We study particle production and unitarity violation caused by a curved target space right after inflation. We use the inflaton field value instead of cosmic time as the time variable, and derive a semiclassical formula for the spectrum of produced particles. We then derive a simple condition for unitarity violation during preheating, which we confirm by our semiclassical method and numerical solution. This condition depends not only on the target space curvature but also on the height of the inflaton potential at the end of inflation. This condition tells us, for instance, that unitarity is violated in running kinetic inflation and Higgs inflation, while unitarity is conserved in α-attractor inflation and Higgs-Palatini inflation.

DOI: 10.1103/PhysRevD.103.103536

I. INTRODUCTION

Inflation is a successful paradigm that describes the beginning of the universe and provides seeds for large scale structure and the cosmic microwave background (CMB) anisotropies. Inflation is typically driven by the potential energy of a scalar field, i.e., an inflaton, that slowly rolls down its potential. After inflation, the inflaton typically oscillates around the minimum of its potential and its energy is released by particle production, a process referred to as (pre)heating. The (pre)heating dynamics is of great importance since the inflationary observables such as the spectral index and tensor-to-scalar ratio depend on the reheating temperature through the duration of the reheating phase. In addition, interesting physical processes in the early universe such as baryogenesis and dark matter production often depend on the reheating temperature.

Recently, it was pointed out that the preheating dynamics of Higgs inflation can be more violent than previously thought [1]. In Higgs inflation the standard model Higgs is identified as the inflaton and, with the help of a nonminimal coupling to gravity, the model is consistent with the CMB observation [2–5], making it one of the most popular inflation models on the market. Reference [1] found that an effective mass term of the Goldstone (or equivalently longitudinal gauge) bosons shows a “spiky” feature as the Higgs passes the origin. The typical energy scale of particles produced by this spike exceeds the cutoff scale of the theory for \( \xi \gtrsim O(100) \), resulting in unitarity violation. In other words, this phenomena invalidates the low energy description of Higgs inflation and requires a UV completion.2 The unitarity violation of Higgs inflation was originally found by studying the dynamics of the inflaton in the Jordan frame, but this is also nicely understood as a result of the target space curvature in the Einstein frame [6,7]. Since there are many other inflation models that have nontrivial target space curvatures in the Einstein frame, it is then natural to ask if unitarity violation happens in those other models.

In this paper, we study particle production and unitarity violation from the target space curvature during preheating in detail. Throughout this work, we study preheating by a set of linearized mode equations, and we neglect the backreaction to the inflaton field. This treatment allows us to obtain analytical expressions for the spectrum after the first inflaton zero crossing.3 In Sec. II, we study particle production and unitarity violation caused by a curved target space right after inflation. We use the inflaton field value instead of cosmic time as the time variable, and derive a semiclassical formula for the spectrum of produced particles. We then derive a simple condition for unitarity violation during preheating, which we confirm by our semiclassical method and numerical solution. This condition depends not only on the target space curvature but also on the height of the inflaton potential at the end of inflation. This condition tells us, for instance, that unitarity is violated in running kinetic inflation and Higgs inflation, while unitarity is conserved in α-attractor inflation and Higgs-Palatini inflation.

The CMB requires \( \xi^2 \approx 2 \times 10^9 \lambda \), where \( \lambda \) is the Higgs quartic coupling, and hence this is the case unless \( \lambda \) is (tuned to be) tiny at the inflationary energy scale.

We discuss different viewpoints on the unitarity issue of Higgs inflation in Sec. III C.

In the case of efficient particle production, the linearized treatment quickly breaks down and—in the case of large occupation numbers—one should resort to lattice simulations for an accurate description of the particle production process. Generally speaking, the linearized equations give a good description of the spectrum after the first inflaton zero crossing. Even when preheating is very strong, it allows us to estimate the typical momentum of the produced particles.
production of a scalar field $\chi$ coupled to the inflaton $\phi$. This section is intended to be generic, and hence we take the effective mass term of $\chi$ to be a general function of $\phi$ and its velocity $\dot{\phi}$ without specifying its origin. In general, it is challenging to study particle production analytically when the kinetic term of the inflaton is nontrivial, since the inflaton is not a simple function of the cosmic time $t$ in such a case. Instead, we use the inflaton field value $\phi$ itself as the time variable and work solely in the scalar field space, not referring to $t$. In this method, the inflaton velocity is expressed as a function of $\phi$ by using an (approximately) conserved quantity such as the inflaton energy density. This enables us to apply a phase integral approximation to obtain a semiclassical formula of the spectrum that reproduces the numerical results quite well.

