Flexible transition metal dichalcogenide nanosheets for band-selective photodetection

Dhinesh Babu Velusamy¹, Richard Hahnkee Kim¹, Soonyoung Cha², June Huh³, Reza Khazaeinezhad⁴, Sahar Hosseinzadeh Kassani⁴, Giyoung Song¹, Suk Man Cho¹, Sung Hwan Cho¹, Ihn Hwang¹, Jinseong Lee¹, Kyunghwan Oh⁴, Hyunyoug Choi² & Cheolmin Park¹

The photocurrent conversions of transition metal dichalcogenide nanosheets are unprecedentedly impressive, making them great candidates for visible range photodetectors. Here we demonstrate a method for fabricating micron-thick, flexible films consisting of a variety of highly separated transition metal dichalcogenide nanosheets for excellent band-selective photodetection. Our method is based on the non-destructive modification of transition metal dichalcogenide sheets with amine-terminated polymers. The universal interaction between amine and transition metal resulted in scalable, stable and high concentration dispersions of a single to a few layers of numerous transition metal dichalcogenides. Our MoSe₂ and MoS₂ composites are highly photoconductive even at bending radii as low as 200 μm on illumination of near infrared and visible light, respectively. More interestingly, simple solution mixing of MoSe₂ and MoS₂ gives rise to blended composite films in which the photodetection properties were controllable. The MoS₂/MoSe₂ (5:5) film showed broad range photodetection suitable for both visible and near infrared spectra.

Two-dimensional (2D) nanosheets of transition metal dichalcogenides (TMDs) such as MoS$_2$, WS$_2$ and MoSe$_2$ have been of great attraction due to their intriguing photoelectronic properties associated with the 2D confined chemical structures from insulators, direct bandgap semiconductors to metals$^{1-3}$. These materials have potential for applications in electronics, optics, energy conversion and storage$^{2,11}$. In particular, the photocurrent conversion at the characteristic photon energies corresponding to their material-dependent energy band gaps is impressive, making them great candidates for wavelength-selective photodetectors$^{12-18}$. Excellent visible photodetection has been, for instance, achieved with devices containing single or few layered MoS$_2$, as well as WS$_2$ fabricated by mechanical exfoliation with Scotch film$^{19}$; convenient but hardly applicable for arrays of the devices.

These promising photovoltage performances of various 2D TMDs is driving a demand for their technological implementation. Furthermore, considering the mechanically flexible nature of the 2D TMDs,$^{20,21}$ arrays of the photodetectors on either plastic or paper would be beneficial for wearable and patchable applications. Several challenges are, however, ahead, for the successful realization. Most importantly, a scalable and universal process suitable for various TMDs irrespective of their detailed chemical structures is required for thin uniform film fabrication on diverse substrates. The method should involve efficient exfoliation of the sheets of 2D TMDs from stacked bulk samples, as well as prevention of re-aggregation of the sheets on film formation. In addition, individual or a few layers of 2D TMDs should be well-connected with each other in the film to readily develop conducting pathways between two electrodes for efficient photocarrier transport.

Many studies were devoted to liquid phase exfoliation and stabilization of TMDs$^{22-33}$ not only because the solvent medium offers an extra driving force for the separation of the sheets but also because 2D TMDs dispersed in solvent can be suitable for various solution-based film processes such as spin-coating, dip-coating and layer-by-layer assembly. To further promote the separation of the sheets, additional interactions with TMDs were required, including ion intercalation$^{22}$, surfactant-driven interaction$^{29}$ and highly boiled medium$^{33}$. Some of the previous approaches are promising and scalable, but limited to specific solvent medium. In addition, photoelectronic properties of mechanically flexible TMD films have not been extensively investigated, in particular, comparable with those with mechanically exfoliated sheets. The non-destructive dispersion strategy with synthetic polymers can be additionally beneficial due to their long and flexible chains that adhere to the surface of TMDs and thus provide sufficient physical gaps between two sheets to mitigate the strong van der Waal interactions of the sheets$^{34}$. We envisioned that end-functionalized polymers can meet the requirements aforementioned with end-functional groups universally interactive with various TMDs. Flexible polymer chains dangled with end-functional moieties firmly anchored on the surface of TMDs in solvents can allow for good dispersion of the sheets with their minimum amount, leading to flexible composite films with many conducting pathways.

