Abstract

This paper presents an implementation of a Boundary Integral Equation (BIE) to compute the acoustic scattering from an individual fish, modelled as a coupled swimbladder-fish flesh configuration. The BIE formulation is used to analyze the problem of two penetrable scatterers immersed in a homogeneous medium in the particular case when one of them is strictly inside the other. The BIE is discretized and numerically solved by the Boundary Element Method (BEM) for triangular meshes. The numerical implementation is verified against benchmark solutions reported in the literature. The model is applied to evaluate the forward and backscattering response from a coupled swimbladder-fish body configuration where the geometries of both objects were obtained from a tomographic scan of a \textit{Merluccius hubbsi} specimen. From the acoustic scattering viewpoint, the swimbladder behaves as a gas-filled object while the fish-flesh acts like a weakly scatterer. The numerical results suggest that the complex specific species geometries of the swimbladder and the fish flesh, when fully coupled, can lead to substantial differences with respect to the simplified models normally in use in the area of aquatic ecosystem research.

1 Introduction

Modelling of the scattering from a single fish is a problem which has been extensively studied over the past decades \cite{1,2,3}. Since the swimbladder plays a fundamental role from the acoustic viewpoint \cite{4}, many models for the evaluation of scattering by individual fish, which exclusively consider the swimbladder and neglect any other contribution, have been reported \cite{5,6}. The swimbladder has been modelled as a non-penetrable body with a pressure-release (Dirichlet) condition on its boundary or as a fluid (gas-filled) body with a canonical geometry (cylinder, sphere or spheroid) \cite{7,8}. This last case requires the solution of a substantially more involved transmission problem since the acoustic field inside the object representing the swimbladder is required.

More realistic models simultaneously include the contribution of the swimbladder and the surrounding body (fish flesh, bones and internal organs) by adding both contributions either coherently or incoherently. This kind of approach does not take into account the interaction between the aforementioned scattering components \cite{2,3,9} which, as shown
in [7], is inadequate under certain conditions. In fact, the body of the fish and the swimbladder should not have to be considered separately but as a coupled acoustic system. On the other hand, in some other references [2, 10, 9], exact or approximate methods are applied to simplified geometries such cylinders and prolate spheroids which are used to model the scatterers.

Other methods based on heuristic assumptions such as the deformed cylinder model [11] or the Born approximation and its subsequent variants, Distorted Wave Born Approximation (DWBA) and phase-compensated DWBA [12, 13], have been used to model inhomogeneous scatterers.

The Boundary Element Method (BEM) has also been widely used to predict scattering by fish [5, 14]. Among its advantages, it can be pointed out the fact that this method can handle complex geometries. Additionally, its solution is not based on heuristic approximations such as the above mentioned approaches. However, fish scattering predicted by BEM has mainly been applied to individual targets (i.e. considering either the fish body or the swimbladder) [5, 8].

Moreover, there are reported articles where both contributions, fish bones and swimbladder, are taken into account in acoustic scattering by fish, through the method of fundamental solutions [10]. The scattering from a fish with complex geometry, acquired through CT-scan technology, is computed in [6]. Their authors consider two types of models. At first, only the swimbladder response is taken into account and the computations are carried out by the conformal mapping-based Fourier Matching Method (FMM) [15], which is suitable exclusively for axi-symmetric bodies. Secondly, in order to take into account the swimbladder and fish body, they use the Kirchhoff Ray Model (KRM) [16, 3], where both contributions are coherently added.

As far as the authors are aware, there seems to exist a relative void of studies that account for the interaction between the fish flesh and the swimbladder, without simplifying hypotheses about the shape of the bodies. This problem can be modelled by a BEM formulation that considers a double transmission scattering problem (i.e. a penetrable scatterer inside another). In this work a BEM approach is used for the double transmission scattering problem that is suitable to manage complex geometries represented by an ensemble of triangular facets but still keeping the simplification on the complex anatomy of a real fish by assuming homogeneous material properties within each scatterer volume. This paper is structured as follows. In Section 2 the complete integral-equation formulation of the problem is provided. Section 3 presents comparisons with benchmark solutions previously reported in the literature [17] as a means to get a model verification. In the Section 4 the model is applied to a complex geometry acquired from computer tomography of the fish specimen Merluccius hubbsi. Finally, the Section 5 summarizes the main conclusions of the work.

2 BEM Model formulation

2.1 Acoustic problem and integral formulation

The acoustic scattering problem by two fluid objects (i.e. acoustically penetrable objects) when one of them is completely inside the other is schematically shown in Figure 1.

An incident harmonic acoustic pressure field $u^{\text{inc}}$, typically a plane wave propagating with frequency $\omega$ and direction $\hat{k}_0$ in an unbounded homogeneous medium that interacts with two penetrable objects delimited by boundary surfaces $\Gamma_1$ and $\Gamma_2$, whose respective exterior normals are $\hat{n}_1$ and $\hat{n}_2$. These boundaries delimit three volumetric regions $R_i$.
Figure 1: Scheme for the acoustic scattering of an incident field $u^{\text{inc}}$ by two homogeneous objects immersed in an unbounded domain, with boundaries $\Gamma_1$ and $\Gamma_2$ which define three volumetric regions $R_i$ ($i = 0, 1, 2$) with physical properties $k_i, c_i, \rho_i$ (wave number, sound speed and density, respectively).