We then address the question of unitarity violation in Sec. III. In particular, we find that the following simple condition works as a criterion for unitarity violation:

$$V(\Phi) \gtrsim \Lambda^4,$$

(1.1)

where $V(\Phi)$ is the height of the inflaton potential at the end of inflation with $\Phi$ the inflaton amplitude, and $\Lambda$ is the typical mass scale of the target space curvature. Note that $\Lambda$ is the cutoff scale of the theory at the same time since it enters the scattering amplitude of, e.g., $\phi \phi \to \chi \chi$. For instance, $V(\Phi) \sim \lambda M_p^4/\xi^2$ and $\Lambda \sim M_P/\xi$ for Higgs inflation with $\lambda$ the Higgs quartic coupling and $M_P$ the reduced Planck scale [8–12], and hence the condition (1.1) reads

$$\lambda \xi^2 \gtrsim 1,$$

(1.2)

which agrees with the condition known in the literature [1]. The condition (1.1) tells us that not only the target space curvature but also the height of the inflaton potential is important for unitarity violation. We derive this condition based on an intuitive argument, and confirm it by the method developed in Sec. II as well as numerical computations. We find in particular that this condition explains the different character of the preheating dynamics of Higgs and Higgs-Palatini inflation [13–15]. We also point out that unitarity violation can occur in running kinetic inflation [16,17], which, to our knowledge, has not yet been noted in the literature (except for a brief comment in Ref. [1]). In addition, we see that the method in Sec. II provides a good approximation of the spectrum even when unitarity is preserved.

Although our main focus is on the preheating dynamics after inflation, particle production and unitarity violation from the target space curvature are possible even beyond this context. As an example, we comment on a supersymmetric axion model in the end of Sec. III. This model acquires a nontrivial target space as an induced metric after integrating our heavy degrees of freedom. The radial component of the Peccei-Quinn field, or the saxion field, plays the role of $\phi$, and its motion induces a spiky feature in the effective mass term of the axion $\chi$ that may cause unitarity violation within the low energy description.

We finally summarize our results in Sec. IV, with comments on possible UV completions of running kinetic inflation and Higgs inflation.

II. SEMICLASSICAL ANALYSIS OF PARTICLE PRODUCTION IN FIELD SPACE

In this section, we study the particle production of a scalar particle $\chi$ during an inflaton oscillation epoch after inflation. In particular, we use the inflaton field value instead of the cosmic time as our time variable, which we may refer to as an analysis in the (scalar) field space. This enables us to derive a semiclassical expression of the occupation number after one inflaton oscillation. We will show that the semiclassical analysis reproduces numerical results well in two specific cases. These results turn out to be useful to understand particle production from a target space curvature, as we will see in Sec. III. We ignore the Hubble expansion in this section since it is irrelevant for our discussion.

A. Preliminary

In this subsection, we summarize the basic equations for particle production. We consider the following Lagrangian for the inflaton field $\phi$:

$$\mathcal{L} = \frac{1}{2} h_{\phi\phi} (\partial \phi)^2 - V,$$

(2.1)

where $h_{\phi\phi} = h_{\phi\phi}(\phi)$ and $V = V(\phi)$ are general functions of $\phi$. We will see in Sec. III that this form of Lagrangian describes, e.g., running kinetic inflation [16,17], Higgs inflation [2–4], $\alpha$-attractor inflation [18,19] and Higgs-Palatini inflation [13,14]. The inflaton equation of motion is given by

$$h_{\phi\phi} \ddot{\phi} + \frac{1}{2} h_{\phi\phi}' \dot{\phi}^2 + V' = 0,$$

(2.2)

where the dot and prime denote the derivatives with respect to $t$ and $\phi$, respectively. This system has a conserved quantity.