Here we present mechanically flexible TMD nanosheets for band-selective photodetection. Our strategy of modifying TMDs with amine-terminated polymers successfully offers a scalable platform suitable for fabricating various flexible TMD/polymer composite films in which few-layer TMD nanosheets are properly separated from each other and embedded in a polymer matrix. The pivotal process for the platform is the extremely efficient liquid exfoliation of TMDs with primary amine-terminated polymers whose end-functional amines are firmly anchored on the surface of TMDs due to strong Lewis acid–base interaction between transition metal and non-pair electrons of amine, allowing us to develop various uniform composite films with numerous combinations of TMD nanosheets and end-functionalized polymers. Films of MoSe$_2$ nanosheets with amine-terminated poly(styrene) (PS-NH$_2$) exhibited excellent photodetection with an ON/OFF photocurrent ratio of 10$^5$, a detectivity of 4 × 10$^{12}$ Jones, a responsivity of 16 A W$^{-1}$ and a response time of 100 ms on 1,064-nm illumination, even when the films were severely deformed at a bending radius of ∼200 μm. Moreover, simple solution mixing of MoSe$_2$ and MoS$_2$ modified with NH$_2$-PS offers an extremely convenient route for tuning the photodetection properties, and thus a blended composite film allows for broad range photodetection from visible to near infrared (NIR). The band-selective photodetection of our blended films is also evidenced by thorough investigation of photo-induced, carrier-relaxation dynamics.

**Results**

**Universal exfoliation of TMDs with amine-terminated polymers.** In this work, we achieved successful exfoliation of numerous TMD nanosheets such as MoS$_2$, WS$_2$, MoSe$_2$, WSe$_2$, ReSe$_2$, ZrTe$_2$ and NbSe$_2$ with amine-terminated polymers. The principle is based on the Lewis-like acid–base interaction$^{22,35}$ between the transition metal and primary amine, as shown in the scheme in Fig. 1. The representative amine-terminated polymers employed here are glassy PS, poly(methyl methacrylate), rubbery poly(butadiene), semi-crystalline poly(ethylene), poly(ethylene oxide) (PEO) and poly(styrene-b-isoprene) copolymer. The interaction between the donated lone pairs of nitrogen atoms and electron-accepting metal atoms was evidenced by Fourier transform infrared spectroscopic (FT-IR) for the case of MoSe$_2$ modified with PS-NH$_2$ (Supplementary Note 1). The characteristic peak at 1,600 cm$^{-1}$ corresponding to neat NH$_2$ was significantly shifted to ∼1,650 cm$^{-1}$, which resulted from the N–H bonds bent due to the transition metal–amine interaction, as shown in Fig. 1. Upshift of N–H mode occurred when primary amines interact with transition metal$^{36,37}$. In addition, the computation of IR spectra for model systems (PS-NH$_2$, MoSe$_2$/PS-NH$_2$) based on density functional theory frequency calculation also shows that the peak corresponding to bending vibration of the NH$_2$ in the absence of MoSe$_2$ was shifted to higher frequency in the MoSe$_2$/PS-NH$_2$ bound state, which consolidates our experimental observation (Supplementary Fig. 1).

Amine groups of polymers efficiently interact with transition metals when surface of TMD nanosheets is exposed upon sonication step. Simultaneously, flexible polymer chains from the anchored amine on the TMD surface are fully extended in their good solvent medium. Firmly anchored polymer chains on the TMD surface prevent the exfoliated nanosheets from re-aggregating on solvent evaporation. It should be noted that our process does not involve the intercalation of TMD nanosheets, different from ones previously developed with metal ions$^{22-25}$ (Supplementary Fig. 2; Supplementary Note 1). The successful interaction between amine groups of polymers and transition metals in the TMD nanosheets is confirmed by density functional tight binding$^{38-40}$ and Born–Oppenheimer molecular dynamics simulation (Supplementary Fig. 3). Combined with conventional sonication and centrifugation processes, we were able to exfoliate the bulk TMDs into few-layer nanosheets on a large scale, as shown in the photograph in Fig. 1.