$(i = 0, 1, 2)$ whose physical properties $c_i, \rho_i$ (sound speed and density) determine the corresponding wavenumbers $k_i = \omega/c_i$. The region $R_0$ is the medium where the field $u^{\text{inc}}$ propagates and is the only one that is unbounded.

In each region $R_i$ the resulting pressure field $u_i$ is a solution of the scalar Helmholtz equation $(\nabla^2 + k_i^2) u_i = 0$. This field $u_i$ is the complex valued space-dependent part of the sound pressure field in the time-harmonic case. In the unbounded region $R_0$ the total field is $u_0 + u^{\text{inc}}$, where $u_0$ is the so called scattered field. The scattered field $u_0$ must verify a Sommerfeld radiation condition at infinity, whereas at the boundaries $\Gamma_j$ ($j = 1, 2$) the transmission boundary conditions must be verified, i.e. the total field and its normal velocity, $v_n = -i/(i\omega\rho) \partial_n u$ where $i^2 = -1$, must be continuous across the interfaces $\Gamma_j$ between the regions.

For the acoustic problem under consideration, these continuity conditions lead to

\[
\begin{align*}
  u^{\text{inc}}(x) + u_0(x) &= u_1(x) \\
  \frac{1}{\rho_0} \partial_n u^{\text{inc}}(x) + \frac{1}{\rho_0} \partial_n u_0(x) &= \frac{1}{\rho_1} \partial_n u_1(x) \\
  u_1(x) &= u_2(x) \\
  \frac{1}{\rho_1} \partial_n u_1(x) &= \frac{1}{\rho_2} \partial_n u_2(x)
\end{align*}
\]  

for $x \in \Gamma_j$ \hspace{1cm} (1)

where $u^{\text{inc}}(x) = e^{ik_0k_0x}$.

In the Boundary Integral Equation (BIE) formulation, the Helmholtz equation occurring at each region is reformulated as an integral equation. Thus, the field $u$ in each region can be represented by linear combinations of Single Layer Potential (SLP) and Double Layer Potential (DLP) integral operators. Explicitly,
\[ u_0(x) = d_{01} K_0 \psi_1(x) + s_{01} S_0 \phi_1(x) \] for \( x \in R_0 \)

\[ u_1(x) = d_{11} K_1 \psi_1(x) + s_{11} S_1 \phi_1(x) + d_{12} K_1 \psi_2(x) + s_{12} S_1 \phi_2(x) \] for \( x \in R_1 \) \hspace{1cm} (2)

\[ u_2(x) = d_{22} K_2 \psi_2(x) + s_{22} S_2 \phi_2(x) \] for \( x \in R_2, \)

where

\[ S_i \phi_j(x) = \int_{\Gamma_j} G_{k_i}(x, y) \phi_j(y) dS_y \]

\[ K_i \psi_j(x) = \int_{\Gamma_j} \partial_n y G_{k_i}(x, y) \psi_j(y) dS_y, \] \hspace{1cm} (3)

are the SLP and the DLP operators, respectively, evaluated on the unknown functions \( \phi_j, \psi_j \) (the \( j \) subscript refers to the boundary \( \Gamma_j \) \( (j = 1, 2) \)) and \( G_{k_i} \) is the free-space 3D Green function for the Helmholtz equation in the wavenumber \( k_i \), namely,

\[ G_{k_i}(x, y) = \frac{e^{ik_i|x-y|}}{4\pi|x-y|}. \]

The \( d_{ij}, s_{ij} \) that appear in Eq. (2) are real constants which will be fixed later. In the expressions given in Eq. (3) the vector position \( y \) corresponds to points on the boundaries \( \Gamma_j \) where the surface’s integration is carried out.

In order to build the normal velocity it is necessary to take the derivative with respect to the exterior normal of the fields \( u_i \), which are now expressed in terms of integral operators according to Eq. (2). This procedure leads to two new operators,

\[ K'_i \phi_j(x) = \partial_n x \left( \int_{\Gamma_j} G_{k_i}(x, y) \phi_j(y) dS_y \right) \]

\[ T_i \psi_j(x) = \partial_n x \left( \int_{\Gamma_j} \partial_n y G_{k_i}(x, y) \psi_j(y) dS_y \right), \]

generically known as the normal derivative operators.

The solution of the acoustic scattering problem, previously given in terms of the fields \( u_i \), has been transformed in the search of the unknown functions \( \phi_j, \psi_j \) for each boundary \( \Gamma_j \). In the literature these functions are called densities.

The next step in the integral formulation of the problem is to build a set of four integral equations for the four unknowns, which is achieved by using the field prescription according to Eq. (2) to evaluate the transmission conditions, Eq. (1). This process results in a Boundary Integral Equation (BIE).

By inserting the prescriptions of Eq. (2) into Eq. (1), applying the operator’s jump conditions \cite{18}, and choosing constants \( \{d_{ij}, s_{ij}\} \) according to

\[ d_{01} = \rho_0, \quad d_{22} = \rho_2, \quad s_{01} = \rho_0^2, \quad s_{22} = \rho_2^2; \]

\[ d_{11} = \rho_1, \quad d_{12} = \rho_1, \quad s_{11} = \rho_1^2, \quad s_{12} = \rho_1^2, \] \hspace{1cm} (4)

a BIE over the points \( x \) of \( \Gamma_j \) for the densities \( \psi_j, \phi_j \) \( (j = 1, 2) \) is obtained. The system

\[ \text{The following article has been submitted to The Journal of Acoustical Society of America.} \]