Since the target space is trivial if there is only one scalar field, we always assume that there are (at least) two scalar fields in this paper. Remember that, for instance, Higgs inflation has four real scalar degrees of freedom.

$^{5}$This corresponds to the action in the Einstein frame for (Palatini) Higgs inflation.
\[
\frac{1}{2} h_{\phi \phi}(\phi) \dot{\phi}^2 + V(\phi) = V(\Phi),
\]
where \( \Phi \) is the initial inflaton amplitude.

We consider the production of a scalar particle \( \chi \) whose action is given by
\[
\mathcal{L}_\chi = \frac{1}{2} (\partial \chi)^2 - \frac{1}{2} m_\chi^2 (\phi, \phi) \chi^2.
\]
Here we do not specify the origin of the mass \( m_\chi^2 \) and take it as a general function of \( \phi \) and \( \dot{\phi} \). We will study the mass originating from the curvature of the scalar field target space in Sec. III. Moving to Fourier space, we obtain the mode equation as
\[
\ddot{\chi}_k + (k^2 + m_\chi^2) \chi_k = 0.
\]
We impose plane wave initial conditions
\[
\chi_k = \frac{1}{\sqrt{2 \omega_k}}, \quad \dot{\chi}_k = -i \sqrt{\frac{\omega_k}{2}},
\]
where the frequency is given by
\[
\omega_k^2 = k^2 + m_\chi^2.
\]
Since the mass term and hence the frequency depend on time through \( \phi \) and \( \dot{\phi} \), positive and negative frequency modes get mixed with each other as time evolves, which is interpreted as particle production (see, e.g., Ref. [20]). This mixing is described by the Bogoliubov coefficients \( \alpha_k \) and \( \beta_k \) whose equations of motion are given by
\[
\dot{\alpha}_k = \frac{1}{4 \omega_k^2} \frac{d \omega_k^2}{dt} \beta_k e^{2i \int \omega_k dt},
\]
\[
\dot{\beta}_k = \frac{1}{4 \omega_k^2} \frac{d \omega_k^2}{dt} \alpha_k e^{-2i \int \omega_k dt}.
\]
The initial condition (2.6) translates to
\[
\alpha_k = 1, \quad \beta_k = 0,
\]
at the initial time. Finally, the occupation number of a given mode is computed as
\[
f_k = |\beta_k|^2.
\]

**B. Inflaton field value as a time variable**

If \( h_{\phi \phi} \) is nontrivial, the dynamics of the inflaton \( \phi \) generally depend on \( t \) in a complicated manner, and an analytic expression can be obtained only in a some specific cases and/or for a limited field range. This makes an analytical estimation of the particle production quite difficult (see, e.g., Ref. [1] in the context of Higgs inflation).

In this paper, we propose using the inflaton field value \( \phi \) instead of \( t \) as the time variable to study the particle production within one oscillation. The inflaton field value \( \phi \) is a monotonic function of \( t \) within half of an oscillation, and hence it is equally a good time variable. The inflaton velocity \( \dot{\phi} \) can be expressed as a function of \( \phi \) by exploiting the conserved quantity (2.3). A virtue of this method is that, once \( h_{\phi \phi} \) and \( V \) are given, it is straightforward to derive an analytic formula for \( m_\chi^2 \) in terms of \( \phi \) without any approximation, as we will see explicitly below. This enables us to perform a semiclassical analysis of the particle production and estimate the spectrum analytically.