To demonstrate the effectiveness of our strategy, we extensively investigated the dispersion of MoSe$_2$ nanosheets with PS-NH$_2$ (Supplementary Note 2). The suspension of bulk MoSe$_2$ with 1 mg ml$^{-1}$ PS-NH$_2$ in Fig. 2a exhibits the characteristic absorbance spectrum of MoSe$_2$ (blue colour) after optimization.
MoSe2, PS-NH2 and MoSe2-PS-NH2 are shown. Few-layer MoSe2 and MoS2 layers, thereby ensuring good exfoliation and dispersion. FT-IR spectra of attraction and the polymer chains provide further separation between the atoms and the electron-accepting metal atoms weakens the self layer–layer and grey spheres, respectively. The amine-terminated polymers are toluene26,29,41. The increased absorbance at the short wavelength confirmed the exfoliation and dispersion of MoSe2 nanosheets spectroscopy, Raman spectroscopy and X-ray diffraction further Fig. 6). Additional experiments using X-ray photoelectron Fig. 5) and the results are the same as Fig. 2a (Supplementary exfoliation of various TMDs using different types of amine-terminated end-functionalized polymers in organic solvents. Hexagonal layers of transition metal atoms (M) sandwiched between two layers of chalcogenides (X) are represented by a stoichiometry of MX2 by the yellow and grey spheres, respectively. The amine-terminated polymers are simplified for clarity. Interaction between the lone electron pairs of nitrogen atoms and the electron-accepting metal atoms weakens the self layer–layer attraction and the polymer chains provide further separation between the layers, thereby ensuring good exfoliation and dispersion. FT-IR spectra of MoSe2, PS-NH2 and MoSe2-PS-NH2 are shown. Few-layer MoSe2 and MoS2 nanosheets dispersed on the 2-1 scale are apparent in the photographs (Scale bar, 5 cm).

Fig. 1 | Liquid phase exfoliation of TMDs with end-functionalized polymers. Schematic representation of the proposed mechanism for the exfoliation of various TMDs using different types of amine-terminated end-functionalized polymers. The effect of the molecular weight of PS-NH2 (9.5, 25 and 40 k, and 108 k g mol−1) on the exfoliation of MoSe2 additionally supports our arguments. For initial polymer concentrations of 1 and 5 mg ml−1, the absorbance nearly linearly decreased with increasing molecular weight of polymers due to the decrease of the total number of end-amine groups with increasing molecular weight of the polymers, as shown in Fig. 2d. Based on the results, 9.5 k PS-NH2 was further utilized for the exfoliation and dispersions of the TMDs (Supplementary Fig. 10).

A key advantage of our method is the capability of dispersing MoSe2 in many solvents. Eight different solvents were examined, which were all good solvents for PS. The results were well-fitted on a single absorbance versus concentration plot of dispersed MoSe2, which implies that the MoSe2 nanosheets were uniformly dispersed without aggregation, as shown in Fig. 2c (Supplementary Figs 11 and 12). The maximum amount of dispersed MoSe2 as a function of the PS-NH2 concentration depends on the solvent surface energy and the degree of solubility of PS with solvents26,29,30,34 where the results are shown in Fig. 2d. The concentration of dispersed MoSe2 increases with increasing PS-NH2 concentration but rarely changes when the polymer concentration is 5 mg ml−1, indicating the saturation of interaction sites available on the TMD surface. Notably, for all of the solvents examined, at least 0.55 mg ml−1 MoSe2 was stably dispersed and ~ 1.6 mg ml−1 MoSe2 was successfully exfoliated with our PS-NH2 in NMP (Supplementary Fig. 13). The maximum yield percentage of the dispersed MoSe2 is > 12% in NMP. (Fig. 2d) Compared with previous works25–32, the maximum amount of dispersed MoSe2 is substantially high and, in particular, it should be noted that the scalable exfoliation of MoSe2 in various solvents was achieved without re-aggregation for a period of > 3 weeks (Supplementary Fig. 14). As proposed in Fig. 1, other amine-terminated polymers also produced MoSe2 dispersed in various solvent medium, as shown in Fig. 2e. By choosing PEO, for example, a large amount of MoSe2 nanosheets was dispersed in polar media including ethanol and water. To confirm the universality of our method, we dispersed six additional TMDs including MoS2, WS2, WSe2, ReS2, ZrTe2 and NbSe2 with PS-NH2 in toluene where their absorbance spectra are shown in Fig. 2f (Supplementary Fig. 15).29,41

The microstructures of the exfoliated nanosheets were investigated using both surface probe and electron microscopy, where the results show that the thickness of the single-layer MoSe2 was 1.0 ± 0.15 nm, which is thinner than that of pristine MoSe2 (ref. 16) (~ 0.7 nm) due to the attached polymer chains on both sides of the nanosheet. The single crystalline nature35 of the single- and few-layer MoSe2 was preserved during the exfoliation process as well (Supplementary Fig. 16). Statistical analysis of both the lateral size and thickness of the exfoliated MoSe2 nanosheets (Supplementary Fig. 17) suggests that ~70% of the MoSe2 nanosheets was one to three layers with broadly
distributed lateral dimensions ranging from 400 to 800 nm. To demonstrate the ability of controlling the number of TMD layers by our dispersion process with amine-terminated polymers, we varied the centrifuge rate. Statistical analysis of various samples with different centrifuge rates shows that the mean number of layers decreases with the rate and at an optimized condition, a few layered TMDs dispersion was obtained (Supplementary Fig. 17). As expected, bulk and many layers of MoSe2 nanosheets prepared by low centrifugation rate do not exhibit any noticeable PL. In addition, electron microscopy results of both bulk and exfoliated TMDs including MoS2, WS2, WSe2, ReS2, ZrTe2 and NbSe2 with PS-NH2 in toluene evidence the universality of our method (Supplementary Fig. 18).