\[ \text{After it is published, it will be found at http://scitation.aip.org/JASA.} \]
\[ I, \text{ in the integral operator's language, is} \]
\[
\begin{align*}
(r_0K_0 - r_1K_1 + \alpha_01)\psi_1(x) + (r_0^2S_0 - r_1^2S_1)\phi_1(x) + \\
-\rho_1K_1\psi_2(x) - \rho_1^2S_1\phi_2(x) &= -u^{\text{inc}}(x) \\
-M_{01}\psi_1(x) + (\alpha_01 - r_0K_0 + r_1K_1')\phi_1(x) + \\
+T_1\psi_2(x) + \rho_1K_1'\phi_2(x) &= \frac{1}{\rho_0}\partial_n{u^{\text{inc}}}(x)
\end{align*}
\]
\[ \text{for } x \in \Gamma_1 \]
\[
\begin{align*}
\rho_1K_1\psi_1(x) + \rho_1^2S_1\phi_1(x) + (\rho_1K_1 - \rho_2K_2 + \alpha_12)\psi_2(x) + \\
+(\rho_1^2S_1 - \rho_2^2S_2)\phi_2(x) &= 0 \\
-T_1\psi_1(x) - \rho_1K_1'\phi_1(x) - M_{12}\psi_2(x) + (\alpha_12 - \rho_1K_1' + \rho_2K_2')\phi_2(x) &= 0
\end{align*}
\]
\[ \text{for } x \in \Gamma_2, \]

where \( \alpha_01 = (r_0 + \rho_1)/2, \alpha_12 = (\rho_1 + \rho_2)/2 \) and \( M \) is another operator, called the Müller operator and defined as
\[
M_{s\ell}\psi_j(x) \equiv T_{s}\psi_j(x) - T_{\ell}\psi_j(x).
\]

The particular choice of constants in \( I \) is aimed to force the turning up of the Müller operator \( \[ I \] \) since its behavior regarding the singularity degree is advantageous over the use of the \( T \) operator, which is hypersingular. Consequently, its numerical evaluation can be managed without special techniques (as mentioned by \[ 19 \] in section 5.2.1, for example).

The system of integral equations obtained in this section is based on \[ 20 \] and \[ 21 \]. The reader is referred to these references for a more detailed treatment.

### 2.2 Numerical method

The system \( \hat{I} \) can be solved through a discretization process over the boundaries \( \Gamma_j \), which turns it in a finite-size matrix system. This leads to a Boundary Element Method formulation. For this step the standard procedure is to assume the following two approximations.

1. Each surface \( \Gamma_j \) is approximated by a planar triangular mesh (i.e., a set of triangles \( \{\Delta_{j\ell}\} \) with \( \ell = 1, 2, \ldots N_j \)), so that
\[
\Gamma_j = \bigcup_{\ell=1}^{N_j} \Delta_{j\ell},
\]
where \( \Delta_{j\ell} \) is the \( \ell \)-th triangle whose centroid is \( x_{j\ell} \) and \( N_j \) is the total number of triangles of the mesh that represents the \( \Gamma_j \) boundary.

2. The unknown densities \( \psi_j \) and \( \phi_j \) are considered as piecewise constant functions in each triangle, that is,
\[
\psi_j(x) = \sum_{\ell=1}^{N_j} \psi_{j\ell}I_{\Delta_{\ell}}(x) \quad \phi_j(x) = \sum_{\ell=1}^{N_j} \phi_{j\ell}I_{\Delta_{\ell}}(x),
\]
where \( \psi_{j\ell}, \phi_{j\ell} \) are unknown complex numbers and \( I_{\Delta_{\ell}}(x) \) is the indicator function of the \( \ell \)-th triangle, defined as
\[
I_{\Delta_{\ell}}(x) = \begin{cases} 
1 & \text{if } x \in \Delta_{\ell} \\
0 & \text{otherwise}
\end{cases}
\]

The following article has been submitted to The Journal of Acoustical Society of America. After it is published, it will be found at http://scitation.aip.org/JASA.
In order to find the densities, the prescription given in Eq. (7) is introduced in the BIE system (5). This procedure transforms each integral over the boundary \( \Gamma_j \) into a sum of integrals over each triangle \( \Delta_j^i \).

The resulting system remains, of course, valid for all \( x \in \Gamma_j \), so that in particular is valid for the set of centroids \( \{ x_j^i \} (\ell = 1, 2, \ldots, N_j) \) belonging to the boundary \( \Gamma_j \). When these discretized equations are evaluated in both sets \( \{ x_1 \}, \{ x_2 \} \), a matrix system of size \( m \times m \) is obtained, with \( m = 2(N_1 + N_2) \). The unknown values are the complex quantities \( \{ \psi_j^i, \phi_j^i \} \).

These equations can be expressed as a square matrix system, namely,

\[
A \begin{pmatrix} \psi_j^1 \\ \phi_j^1 \\ \psi_j^2 \\ \phi_j^2 \\ \vdots \\ \psi_j^{N_j} \\ \phi_j^{N_j} \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}
\]

where the square matrix \( A \) has \( 2(N_1 + N_2) \) rows, and the unknowns \( \psi_j^i, \phi_j^i \) and data vectors \( f, g \) are defined as

\[
\psi_j^i = \begin{pmatrix} \psi_j^1 \\ \psi_j^2 \\ \vdots \\ \psi_j^{N_j} \end{pmatrix}, \quad \phi_j^i = \begin{pmatrix} \phi_j^1 \\ \phi_j^2 \\ \vdots \\ \phi_j^{N_j} \end{pmatrix},
\]

\[
f = -\begin{pmatrix} \text{inc}(x_1^1) \\ \text{inc}(x_2^1) \\ \vdots \\ \text{inc}(x_{N_1}) \end{pmatrix}, \quad g = \begin{pmatrix} \rho_0 \partial_n \text{inc}(x_1^1) \\ \rho_0 \partial_n \text{inc}(x_2^1) \\ \vdots \\ \rho_0 \partial_n \text{inc}(x_{N_1}) \end{pmatrix}.
\]

The \( A \)-matrix full expression is given in the next subsection.