In terms of \( \phi \) instead of \( t \), the Bogoliubov coefficients satisfy
\[
\frac{d \alpha_k}{d \phi} = \frac{1}{4 \omega_k^2} \frac{d \omega_k^2}{d \phi} \beta_k \exp \left( 2i \int \phi \frac{d \omega_k}{\phi} \right),
\]
\[
\frac{d \beta_k}{d \phi} = \frac{1}{4 \omega_k^2} \frac{d \omega_k^2}{d \phi} \alpha_k \exp \left( -2i \int \phi \frac{d \omega_k}{\phi} \right),
\]
where \( \omega_k \) is now understood as a function of \( \phi \). The exponent contains the velocity \( \dot{\phi} \) due to a change of integration variable. It follows from Eq. (2.3) that \( \dot{\phi} \) is expressed as a function of \( \phi \) as
\[
\dot{\phi}^2 = \frac{2}{h_{\phi \phi}(\phi)} \left( V(\Phi) - V(\phi) \right).
\]
Since \( \dot{\phi} \) has a definite sign within half of an oscillation, there is no issue in solving the square in this equation. We define \( \Phi \) as the inflaton amplitude at the end of inflation. Focusing on particle production after inflation and ignoring particle production during inflation, we take the initial condition as
\[
\alpha_k(\Phi) = 1, \quad \beta_k(\Phi) = 0,
\]
and solve the equations until \( \phi = -\Phi \). The occupation number after the first zero crossing is then given by
\[
f_k = |\beta_k(-\Phi)|^2.
\]
Here is a comment. Although we restrict ourselves to Eq. (2.1) in this paper, it is obvious that the idea of using \( \phi \) instead of \( t \) as a time variable can be applied for a broader class of models, such as the generalized Galileon theory [21,22]. One caution here is that it is sometimes nontrivial to find an approximately conserved quantity. The energy density is approximately conserved even if one turns on the cosmic expansion in the model (2.1), and hence one can use it to express \( \phi \) by \( \phi \) as long as the process of one’s interest occurs faster than the expansion as we will see in Sec. III.
For a more general model, however, the energy density can highly oscillate, and cannot be used to express $\phi$ in terms of $\Phi$ (see, e.g., Ref. [23,24]). In such a case, an adiabatic invariant discussed in Ref. [25] will be a useful alternative to the energy density.

### C. Semiclassical analysis

We now explain our semiclassical analysis to estimate the occupation number. We exploit the Born approximation, $\alpha_k \approx 1$, that is valid when the occupation number is small, which results in

$$\frac{d\beta_k}{d\phi} \approx \frac{1}{4\alpha_k^2} \frac{d\omega_k^2}{d\phi} \exp \left( -2i \int_\phi^\infty d\phi \frac{\omega_k}{\phi} \right).$$

(2.15)

This equation is trivially integrated as

$$f_k \approx \frac{\pi^2}{4} \left| \sum_{\phi_\omega} \text{Res}_{\phi=\phi_\omega} \left[ \frac{1}{\omega_k^2} \frac{d\omega_k^2}{d\phi} \exp \left( -2i \int_0^\phi d\phi \frac{\omega_k}{\phi} \right) \right] \right|^2.$$  

(2.18)

where the sum is taken over all the poles $\phi = \phi_\omega$ in either the upper or lower half planes. If the inflaton has a $\mathbb{Z}_2$ symmetry $\phi \leftrightarrow -\phi$, the poles always appear in pairs, and hence there is no difference between taking either the upper or lower half plane, as long as one ensures that the spectrum is exponentially suppressed, not enhanced, in the final expression. Since the overall phase does not contribute to the spectrum, we take the lower end of the integral in the exponent as $\phi = 0$ in this formula. Figure 1 describes the schematic picture of our procedure outlined above.

Here we clarify our assumptions and limitations of the above formula. First, we used the Born approximation, and hence the above formula works only when the occupation number does not exceed unity. We will see below that this is indeed a good approximation in the case of our interest. Second, we took the limit $\Phi \rightarrow \infty$ for the end points of the integral. This limit corresponds to, e.g., $\xi \gg 1$ in Higgs inflation, which is indeed the case of our main interest. We will also see in Sec. II D that this approximation is valid even when $\xi = 10^2$, for which unitarity is preserved. Third, we implicitly assumed that the modes of our interest satisfy $\omega_k^2 > 0$ so that $\alpha_k$ and $\beta_k$ are well defined. If a mode becomes tachyonic during an inflaton oscillation, however, one has to smoothly connect the regions $\omega_k^2 > 0$ and $\omega_k^2 < 0$ as in Ref. [28]. This requires a separate treatment that is beyond the scope of this paper. In our context, whether this happens depends on the sign of the target space curvature, and this prevents us from applying the above semiclassical method to, e.g., $\alpha$-attractor inflation.