NIR photodetection of flexible MoSe2 nanosheets with PS-NH2
To prepare a flexible composite film for use in high performance photodetectors, a suspension of MoSe2 nanosheets modified with PS-NH2 was carefully poured on a filter paper through which the solvent with non-interacted PS-NH2 chains was quickly removed. A micron-thick composite film was developed with PS-NH2 was carefully poured on a filter paper through which the solvent with non-interacted PS-NH2 chains was quickly removed. A micron-thick composite film was developed on the filter paper, as shown in Fig. 3a. The surface and cross-sectional structures of the composite film exhibit that few-layer MoSe2 nanosheets were stacked with each other, in which the normal surface of the nanosheets is preferentially aligned parallel to the film normal direction. Subsequent thermal deposition of metal electrodes gave rise to mechanically flexible arrays of twoterminal, parallel-type photodetectors, as schematically depicted in Fig. 3a. On illumination with a NIR laser with a wavelength of 1,064 nm, our composite film became conductive due to photo-excited carriers in the exfoliated MoSe2 nanosheets. The photocurrent increases with increasing laser power, yielding a maximum I_on/I_off ratio of ~105 at a power density and bias.
Figure 3 | NIR photodetection performance of thin TMD composite films. (a) Schematic illustration and photographs of the two-terminal, parallel-type photodetector device cells consisting of MoSe₂ nanosheets exfoliated with PS-NH₂. The composite film was deposited on nylon membrane filter paper by a vacuum filtration method. SEM images of the surface and cross-sectional structure of the composite film reveal that few-layer MoSe₂ nanosheets are stacked with each other with the normal surface of the nanosheets preferentially aligned parallel to the film normal direction. (Scale bars: (i) 6 mm; (ii) 500μm and (iii and iv) 500 nm) (b) Linear and (c) semi-log scale I–V characteristics of the MoSe₂ photodetector in the dark and under different light intensities of NIR light at a wavelength of 1,064 nm with a bias voltage of ±10 V. The photocurrent increases with increasing light intensity due to photoexcited carriers in the exfoliated MoSe₂ nanosheets. (d) Band diagram of the MoSe₂ photodetector device. (e) The corresponding responsivity, specific detectivity and external quantum efficiency values of the photodetector as a function of the NIR intensity at a bias voltage of 9 V. (f) Photoswitching behaviour of the photodetector under alternating ON and OFF NIR light with an intensity of 238 mW cm⁻². Both the switch-ON and -OFF times of the detector were ~100 ms. (g) Ratios of the photocurrent to the dark current of the MoSe₂ composites with different amine-terminated polymers. The current ratios of various TMD composites with PS-NH₂ are also shown. All of the values were obtained at a light intensity of 238 mW cm⁻².
voltage of 238 mW cm\(^{-2}\) and 10 V, respectively, as shown in Fig. 3bc (Supplementary Fig. 19).

There exist mainly three sources of photocurrent arising from TMDs on visible and NIR exposure: (1) photoconduction by photo-induced band excited carriers that can be dissociated into free electrons and holes thermally or by a large electric field; and (2) one by photo-excited carriers decaying into heat that makes TMDs warm, resulting in the reduction of electrical resistance, that is, bolometric photocurrent. (3) Photothermoelectric generation of current by light illumination across metal–TMD interface. In our TMD composite film, we believe that the model by the photo-induced band excitation was dominant while both bolometric and photothermoelectric effect are very marginal (Supplementary Fig. 20). As schematically shown in a band diagram of our two-terminal device of Fig. 3d, the photo-excited carriers in conduction band of MoSe\(_2\) are drifted to Au electrode with quasi-Ohmic contact under bias field\(^{4,46,47}\).

The amine-terminated polymer matrix may further promote exciton dissociation on NIR exposure by two possible mechanisms as evidenced in polymer composites with networked semiconducting carbon nanotubes\(^{48}\): (1) Exciton separation by thermal energy built up in the insulating polymer around TMDs; and (2) dissociation by enhanced local electric field at the interface formed by the insulating polymer and TMDs due to the potential barrier formed by the insulating polymer (Supplementary Note 3). The photodetection performance is independent of film thickness ranging from 500 nm to 2 \(\mu\)m, which implies that the laser was able to penetrate through the entire micron-thick film (Supplementary Fig. 21). In addition, no degradation of PS-NH\(_2\) was observed on NIR and visible laser exposure (Supplementary Fig. 22).

