detrimental activity of kinases and MAPK pathways is determined by the type of intracellular or extracellular stimuli that challenges redox homeostasis, for example whether the action is acute or prolonged, mild or severe, but is also dependent on the cell type. All these aspects also apply to PARP1. In addition to conditions listed above, PARP1-dependent cell life or death fate is determined by the pathway to which PARP1 contributes (pro-survival or suicidal), the direction (inhibition or stimulation) and mode of mutual interdependence with its interacting partner (direct protein-protein binding or covalent modification, i.e. ADP-ribosylation). Oxidants are one of major agents triggering mono- or poly-ADP-ribosylation; the severity of oxidative stress determines the length of ADP polymer synthesized, thus also impinging on the beneficial or detrimental effect of PARP1 activation, since NAD+ is utilized as a substrate for ADP-ribosylation. High doses of $H_2O_2$ cause metabolic catastrophe, parthanatos, and activation of detrimental signaling pathways, while moderate PARylation protects cells from mild oxidative stress by attracting DNA repair complexes, clearing and removal of oxidized or damaged proteins, and re-establishing homeostasis [28,29].

### 5. Cell cycle determines DNA repair mechanisms

PARP1 actively contributes to numerous repair pathways of oxidative DNA lesions, which comprise covalent modifications of nucleo-bases as well as single and double strand breaks (SSB and DSB, respectively). The deformability of DNA within SSB is recognized by two flexibly linked N-terminal zinc fingers, and initiates self-assembly of remaining PARP1 domains leading to activation of the C-terminal catalytic domain [30]. NAD+ is utilized as a substrate for ADP-ribosylation. High doses of $H_2O_2$ cause metabolic catastrophe, parthanatos, and activation of detrimental signaling pathways, while moderate PARylation protects cells from mild oxidative stress by attracting DNA repair complexes, clearing and removal of oxidized or damaged proteins, and re-establishing homeostasis [28,29].
non-homologous end joining (C-NHEJ) (Fig. 4). Thus PARP1 has become a target for anticancer interventions. G1/G0 arrest shifts error-free HR and Alt-NHEJ to error-prone C-NHEJ, but low PARP1 impairings also BER and SSBR [32–34]. According to our new data, PARP1 repressing by CDK4/6 inhibitors reduces PARP1-dependent 8-oxoguanine glycoylase (OGG1) activity, causing accumulation of single strand breaks and thereby increasing cell vulnerability to anticancer drugs and H2O2-induced oxidative stress [35]. The direct binding of OGG1 to PARP1 is stimulated by increased oxidant level, and for full activity PARP1 is recruited to some genomic loci by PARP1 [36–38]. PARP1 and is stimulated by increased oxidant level, and for full activity OGG1 requires acetylation by EP300, which physically interacts with PARP1 and is recruited to some genomic loci by PARP1 [36,37].

PARP1 has been postulated to cooperate with transcription factor(s) that activate expression of genes encoding proteins contributing to DNA repair [38]. Although such a premise must be experimentally confirmed, PARP1 is a bona fide co-regulator of NF-κB, p53, PI-1, E2F1, and BRCA1, which control promoter activation, epigenetic landscape and miRNA transcription of DNA repairing machinery. The confirmation for likely cooperation of PARP1 in regulation of DNA repair gene transcription comes from observations in human growth arrested monocytes differentiating to proliferating macrophages [39]. This process was associated with increased PARP1 expression, but also with transcriptional activation of XRCC1, ligase IIIa, OGG1 and catalytic subunit of DNA-dependent protein kinase (DNA-PKcs). Severe DNA repair defects that impacted base excision repair and double-strand break repair in monocytes sensitized these cells to death by γ-butyro- hydroperoxide and irradiation with γ-rays, while macrophages revealed almost complete resistance to these redox-challenging agents.

To conclude, PARP1 provides cell with protection against oxidants at different levels: by activating expression of proteins setting up anti-oxidant defense and redox sensitive signaling pathways, and by fine tuning of DNA repair machinery. Therefore PARP1 expression, which is defined by the proliferative status of cells, can determine cell resistance to oxidants, even though an adaptive response is only apparent within a narrow dose window.