![Integration contours in the complex $\phi$-plane, for two different types of pole structure, corresponding to the two examples in Sec. II D. The extension of the integration range from $[-\Phi, \Phi]$ to $[-\infty, \infty]$ is justified when the particle production dominantly occurs only around the origin $|\phi| \lesssim \Lambda(\ll \Phi)$. The extended integration contour can then be closed at complex infinity, reducing the integral to the sum of the residues at the poles.](image-url)
In the following, we demonstrate how the general procedure we outlined above works in practice with two examples. These results will be extensively used in Sec. III.

**D. Examples**

In the following examples, we take the following metric

\[ h_{\phi \phi} = 1 + \frac{\phi^2}{\Lambda^2}, \]  
(2.19)

where \( \Lambda \) is a suppression scale. The conserved quantity then determines

\[ \dot{\phi}^2 \simeq \frac{2V(\Phi)}{1 + \phi^2/\Lambda^2}, \]  
(2.20)

where we further ignored the \( V(\phi) \) term in the numerator which is valid in the limit \( \Phi/\Lambda \to \infty \). In this example, the approximation that lets Eq. (2.17) follow from Eq. (2.16) also corresponds to the limit \( \Phi/\Lambda \to \infty \).

**1. Example 1: Mass with simple poles**

Here we take the effective mass term

\[ m^2_\chi = c \frac{\dot{\phi}^2}{\Lambda^2}, \]  
(2.21)

where \( c \) is a numerical factor. By using Eq. (2.20), this can be rewritten as

\[ m^2_\chi \simeq 2c \frac{V(\Phi)}{\Lambda^2} \frac{1}{1 + \phi^2/\Lambda^2}, \]  
(2.22)

which has a pair of simple poles. The quantities necessary for the semiclassical analysis are given by

\[ \frac{1}{\alpha^2} \frac{d}{d\phi} \phi^2 = -\frac{2\dot{\phi}}{1 + \phi^2/\Lambda^2} \frac{1}{\bar{k}^2(1 + \phi^2) + 1}, \]  
(2.23)

\[ \frac{\alpha^2}{\phi^2} = c(\bar{k} + \phi^2) + 1, \]  
(2.24)

where we defined the dimensionless parameters

\[ \bar{\phi} \equiv \frac{\phi}{\Lambda}, \quad \bar{k}^2 = \frac{1}{2c} \frac{k^2 \Lambda^2}{V(\Phi)}. \]  
(2.25)

The prefactor of the integral has poles at

\[ \bar{\phi} = \pm i, \quad \pm i \frac{\sqrt{1 + \bar{k}^2}}{\bar{k}}, \]  
(2.26)

and hence Eq. (2.18) reads

\[ f_k \simeq \frac{\pi^2}{4} \exp \left[ -\sqrt{c} \left( \frac{1 + \frac{1}{\bar{k}}}{\bar{k}} \arctan(\bar{k}) \right) \right] \]  
\[ - \exp \left[ \frac{-\pi \sqrt{c \bar{k}^2 + 1}}{2 \bar{k}} \right]^2. \]  
(2.27)

For comparison, we also solve Eqs. (2.2) and (2.8) numerically, using a quartic potential

\[ V(\phi) = \frac{\lambda}{4} \phi^4. \]