The photocurrent \(I_{ph}\) arising from photo-excited photocarriers has in general the relation of \(I_{ph} \propto P^2\), and in consequence the current linearly increases with laser power in both log scale\(^{13}\). In our system, a similar linear relation was observed in the low power regime but the linearity was deviated at high power > 200 mW cm\(^{-2}\) with another slope (Supplementary Fig. 19). The rapid increase of photocurrent at high power illumination is known as superlinearity dependence, which has been found in several materials systems but no satisfactory understanding has been made\(^{49–53}\). Recently, the superlinear photoresponse was also observed in TMD system in which CVD-grown monolayers of chemically alloyed TMDs exhibited very strong superlinearity in particular at high power regimes, which is similar to our results\(^{54}\).

The superlinear behaviour at high light intensity was explained using a simplified model with three different types of recombination centres in which initially empty and filled intragap states exist close to the conduction and valence band, respectively. At increased laser intensity, the occupancy change of these centres arising from shifts in the quasi Fermi levels makes the carrier lifetime longer and in turn the recombination rate slower, leading to superlinear photocurrent.

Both the specific detectivity \((D^*)\) and external quantum efficiency values\(^{55}\) of our detector increased with increasing laser power up to \(4 \times 10^{12}\) Jones and \(3 \times 10^3\), respectively, as shown in Fig. 3e (Supplementary Note 3). The maximum photoresponsivity of our device was \(\sim 16\ A\ W^{-1}\) at a power intensity of 238 mW cm\(^{-2}\). Notably, our NIR photodetector arrays demonstrated very high cell-to-cell and batch-to-batch reliabilities (Supplementary Fig. 23). The device also exhibited a very fast current switching feature in which a sharp response and decay of photocurrent within \(\sim 100\ ms\) was observed on turn-ON and -OFF of the pulsed laser illumination, as shown in Fig. 3f (Supplementary Fig. 24). In conventional TMD phototransistors (air-exposed TMDs as a channel material), the photo-switching characteristics are primarily determined by the photoconductive effect\(^{56}\). In this case, the ON/OFF photocurrent ratio is strongly deteriorated with increasing switching cycle. This is because the air-exposed TMD channel exhibits strong charge-transfer effect between TMDs and the adsorbed H\(_2\)O or O\(_2\), such that more photo-induced carriers contribute to the charge transfer with decreasing the switching cycle. On the contrary, our photoresponse shows nearly identical ON/OFF photocurrent ratio regardless of the switching cycle (Supplementary Fig. 24).

Band-selective photodetection of mixed TMDs with PS-NH\(_2\).