### 2.2.1 Matrix definition

The matrix system has a symmetry which is emphasized in the four-block structure of submatrices \( B_i, D_i \) and \( I_i \) \( (i = 1, 2) \), namely,

\[
A = \begin{pmatrix} D_1 & B_1 \\ B_2 & D_2 \end{pmatrix} + \begin{pmatrix} \alpha_{01} I_1 & 0 \\ 0 & \alpha_{12} I_2 \end{pmatrix}.
\]

The matrices \( I_1 \) and \( I_2 \) are identities with dimensions \( 2N_1 \) and \( 2N_2 \), respectively. Each \( D_i \) is a matrix of \( 2N_i \times 2N_i \) size and has the form

\[
D_1 = \begin{pmatrix} (\rho_0 K_0 - \rho_1 K_1)^{[1,1]} & (\rho_0^2 S_0 - \rho_1^2 S_1)^{[1,1]} \\ -M_{01}^{[1,1]} & (-\rho_0 K_0' + \rho_1 K_1')^{[1,1]} \end{pmatrix}
\]

The following article has been submitted to The Journal of Acoustical Society of America. After it is published, it will be found at [http://scitation.aip.org/JASA](http://scitation.aip.org/JASA).
\[
D_2 = \begin{pmatrix}
(\rho_1 K_1 - \rho_2 K_2)^{[2,2]} & (\rho_1^2 S_1 - \rho_2^2 S_2)^{[2,2]}
\end{pmatrix}
\]

The matrices \( B_1, B_2 \) have size \( 2N_1 \times 2N_2 \) and \( 2N_2 \times 2N_1 \), respectively, and its expressions are

\[
B_1 = \begin{pmatrix}
-\rho_1 K_1^{[1,2]} & -\rho_1^2 S_1^{[1,2]} \\
T_1^{[1,2]} & \rho_1 K_1^{[1,2]}
\end{pmatrix},
B_2 = \begin{pmatrix}
\rho_1 K_1^{[2,1]} & \rho_1^2 S_1^{[2,1]} \\
-\rho_1 K_1^{[2,1]} & \rho_1 K_1^{[1,2]}
\end{pmatrix}.
\]

The discrete version of a generic operator \( U_q^{[a,b]} \in \mathbb{C}^{N_a \times N_b} \) (\( a, b = 1, 2 \)) with kernel \( \Phi(k_q; x, y) \) follows the notation

\[
(U_q^{[a,b]})_{\ell s} = \int_{\Delta^b_s} \Phi(k_q; x^a_\ell, y) dS_y
\]

for the \( \ell s \)-element. Thus, the first superindex \( (a) \) refers to the boundary where the evaluation point is located whereas the second \( (b) \) refers to the boundary to which the triangle \( \Delta^b \) over which the surface integration is carried out belongs. The matrix row-index \( \ell \) is associated with a particular evaluation point \( x^a_\ell \) while the column index \( s \) is associated with the particular element \( \Delta_s \). The subindex \( q \) identifies the corresponding wavenumber \( k_q \). For example,

\[
(S_1^{[1,2]})_{\ell s} = \int_{\Delta^2_s} G_{k_1}(x^1_\ell, y) dS_y,
\]

implies integration over the \( s \)-th triangle of the boundary \( \Gamma_2 \) and evaluation on centroid \( x^1_\ell \) belonging to the boundary \( \Gamma_1 \), all for the wavenumber \( k_1 \).

### 2.3 Scattered field and TS computation

Once the densities \( \{\psi_j, \phi_j\} \) have been obtained, the scattered field at an exterior point \( x \) can be calculated by evaluating the first Eq. in (2) with the piecewise approximation made at Eq. (7). Therefore, the discretized version of the external field is

\[
u_0(x) = \sum_{\ell=1}^{N_1} \left( \rho_0 \psi^1_\ell \int_{\Delta^1_\ell} \partial_n G_{k_0}(x, y) dS_y + \rho_0^2 \phi^1_\ell \int_{\Delta^1_\ell} G_{k_0}(x, y) dS_y \right).
\]

When the exterior point \( x \) is located far away the scatterer object (\( |x| \to \infty \)), it is possible to use the asymptotic expression of the Green function and its normal derivative, namely,

\[
G_{k_0}(x, y) = \frac{e^{ik_0|x|}}{4\pi|x|} \left[ e^{-ik_0|x-y|} + O \left( \frac{1}{|x|} \right) \right]
\]

\[
\partial_n G_{k_0}(x, y) = \frac{e^{ik_0|x|}}{4\pi|x|} \left[ \partial_n e^{-ik_0|x-y|} + O \left( \frac{1}{|x|} \right) \right].
\]
Substituting the above expressions into Eq. (12) the scattered field turns out
\[ u_0(x) = e^{i k_0 |x|} \left[ f_\infty(\hat{x}) + \mathcal{O} \left( \frac{1}{|x|} \right) \right], \]
where \( \hat{x} = x/|x| \) is the unit vector in the direction of observation –pointing towards the observer–, \( k_0 \) is the wavenumber of the incident field and \( f_\infty \) is the farfield scattering amplitude (a quantity with length’s units) whose expression is
\[ f_\infty(\hat{x}) = \frac{1}{4\pi} \sum_{\ell=1}^{N_f} \left( -i k_0 \psi_1^\ell \rho_0 \int_{\Delta_{\ell}} e^{-i k_0 \hat{x} \cdot y} \hat{x} \cdot n \, dS_y + \rho_0^2 \phi_1^\ell \int_{\Delta_{\ell}} e^{-i k_0 \hat{x} \cdot y} \, dS_y \right). \] (13)