We add an additional term to the mass of the \( \chi \)-particle

\[ m^2_\chi = c \frac{\dot{\phi}^2}{\Lambda^2} + 2c \frac{V(\phi)}{\Lambda^2}, \]  
(2.28)

which is irrelevant for the particle production around \( \phi \sim 0 \), but prevents adiabaticity violation as \( \hat{\phi} \sim 0 \), \( k \to 0 \). We have rescaled the momentum \( k \) by \( \sqrt{\lambda/\Lambda} \), such that all dependence on \( \lambda \) drops out. Here, and in the following, we evaluate the numerical spectrum at the point \( \phi = \phi_s \), which is the first turning point of the inflaton, i.e., the point \( \dot{\phi} = 0 \) after the first zero crossing. In the case where we neglect expansion, \( \phi_s = -\Phi \). In Fig. 2, we compare the numerical solution to the semiclassical formula (2.27). As one can see, the formula (2.27) reproduces the numerical results extremely well. This demonstrates the power of our semiclassical analysis.

Equation (2.27) indicates that the spectrum depends only on the height of the inflaton potential \( V(\Phi) \) and not on its detailed structure. We numerically computed the spectrum with a quadratic potential instead of quartic, and confirmed that the spectrum is indeed intact as long as one takes the coefficient of the quadratic potential (or the inflaton mass) such that \( V(\Phi) \) is the same as the quartic case.

We point out that, as \( c \) increases or \( \tilde{c} \) decreases, the correspondence between the semiclassical approximation and the numerical result becomes worse at small \( k \), as we will see explicitly in Sec. III C. The cause is particle production by ordinary parametric resonance around \( \phi = 0 \), affecting the region of small \( k \). As this type of resonance is well studied in the literature, we will not pursue it any further.

\[ \text{6One often assumes an interaction of the form } \chi^2 \phi^2, \text{ and then the parametric resonance happens at } \phi = 0 \text{ since the adiabaticity is broken at that point. In our case, since the interaction is of the form } \chi^2 \phi^2, \text{ the parametric resonance (if any) happens at } \phi = 0, \text{ not } \phi = 0. \text{ In other words, the phase is shifted by a quarter of the oscillation period.} \]
2. Example 2: Mass with poles of order two

Next, we take the effective mass term as

\[ m_{\chi}^2 = c \frac{\phi^2}{\Lambda^2 + \phi^2}, \tag{2.29} \]

where \( c \) is again a numerical factor. By using Eq. (2.20), this is expressed as

\[ m_{\chi}^2 \approx 2c \frac{V(\Phi)}{\Lambda^2} \frac{1}{(1 + \phi^2/\Lambda^2)^2}, \tag{2.30} \]

and hence it has a pair of poles of order two. The quantities necessary for the semiclassical analysis are

\[ \frac{1}{\omega_k^2} \frac{d \omega_k^2}{d \phi} = -4\bar{\phi} \frac{1}{1 + \phi^2 k^2(1 + \phi^2)^2 + 1}, \tag{2.31} \]

\[ \frac{\omega_k^2}{\tilde{\phi}^2} = c \left[ k^2(1 + \tilde{\phi}^2) + \frac{1}{1 + \tilde{\phi}^2} \right], \tag{2.32} \]

where we again defined the dimensionless parameters as

\[ \bar{\phi} \equiv \frac{\phi}{\Lambda}, \quad \tilde{k}^2 \equiv \frac{1}{2c} \frac{k^2 \Lambda^2}{V(\Phi)}. \tag{2.33} \]

The prefactor of the integral has poles at

\[ \tilde{\phi} = \pm i, \quad \pm i \sqrt{1 + \frac{i}{k}}, \tag{2.34} \]

and hence Eq. (2.18) reads

\[ f_k \approx \frac{g^2}{4} \exp \left[ -2\sqrt{c} \int_{0}^{\phi^*} d\tilde{\phi} F \right] + \exp \left[ -2\sqrt{c} \int_{0}^{\phi^*} d\tilde{\phi} F \right] - 2 \exp \left[ -2\sqrt{c} \int_{0}^{\phi^*} d\tilde{\phi} F \right]^2, \tag{2.35} \]

where we defined

\[ F(\tilde{k}, \tilde{\phi}) \equiv \sqrt{\frac{k^2(1 - \tilde{\phi}^2) + \frac{1}{1 - \tilde{\phi}^2}}{1 - \tilde{\phi}^2}}, \tilde{\phi} \equiv \sqrt{1 \pm \frac{i}{k}}. \tag{2.36} \]