More interestingly, our solution process is capable of fabricating composite films with various TMDs in the same polymer matrix, that is, PS-NH\(_2\), and this method offers a convenient route for band-selective photodetection by simple mixing of two or more different TMDs (Supplementary Note 4). For instance, the excellent photodetection properties of MoSe\(_2\) and MoS\(_2\) on illumination at 1,064 nm and 532 nm, respectively, immediately suggest that the performance of a photodetector can be tuned by mixing two TMDs in a PS-NH\(_2\) matrix (Supplementary Fig. 27). Moreover, our approach allows for a novel photodetector that can detect over a broad optical spectrum range in both visible and NIR regions, as schematically shown in Fig. 4a. Solution-blended composite films of MoSe\(_2\) and MoS\(_2\) in a PS-NH\(_2\) matrix with different compositions showed homogenous mixing of the two TMDs as confirmed by energy dispersive X-ray spectroscopy (EDX) in Fig. 4b (Supplementary Figs 28–30).
Figure 4 | Flexible TMD composite films for band-selective photodetection. (a) Schematic illustration of the photodetector containing a mixture of MoSe$_2$ and MoS$_2$ nanosheets exfoliated with PS-NH$_2$. (b) Energy dispersive X-ray spectroscopy (EDX) mapping of blended Mo$_{2y}$/MoSe$_2$ (5:5), MoSe$_2$ and MoS$_2$ films with PS-NH$_2$. Elemental mapping of the individual atoms in the Mo$_{2y}$/MoSe$_2$ (5:5) film are also showed. (Mo, Blue; Se, Yellow; S, Green; C, Red). The Se and S atoms are uniformly distributed over the composite film, which implies that both MoSe$_2$ and MoS$_2$ are mixed homogeneously. (In all cases: the scale bar, 2 μm) (c) Photoresponse performance of blended composites with different mixing ratio of MoSe$_2$ and MoS$_2$ with PS-NH$_2$ as a function of wavelength in the visible to NIR. (d) Photocurrent and (e) specific detectivity as functions of the composition of the MoSe$_2$ and MoS$_2$ mixtures embedded in PS-NH$_2$ at wavelengths of 532 nm and 1,064 nm with light intensities of 63 mW cm$^{-2}$ and 230 mW cm$^{-2}$, respectively. (f) Ratios of the photocurrent to the dark current of the detectors containing MoSe$_2$, MoS$_2$ and blended Mo$_{2y}$/MoSe$_2$ (5:5) composites with PS-NH$_2$ as a function of the bending radius. MoSe$_2$ and MoS$_2$ composites were examined at a wavelength of 1,064 nm with a light intensity of 230 mW cm$^{-2}$ and 532 nm with a light intensity of 63 mW cm$^{-2}$, respectively. On the other hand, blended Mo$_{2y}$/MoSe$_2$ (5:5) composite film was investigated at both the wavelengths of 1,064 nm and 532 nm with a light intensity of 230 mW cm$^{-2}$ and 63 mW cm$^{-2}$, respectively. (g) Photographs of in situ measurements of the flexible photodetectors at different bending radii.
To demonstrate broadband photoresponse of our blended composites in more detail, we employed a tunable and highly selective laser system (Supplementary Fig. 31) and examined photoresponse performance of blended composites with different mixing ratios of MoS$_2$ and MoSe$_2$ as a function of wavelength as shown in Fig. 4c. The results clearly show that the wavelength at the maximum photocurrent was controlled by the blend ratio. The band-selective photodetection performance of solution-blended composite films of MoSe$_2$ and MoS$_2$ in a PS-NH$_2$ matrix with different compositions was examined at two representative wavelengths—1,064 and 532 nm. The photocurrent and photodetectivity arising from NIR almost linearly decrease while those from visible light increase with increasing amount of MoS$_2$ in the composites, as shown in Fig. 4d,e, respectively (Supplementary Fig. 32). The results clearly indicate that broadband detection is possible, for example, by using a MoS$_2$/MoSe$_2$ (5:5) composite film. Blended composite films (Supplementary Fig. 33) instantly respond to both 1,064 and 532 nm light at the millisecond level, which is very similar to a MoSe$_2$ composite (Fig. 3f).

Our TMD composite photodetector demonstrated high mechanical flexibility. The arrays of photodetectors fabricated on conventional filter paper are readily bendable and photocurrent was detected in situ under various bending conditions, as shown in Fig. 4g. Figure 4f shows three representative composite films with PS-NH$_2$: neat MoSe$_2$, MoS$_2$ and blended MoS$_2$/MoSe$_2$ (5:5). For all three composites, the initial $I_{on}/I_{off}$ ratio values barely changed as a function of the bending radius. The values were still maintained even at a bending radius of ~200 μm. Our mechanically flexible TMD composite photodetectors are also resistant to multiple and repeated deformation. After 1,000 bending cycles at a bending radius of 1 mm, the devices worked properly without any significant deterioration of performance (Supplementary Fig. 34).

**Discussion**

The origin of photocurrent from MoS$_2$ and MoSe$_2$ nanosheets in composites was further revealed by the behaviour of the photo-induced, carrier-relaxation dynamics of the films. Being strongly quantum confined nature of TMD nanosheets, a well-established fact is that TMDs become a direct-gap semiconductor when the thickness is reduced down to a monolayer limit, and the band-to-band excitation generation/recombination is dominant. At the same time, the increased surface-to-volume ratio leads to fact that the photo-induced exciton recombination suffers enhanced non-radiative recombination, where such changes are strongly dependent of the number of layers. Thus, understanding the photo-induced response of TMD nanosheets and the photodetector performance requires detailed information on the light-induced, time-dependent exciton dynamics. It is known that for 2D TMDs, the non-radiative recombination contains multiple exponential decay components, typically in the sub-nanosecond time scale, which are not easily accessible by conventional electronic measurements. In addition, ultrafast spectroscopy measurements can provide not only qualitative information on the layer-number-dependent non-radiative recombination, but also afford quantitative evaluation on the extracted lifetime. Two sets of ultrafast time-resolved pump–probe spectroscopy measurements were performed: optical-pump and optical-probe (OP–OP) and optical-pump and THz-probe (OP–TP) spectroscopy (Supplementary Fig. 35).