Thus, the usual cases of back-scattering and forward-scattering are obtained by considering \( \hat{x} = -\hat{k}_0 \) and \( \hat{x} = \hat{k}_0 \), respectively, i.e.
\[ f_\infty^{bs} \equiv f_\infty(\hat{x} = -\hat{k}_0) \quad f_\infty^{fw} \equiv f_\infty(\hat{x} = \hat{k}_0). \] (14)

In fisheries acoustics, as well as in other SONAR applications, sound scattering by an object is analyzed in the logarithmic scale using the target strength parameter (TS) that can be expressed as
\[ \text{TS} = 10 \log_{10} (|f_\infty|^2) \, \text{dB re} \, 1 \, \text{m}^2. \] (15)

As a summary, once \( \psi_1^\ell \) and \( \phi_1^\ell \) from (8) are known, the TS parameter can be computed by using the numerical evaluation of (13) in the formula given by (15).

3 Model verifications

In order to verify the formulated model, designated from now on as the Coupled BEM model, two types of tests are conducted, by comparisons between model predictions and benchmark results derived from exact solutions.

In first place, the acoustic scattering problem corresponding to a single penetrable obstacle, a prolate spheroid, is considered. Consequently only a scattering boundary \( \Gamma \) is present and the formulation of the problem is simplified (a brief description of this case is worked out in the Appendix). In second place, the acoustic problem of two concentric spheres is considered. This allows to explicitly test the system of Eq. (8).

3.1 Single fluid acoustic problem

For a single fluid obstacle, Coupled BEM model predictions are compared with a benchmark solution previously reported [17]. These authors compute backscattering TS as a function of the incidence angle \( \theta \) for a gas-filled prolate spheroid with semi-axis \( a = 0.07 \) m and \( b = 0.01 \) m, at 38 kHz. In order to compute the scattering response of the same prolate spheroid using the model, a spheroidal mesh with \( N = 44480 \) triangular elements is used. The number of elements in the mesh is selected in order to guarantee that the acoustic wavelength would be several times greater than the distance between vertices (usually five or six times greater) following the recommendation reported in [5].

The comparison between the modelled TS and the TS computed for the exact prolate spheroid solution [22], is exhibited in Figure 2 where a good agreement is observed. The assumed sound speed and density for the gas inside the prolate spheroid were \( c_1 = 345.0 \) m s\(^{-1}\) and \( \rho_1 = 1.24 \) kg m\(^{-3}\), respectively; whereas the corresponding values in the surrounding medium (water) were \( c_0 = 1477.4 \) m s\(^{-1}\) and \( \rho_0 = 1026.8 \) kg m\(^{-3}\). These values were taken from the literature (Table II from [17]) and corresponds to realistic values in aquatic ecosystem research applications.
Figure 2: Comparison of TS vs. incidence angle $\theta$ for a gas-filled prolate spheroid with aspect ratio 1:7, evaluated according to the Coupled BEM model (solid line) and to the benchmark solution (dotted line).

3.2 Two fluids acoustic problem

The acoustic scattering problem for two 3D bounded fluid objects has no exact analytical solution, except in the case of two concentric spheres. In this case, the solution is given in terms of an analytical modal series (partial wave decomposition) coming from the separation of the wave equation in spherical coordinates [23].

In order to compare the values predicted by the Coupled BEM model against the benchmark modal solution, two concentric spheres of radii $r_1 = 0.06$ m and $r_2 = 0.016$ m are considered, where the subscript 1 refers to the external sphere and the subscript 2 to the internal one. Keeping in mind, as in the previous example, applications to fisheries acoustics, the values of sound speed $c$ and density $\rho$ of the material media are taken from [2], and they are also listed in Table 3.2. The medium “0” corresponds to the surrounding water, while media “1” and “2” correspond to the external and internal spheres, respectively.

| Medium | $c$ (m s$^{-1}$) | $\rho$ (kg m$^{-3}$) |
|--------|-----------------|---------------------|
| 0 (water) | 1477.4          | 1026.8              |
| 1      | 1.04 $c_0$      | 1.04 $\rho_0$      |
| 2      | 0.23 $c_0$      | 0.00129 $\rho_0$   |

Table 1: Material properties (sound speed $c$ and density $\rho$) for the media 0, 1, 2 in the two spheres acoustic scattering problem.