In Fig. 3, we compare the full numerical results with the semiclassical formula (2.35) for a quartic potential. To temper the divergence at \( \tilde{\phi} \sim 0, k \to 0 \) we again add a second term to the mass

\[ m_{\chi}^2 = c \frac{\tilde{\phi}^2}{\Lambda^2 + \phi^2} + 2\tilde{c} \frac{V(\phi)}{\Lambda^2}. \tag{2.37} \]

As one can see, the formula (2.35) reproduces the numerical results well, especially for large \( k \), including the oscillatory behavior. This oscillation originates from an interference between \( \tilde{\phi}_\pm \) which are generally complex. For small \( k \) the ordinary parametric resonance around \( \tilde{\phi} = 0 \) causes additional particle production. In practice, this region is less important, as the contribution to the energy density of a mode with momentum \( k \) scales as \( \rho_k \propto k^3 \omega_k \Omega_{f_k} \). The total energy density is thus dominated by the modes with large \( k \), for which the semiclassical approximation works very well. Finally, we again checked that the large \( k \) modes do not change if we use a quadratic inflaton potential instead of quartic as long as \( V(\Phi) \) is the same.

III. UNITARITY VIOLATION
DURING PREHEATING

Recently, particle production after inflation, caused by the curvature of the scalar field target space, has been actively studied in the literature, in particular in the context...
of Higgs inflation. Reference [1] found that the effective mass term of Goldstone modes exhibits a “spiky” feature (see also Ref. [30]) in Higgs inflation, whose origin is now understood as the target space curvature in the Einstein frame [6,7]. The spike is of great phenomenological importance since it produces Goldstone modes whose energy scale can be greater than the cutoff scale of the theory, causing unitarity violation.8 This indicates that one energy scale can be greater than the cutoff scale of the theory if the effective mass term\(^{-1}\) exhibits a feature such as the target space curvature in the Einstein frame:

\[
S = \int d^4x \sqrt{-g} \left[ \frac{M_p^2}{2} R + \frac{1}{2} h_{ab} g^{\mu\nu} \partial_\mu \phi^a \partial_\nu \phi^b - V \right],
\]

where \(M_p\) is the reduced Planck mass scale, \(g_{\mu\nu}\) is the spacetime metric, \(h_{ab}\) is the target space metric, and \(\phi^a\) is a scalar field labeled by its flavor.

Assuming the Friedmann-Lemaître-Robertson-Walker (FLRW) metric, the background equation of motion is given by

\[
0 = \frac{D\dot{\phi}_0^a}{Dt} + 3H \dot{\phi}_0^a + h_{ab} V_b,
\]

\[
H^2 = \frac{1}{3M_p^2} \left[ \frac{h_{ab}}{2} \dot{\phi}_0^a \dot{\phi}_0^b + V \right],
\]

\[
\dot{H} = -\frac{1}{2M_p^2} h_{ab} \dot{\phi}_0^a \dot{\phi}_0^b,
\]

where the subscript “0” is given to background quantities, \(H\) is the Hubble parameter, and \(V_b\) is a shorthand notation for \(\partial V / \partial \phi^b\). The covariant derivative is defined as

\[
\text{See, e.g., Ref. [29] for particle production from the target space curvature during inflation.}
\]

\[
\text{Longitudinal gauge bosons play the same role as the Goldstone modes in a gauged model due to the equivalence theorem.}
\]

\[
\text{The target space in this formalism should be understood as defined only in the Einstein frame as it is variant under the frame transformation. An alternative frame-invariant definition of the target space is possible by including the conformal mode of the metric [38].}
\]
where \( v^a \) is an arbitrary target space vector field and \( \Gamma^a_{bc} \) is the Christoffel symbol constructed from \( h_{ab} \).