To examine the effectiveness of liquid exfoliation of individual TMDs and the corresponding photoresponse of uniformly blended TMDs composite films, we first performed the spectrally and temporally resolved OP–OP measurement on the individual MoS$_2$ and MoSe$_2$ nanosheets modified with PS-NH$_2$, as shown in Fig. 5a,b, and the results are later compared with those from the blended MoS$_2$/MoSe$_2$ composite (Supplementary Note 5). Here ultrashort 400-nm pump pulse excited the carriers into the...
continuum, and the broadband white-light pulse was used to probe the spectrally resolved exciton transients. For MoSe2 nanosheets, Fig. 5a shows pronounced peak at 710 nm (dashed line), while excitation of MoSe2. After a few picosecond decays (~5 ps), negative signal (ΔT/ΔT0 < 0) was observed below/above the A-exciton resonance. The layer-number-dependent dynamical effects are clear difference on the carrier-relaxation dynamics between the exfoliated, bulk and monolayer MoSe2 as shown in Fig. 5c (Supplementary Fig. 36). Being strongly quantum confined 2D nature of TMD, the large surface-to-volume ratio implies multiple and yet very fast exciton dissociation pathways. On the contrary, the carrier relaxation in bulk typically exhibits much slower responses. Figure 5c shows that our TMD/polymer composite film shows very different carrier-relaxation dynamics compared with the bulk. This corroborates that our TMD nanosheets are well-exfoliated. Similar spectral feature (negative ΔT/ΔT0 around the A exciton of MoSe2 after 5- ps delay) was observed for MoS2 nanosheets, as shown in Fig. 5b.

It should be, however, noted that one should be cautious to interpret the optical transient responses since there exist multiple reasons for the observed responses such as exciton linewidth broadening, resonance shift and biexciton formation, together with defect- and Auger-induced recombination. We observed both linewidth broadening and exciton energy shift in our nanocomposite samples but it is not trivial to exactly identify the physical origin of the transient responses from our TMD nanocomposites. For instance, due to the dispersive characters of the MoS2 sheet solution exfoliated with PS-NH2, inhomogeneous broadening of A and B resonances might occur, giving rise to the energy shift. In addition, the 'spectral wing' of B exciton overlapped with that of A exciton for the pump-excited non-equilibrium response may result in the energy shift. Under high pump excitation condition, Auger effect may influence our measured signals. In spite of some unambiguity for interpreting the transient responses, the results sufficiently support our claims that our blended MoS2/MoSe2 composite is well-dispersed individually, rather than just simply mixing two dissimilar TMD powders, corroborating the band-selective photodetection mechanism of Fig. 4.

The THz probe provides a straightforward measure of the photo-induced conductivity dynamics due to the low-energy nature of THz radiation (1 THz = 4.136 meV; Supplementary Note 6). In addition, the OP–TP measurements allowed us to examine the validity of liquid polymer exfoliation of TMDs from the bulk, in which the photogenerated THz intraband carrier relaxation is expected to show different conductivity dynamics between the exfoliated TMD-polymer nanosheets and the bulk (Supplementary Figs 37 and 38). In Fig. 5d, we directly compare the THz dynamics of bulk MoS2 (black) with the few-layer MoS2 nanosheets exfoliated with PS-NH2 (red). Immediately after photoexcitation, both the bulk and few-layer MoS2 show almost the same rising dynamics. This rapidly rising signal reflects the extremely fast (within a 1-ps THz pulse width) intraband carrier relaxation from the continuum to the bound exciton state. For the long decay component, however, the time scale of the two samples is largely different. The inset in Fig. 5d clearly shows that the MoS2-polymer nanosheets possess much faster decay dynamics than that of bulk MoS2, presumably due to the interfacial traps arising from the high surface-to-volume ratio of the few-layer MoS2 nanosheets6,38,59. It is worth mentioning that the existing THz study58 performed similar ultrafast THz experiments and reported the transient decrease of THz conductivity after optical excitation, which is quite different compared with our measurements. There, the negative conductivity dynamics was attributed to the trion formation in highly doped MoS2 monolayer. Because the trion can be observed in the high doping case, the possibility of trion formation is low for the weakly doped system. In fact, the mechanically exfoliated or CVD-grown MoS2 without any electrostatic doping or chemical doping shows a non-degenerated n-type behaviour, so that it is unlikely that the trion formation is contributed to the THz conductivity dynamics for our case. The results of both the OP–OP and OP–TP spectroscopy analyses suggest not only the effectiveness of our exfoliation process with amine-terminated polymers but also the independent response of MoSe2 and MoS2 nanosheets in a blended film, which validates our approach for a band-selective detector.