For modelling this problem under the Coupled BEM approach, two spherical meshes were built. The number of triangular elements were $N_1 = 1142$ and $N_2 = 2274$, for the spheres of radii $r_1$ and $r_2$ respectively. Backscattering TS values for the frequency range 0.01 – 38 kHz, were computed using the modal series and the BEM implementation. Results of their comparison are shown in Figure 3 where a good agreement is again evident.
3.3 Error in TS computations

The criterion reported in [17] is used to estimate the error level of the modelled TS in the previous examples. In that work the authors quantified the error as the mean of the absolute deviation between the modelled TS and the TS computed in the benchmark case (exact solution), i.e.

$$|\Delta TS| = \frac{1}{L} \sum_{i=1}^{L} |TS_i(\text{prediction}) - TS_i(\text{benchmark})|,$$

where $L$ is the total number of frequency or angle calculated values. Values for $|\Delta TS|$ were 0.066 dB and 0.12 dB for the prolate spheroid and the two concentric spheres, respectively.

4 Application to fish tomography

The *Merluccius hubbsi* is one of the most important fishing resources of the Argentine Sea. Moreover, it is the most abundant species of demersal fish (living near the seabed) in the Southwestern Atlantic ocean. Therefore, it plays a prominent role in the marine ecosystems of the Argentinian continental shelf. It is also important to note that their extraction crucially depends on the possibility of detection of fish schools using underwater acoustics. For this reason, a better knowledge of the backscattering of this species, as well as its acoustic scattering in other directions is very important both for fishing activity and for scientific research purposes.

4.1 Meshes and scattering parameters

Computerized tomography (CT) scans performed on a *Merluccius hubbsi* specimen, with spatial resolution of 1.5 mm, allowed for building two 3D triangular meshes to represent the fish body and its swimbladder having $N = 8983$ and $N = 11474$ elements, respectively.

Meshes are exhibited in Figure 4. Top panel shows the fish head and part of the swimbladder. Triangle edges that constitute the fish body-mesh are visualized.
middle panel both scatterers are exhibited and it can be noticed that their relative locations are not concentric. Moreover, the swimbladder longitudinal axis is approximately $10^\circ$ tilted head-up respect to the main body axis. The swimbladder is presented in detail in the bottom panel, its geometry is rather complex, and cannot be approximated by a simple shape such as a sphere, a finite-length cylinder or a spheroid.

![Figure 4: 3D meshes generated from Computer Tomography scan. The top panel shows a detailed view of the head's fish where individual triangular facets are appreciable. The middle panel displays the body-mesh and the swimbladder-mesh inside it so that their relative locations can be visualized. A more detailed view of the swimbladder mesh is shown in the bottom panel, where for clarifying purposes the view has been rotated.](image)

The material properties of the surrounding medium (water), the fish flesh constituting the body and the gas in the swimbladder are taken from the Table 3.2. All the simulations were computed at $f = 38$ kHz, since it is a usual frequency in fisheries acoustics. The body length is 382.5 mm and the scattering can be characterized by the dimensionless parameter $k_0a \approx 31$. For the swimbladder, whose length is 81.8 mm, there are two relevant parameters, namely, $k_1a \approx 6.3$ and $k_2a \approx 28.7$. In both cases $a$ is the appropriate semi-longitude of the scatterer.
Figure 5: Schematic grid for evaluation of TS by fish in the dorsal-ventral aspect (left) and lateral aspect (right). The angle \( \theta \) is associated to the observation direction \( \hat{x} \) as it is illustrated in both panels. To emphasize the swimbladder relative location respect to the fish body, the latter is shown with transparency.

4.2 Backscattering and forward scattering TS computations

Since at 38 kHz both scatterers (body and swimbladder) have an acoustic length of several wavelengths it is expected that the scattering, mainly the backscattering, strongly depends upon morphology and orientation. Keeping these considerations in mind, backscattering and forward scattering evaluations as a function of the observation angle \( \theta \) are conducted for dorsal-ventral aspect (incidence contained in the \( y = 0 \) plane, see scheme in Figure 5 left) and lateral aspect (incidence contained in the \( x = 0 \) plane, see Figure 5 right), for the entire circle \( 0 \leq \theta \leq 360^\circ \) in both cases.

The observation angle \( \theta \) corresponds to the observation direction \( \hat{x} \), as it is stated in the Figure 5. Thus, according to Eq. (14), for the backscattering case the incidence direction \( \hat{k}_0 \) is opposite to \( \hat{x} \) while in the forward scattering both directions are coincident, namely \( \hat{k}_0 = \hat{x} \).

4.2.1 Backscattering computations

The resulting patterns for backscattering TS are presented in this section. As stated in the Section 1, other investigators [5, 6] have modelled the TS of a fish considering only the swimbladder and neglecting the body contribution. This formulation implies

\[
TS = 10 \log_{10}(|f^{bs}_{\infty,Sb}|^2),
\]

where \( f^{bs}_{\infty,Sb} \) is the farfield backscattering yielded by the swimbladder. On the other hand, TS has been also modelled by computing both contributions separately and then adding them incoherently [2] or coherently [9]. In particular, the coherent addition leads to

\[
TS = 10 \log_{10}(|f^{bs}_{\infty,Sb} + f^{bs}_{\infty,B}|^2),
\]

where \( f^{bs}_{\infty,B} \) is the corresponding farfield pattern exclusively from the body. It should be emphasized that a formulation like the proposed in (17) is an approximation because each \( f_{\infty} \) is calculated independently, i.e., without interaction between the scatterers. The BEM approach presented in this work treats the problem including both contributions jointly, within a rigorous framework for a coupled system.
In order to compare the results of the Coupled BEM approach with the aforementioned approximated models, it is useful to establish the following nomenclature: All the TS calculated by using the Coupled BEM approach, which is derived from Eq. (13), will be labelled “Model”. TS patterns obtained considering only the acoustic response from the swimbladder, derived from Eq. (16) and computed through the single scatterer BEM approach (see Appendix) will be labelled “Sb” and, finally, patterns obtained for the coherent sum of the body and swimbladder acoustic responses, according to Eq. (17) and calculated through the evaluation of each $f_\infty$ separately, both using the single scatter BEM approach, will be labelled “Sb + B”.