In summary, we demonstrated a scalable platform suitable for fabricating various flexible TMD/polymer composite films in which few-layer TMD nanosheets were properly separated from each other and embedded in a polymer matrix. The pivotal process for the successful platform is the extremely efficient liquid exfoliation of TMDs with primary amine-terminated polymers whose end-functional amines were firmly anchored on the surface of TMDs. More interestingly, our MoSe2 and MoS2 nanosheets were highly photoconductive even at extreme bending radii as low as 200 μm on illumination of NIR and visible light, respectively. Furthermore, simple solution mixing of MoSe2 and MoS2 gave rise to blended composite films in which the photodetection properties were tunable. The MoS2/MoSe2 (5:5) film showed broad range photodetection suitable for both visible and NIR spectra, as confirmed by photo-induced, carrier-relaxation dynamics.

Methods

Exfoliation of MoSe2 with amine-end-functionalized polymers. TMD powders were purchased from Alfa Aesar and Sigma Aldrich. The amine-terminated polymers and polystyrene homopolymer were procured from Polymer Source Inc., Doval, Canada. The physical properties of the TMD powders and polymers are listed in the Supplementary Tables 1 and 2, respectively. All of the solvents were purchased from Sigma Aldrich. All of the materials were used as received unless otherwise stated. In a typical procedure, 250 mg of bulk MoSe2 powder and 25 mg of PS-NH2 were added into a 30-ml glass vial containing 25 ml of toluene. The solution was sonicated for 45 min by using a tip sonicator with a 10-s On pulse and a 5 s OFF pulse at an amplitude of 50% in an ice bath. The dispersions were allowed to settle for 24 h, and then the top dispersion was decanted and centrifuged for 30 min at 1,500 r.p.m. to remove the unexfoliated and large particles. After centrifugation, the top half of the dispersion was collected and the concentration of MoSe2 nanosheets was determined by standard gravimetric analysis.

Photodetector fabrication. To fabricate the devices, stock solutions were centrifuged for 90 min at 15,000 r.p.m. to remove the excess non-interacted polymers in the dispersions. Then, the precipitated powder was collected and dried to remove the solvents. The resultant powder consisted of ~8:2 (w/w) ratio of MoSe2 and PS-NH2. The desired amount of powder was dispersed in the solvent by bath sonication for 20 min and then filtered under vacuum onto a nylon membrane filter paper with a pore size of 200 nm and a diameter of 25 mm. For the fabrication of the mixture of the TMD composite films, first, powder of the individual TMD nanosheets with polymers was dispersed in the solvent. Then, the solutions were mixed together at different weight ratios by a simple solution blending method and deposited on filter paper. The resulting film was dried in a vacuum oven at 60 °C for 4 h. Parallel Au electrodes with thicknesses of 30 nm were deposited onto a Cu substrate by thermal evaporation under a vacuum of 10−6 Torr using a patterned shadow mask. The length and width of the channels were 50 μm and 200 μm, respectively.

Equipment and characterization. A horn probe tip sonicator (Vibracell CVX; 750 W) was used to exfoliate the TMDs with amine-terminated polymers. Centrifugation was carried out using a Hettich Mikro 22R centrifuge. The optical absorbance spectra were measured by a ultraviolet–visible–NIR spectrophotometer (JASCO V-530) using 1-cm quartz cuvettes. FT-IR studies were performed using a JASCO FT-IR 3008 apparatus (Tokyo, Japan) with KBr as a standard. The thermogravimetric analysis (TGA) of the samples was carried out using a TA Q500 thermal analyser at a heating rate of 10 °C min−1 under a nitrogen atmosphere. X-ray photoelectron spectroscopy (X-alpha Thermo VG, K.) measurements were performed using a monochromatized Al Kα X-ray source (Al Kα line: 1486.6 eV). Raman and PL measurements (LabRamAramis) were carried out using a 532-nm laser at a power of 0.5 mW and an exposition time of 10 s. X-ray diffraction patterns were

Author contributions

C.P., H.C. and D.B.V. conceived and designed the experiments. D.B.V. performed the dispersion, and fabrication of the photodetector devices. G.S. and S.M.C. performed the morphology characterization. D.B.V., R.H.K., R.K., S.H.K., S.H.C., J.H., J.L., and K.O were involved in the measurements and characterization of the photodetector devices. S.C. carried out the ultrafast spectroscopy measurements. J.H. carried out the molecular dynamics simulation. C.P. and H.C. supervised the project. C.P., H.C., and D.B.V. analysed the data and wrote the paper. All authors discussed the results and commented on the manuscript.