The resulting patterns for backscattering TS according to the three types of evaluation are shown in Figure 6 as a polar plot. In the left panel (dorsal-ventral aspect) it is clear that the presence of TS maxima at 99° and 277° is associated with orientations where the swimbladder yields a greater normal surface (see Figure 5, left) with respect to the incidence direction. Those orientations are precisely the directions where the swimbladder contribution and the fish body plus the swimbladder as a whole, shows the best match. However, that match deteriorates near the longitudinal axis of the fish, i.e., in the head-tail direction, where the interaction between body and swimbladder, explicitly considered by the coupled BEM approach, is relevant and therefore the coherent sum does not provide a good match of the corresponding curves.

When the lateral aspect of the fish is considered (Figure 6, right panel), it is found that the curve that exclusively represents the contribution of the swimbladder differs from the curve generated by the model to a great extent in comparison with the previous case (i.e. dorsal-ventral aspect). This observation can be justified because the insonified area that the swimbladder offers to the acoustic incident wave is undoubtedly smaller at the fish lateral aspect than at the fish dorsal-ventral one.

Model results of the TS parameter are traditionally presented as 2D polar plots as shown in Figure 6. A proper 3D plot visualization of the scattering phenomenon has been reported (e.g., see [24]). An alternative type of visualization for backscattering responses is
proposed in this work for all possible incidence $\hat{k}$ directions, as it can be observed in Figure 7 where each direction is identified with a point on the surface of a sphere surrounding the scatterer and its colour provides a measure of the backscattering TS magnitude. With the purpose of helping the visualization of the results in the corresponding plots, the sphere has been divided into six patches which are shown in pairs in Figure 7. These pairs of patches are identified with the names that appear above them (i.e. Dorsal/Ventral, Left/Right and Head/Tail). Additionally, within each sphere the mesh of the fish has been plotted in order to indicate its relative location. For example, maximum TS is achieved at the directions whose colour has the highest value in the colour-bar scale located at the right side of the figure. That happens when swimbladder is approximately orthogonal to the incident wave front. The ranges of TS values obtained for each pair of patches were $[-82.1, -29.9]$ dB, $[-89.02, -32.1]$ dB and $[-63.1, -45.1]$ dB, respectively.

Figure 7: 3D Visualization of backscattering TS by fish for every possible incidence angle represented on the surface of a sphere. Each direction is identified with a point on the surface of a sphere surrounding the scatterer and its colour provides a measure of the backscattering TS magnitude. The sphere is divided into six patches that are shown in pairs Dorsal/Ventral (top panel), Left/Right (middle panel) and Head/Tail (bottom panel). Within each sphere the mesh of the fish is plotted in order to indicate its relative location.
4.2.2 Forward scattering computations

Although forward scattering has been studied less extensively than backscattering (partly because of its greater experimental difficulty) it also has interesting applications. The forward scattering can be applied in fish detection methodologies, therefore it has been addressed with simplified models [7], [25]. Furthermore, the estimation of attenuation through the medium is related to the forward scattering $f_{\infty}$ [12].

The corresponding patterns for the forward scattering case are shown in Figure 8, where a curve “B”, representing exclusively the acoustic response from the fish body –calculated using the single scatterer’ BEM approach–, has been added.

![Figure 8: Forward scattering TS as a function of angle $\theta$ in the dorsal-ventral aspect (left panel) and lateral aspect (right panel). Swimbladder and fish body are considered as a gas-filled and weakly scattering objects, respectively. Both contributions are taken into account in different ways. In the Coupled BEM approach (solid line) the interaction between swimbladder and fish body is explicitly considered. The curve “Sb” shows exclusively the response of the swimbladder (dotted line); the curve “Sb+B” shows the response of the swimbladder coherently added to the fish body (dashed line) and the curve “B” shows exclusively the response of the fish-body (dotted-dashed line).](image)

The left panel of Figure 8 displays the dorsal-ventral aspect pattern whereas the right panel shows the lateral aspect. The forward scattering has a smooth behavior regards to the angle. In a weakly scattering situation, which occurs certainly for the fish body given the parameters used ($c_1 = 1.04c_0$ and $\rho_1 = 1.04\rho_0$, c.f. Table 3.2), the forward response is almost independent of orientation because it is mainly a volume phenomenon. For the dorsal-ventral and lateral aspects the model predicts practically the same patterns. The swimbladder response “Sb”, which has two lobes under both aspects, is remarkably smaller than all the others and it can be seen that the coherent sum “Sb + B” always exceeds the response obtained from the model.

The minimum and maximum difference between coherent sum and the model are 0.84 and 2.08 dB (dorsal-ventral aspect) or 0.56 and 2.11 dB (lateral aspect), respectively.

4.3 Near-field and internal field calculations

In Section 3 the predictions derived from the formulated model were verified for the farfield case whereas in this Sub-Section, the near-field and internal fields are evaluated over a plane that cuts longitudinally in two halfs the parallelepiped in which the swimbladder is...
inscribed. This plane is illustrated in the Figure 9 (left), where the intersection curves between the fish body and the swimbladder with the plane can also be seen.

The right panel of the Figure 9 shows the the absolute value of the acoustic field on the plane. Again, the curves intersecting body and swimbladder with the plane, have been indicated. The plotted fields are \( u = u_0 + u^{inc} \) in the exterior to the fish (the total field), \( u_1 \) in the fish flesh and \( u_2 \) inside the swimbladder. An arrow indicating the incident field direction, a plane wave, has also been illustrated.

Figure 9: Diagram of fish and its intersection with a plane that cuts in two halves the parallelepiped in which the swimbladder is inscribed (left). Evaluation of the absolute value of the near-field and the internal fields over this plane (right). The resulting contour of the intersection between the plane and the mesh-scatterers can be observed in both panels (solid line). The plane wave incidence direction is indicated by an arrow.

It can be clearly observed in the figure that the acoustic field verifies continuity across the different media. It should be noted that the changes in the field produced by the fish flesh are very weak while those due to the swimbladder lead to a high contrast (i.e. the field barely changes when entering the fish flesh from the exterior but this is not the case when the field enters the swimbladder from the fish internals) as it can be seen in the figure. This state of affairs is undoubtedly tuned by the impedance mismatch between the corresponding media; the data in Table 3.2 prescribe a high contrast between the swimbladder and the fish body and a minor one between the fish body and the surrounding water.

5 Conclusions

A model has been formulated to describe the scattering produced by two penetrable objects immersed in an homogeneous medium. This model is based on a BIE formulation, subsequently discretized and solved numerically through a coupled BEM method. Verification of the good agreement between the model predictions and the results obtained by exact solutions in some benchmark cases was accomplished (Section 3).

In particular, the model has been applied to compute the scattering produced by a fish of the hake type, *Merluccius hubsi* (Section 4) whose morphology was obtained from a CT tomography while the estimated values assumed for its physical properties (\( c \) and \( \rho \), sound speed and density, respectively) are typical values reported in the literature for real fish. From the standpoint of the model, fish flesh and swimbladder are considered as two
penetrable and interacting objects. However, it is emphasized that any extension of the model to enable the incorporation of other parts of the fish (e.g. spine) does not require further development and can be done following the same lines.

Results for backscattering and forward scattering TS have been obtained and compared with the individual responses of the swimbladder and the body as well as with its coherent sum (swimbladder and body contributions considered separately, i.e. without interaction between them). For the physical situation under consideration, it was found that the relative contributions of the swimbladder and the fish body vary depending of the scattering direction.

In the backscattering case it turned out that for the directions where the swimbladder presents its greater area to the incident wave, the coherent sum and the model do not show significant differences. On the other hand, in the case of forward scattering the behaviour is totally different. The swimbladder is not dominant as in the previous case and the coherent sum always overestimates the interacting field provided by the coupled BEM. In this scenario the body-swimbladder interaction should be taken into account explicitly since if it is not considered, errors up to 2 dB could appear in the calculated TS.

The model is also capable of computing the acoustic field within the fish as it is presented in Section 4.3 for a particular plane.

The correct modelling of the interaction between the various constituent parts of a fish, in the idealization that each of them can be characterized by constant values of sound speed $c$ and density $\rho$, allows to progress in the further understanding of the acoustic response of individual specimens. The model can be useful for determining specific characteristics that allow to discriminate one species from another. Then, based on the knowledge of the most relevant characteristics that describe the acoustic scattering behavior, simplified models aimed to predict the response by schools of fish can be formulated.

The original computational codes are released and can be downloaded from one of the author’s github repository, so that the reproducibility of the results obtained is guaranteed [26].

Acknowledgments

Appendix: BEM applied to a single fluid scatterer

The acoustic scattering by a single fluid object can be considered as a particular case of the two objects problem in which the inner object in Figure 1 is suppressed. Therefore, the natural boundary conditions lead to

\[
\begin{align*}
    u^{\text{inc}}(x) + u_0(x) &= u_1(x) & \text{for } x \in \Gamma_1 \\
    \frac{1}{\rho_0} \partial_n u^{\text{inc}}(x) + \frac{1}{\rho_0} \partial_n u_0(x) &= \frac{1}{\rho_1} \partial_n u_1(x) & \text{for } x \in \Gamma_1
\end{align*}
\]

The acoustic fields are expressed as

\[
\begin{align*}
    u_0(x) &= d_{01} K_0 \psi_1(x) + s_{01} S_0 \phi_1(x) \\
    u_1(x) &= d_{11} K_1 \psi_1(x) + s_{11} S_1 \phi_1(x)
\end{align*}
\] (18)

where the constants \( d_{ij} \) and \( s_{ij} \) are chosen as

\[
\begin{align*}
    d_{01} &= \rho_0, & s_{01} &= \rho_0^2, & d_{11} &= \rho_1, & s_{11} &= \rho_1^2.
\end{align*}
\]

By straightforward calculations similar to the ones performed in Section 2, the discretized versions of densities \( \psi_1 \) and \( \phi_1 \) of (18) are \( \psi^1 \) and \( \phi^1 \), respectively. They should satisfy the system

\[
(D_1 + \alpha_{01} I) \begin{pmatrix} \psi^1 \\ \phi^1 \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}, \tag{19}
\]

where \( \alpha_{01} = (\rho_0 + \rho_1)/2 \), matrix \( D_1 \), \( f \) and \( g \) depend only on \( \Gamma_1 \). They are defined in Eqs. (11) and (9).

The TS values are obtained by computing \( f_\infty \), according to Eq. (13) where the \( \psi^1 \) and \( \phi^1 \) are now the solutions of the system (19).