We may fix the gauge degrees of freedom of the general coordinate transformation as

\[
ds^2 = \mathcal{N}^2 dt^2 - a^2(dx^i + \beta^i dt)(dx^j + \beta^j dt),
\]

where \( \mathcal{N} \) is the lapse function, \( \beta^i \) is the shift vector and \( a \) is the scale factor. Here we ignored the tensor part since it is irrelevant for our discussion. The equations of motion of \( \mathcal{N} \) and \( \beta^i \) provide constraint equations, which are solved to leading order in perturbations as

\[
\mathcal{N} - 1 = \frac{H}{\phi_0} eT_{ab}q^a,
\]

where

\[
q^a \equiv \phi^a - \phi_0^a, \quad \dot{\phi}_0 = \sqrt{h_{ab}\dot{\phi}_0^a\phi_0^b},
\]

\[
n^a = \frac{\phi_0^a}{\phi_0}, \quad e = \frac{\dot{\phi}_0^2}{2M_p^2 H^2},
\]

and the flavor indices are lowered by \( h_{ab} \). Here we do not show the solution of \( \beta^i \) explicitly since the quadratic action is linear in \( \beta^i \) and hence it drops independently of its explicit form after substituting the above form of \( \mathcal{N} \). The linearized equation of motion of the perturbation is then given by

\[
0 = \frac{D^2 q^a}{Dt^2} + 3H \frac{Dq^a}{Dt} - \frac{1}{a^2} \partial^2 q^a + h^{ab}M_{bc}^2 q^c,
\]

where \( [39] \)

\[
M_{ab}^2 = \nabla_b V_a - \hat{\phi}_0^a \phi_0^d R_{acdb} + \frac{2H}{\phi_0} \epsilon(V_a T_b + V_b T_a) + 2(3 - e)\epsilon H^2 T_a T_b,
\]

and all the geometrical quantities are constructed from \( h_{ab} \). Note in particular that the second term of Eq. (3.10) originates from the target space curvature \( R_{acdb} \).

From now, for simplicity, we consider the two-field case, with the inflaton \( \phi \) and another particle \( \tilde{\chi} \). We assume that \( \tilde{\chi} \) does not have any background field value, and focus on production of \( \tilde{\chi} \). Thus, in the following, we omit the subscript “0” as \( \phi \) is always a background inflaton field and \( \tilde{\chi} \) (or equivalently \( \chi \) defined below) is always a perturbation. Assuming a \( \mathbb{Z}_2 \) symmetry under which only \( \tilde{\chi} \) is odd, the mode equation of \( \tilde{\chi} \) is always decoupled from the fluctuation of the inflaton.\(^\text{10}\) We may redefine \( \tilde{\chi} \) as

\[
\chi \equiv \sqrt{h_{xx}} \tilde{\chi}.
\]

where \( h_{xx} \) here is a function of only the background field \( \phi \). Then the equation of motion simplifies significantly to

\[
0 = \ddot{\chi} + 3H \dot{\chi} - \frac{1}{a^2} \partial^2 \chi + m_{\chi}^2 \chi,
\]

where

\[
m_{\chi}^2 = \nabla^2 V - \dot{\phi}^2 R \phi \phi \chi.
\]

Here we used the fact that\(^\text{11}\)

\[
\dot{\chi} = \sqrt{h_{xx}} \frac{D\tilde{\chi}}{dt},
\]

and that the \( \mathbb{Z}_2 \) symmetry ensures that \( V_{\chi} = 0 \) at the background level. The second term of Eq. (3.13) induces the spiky feature and its geometrical nature is clear in this formalism.

It is then a standard exercise to move to Fourier space and quantize the modes. The equations of motion of the Bogoliubov coefficients \( \alpha_k \) and \( \beta_k \) are given by

\[
\frac{d\alpha_k}{d\tau} = \frac{1}{4\omega_k^2} \beta_k e^{2i\int dt_0 \chi},
\]

\[
\frac{d\beta_k}{d\tau} = \frac{1}{4\omega_k^2} \alpha_k e^{-2i\int dt_0 \chi},
\]

where \( \tau \) is comoving time. The frequency is given by

\[
\omega_k^2 = k^2 + a^2 m_{\chi}^2 - \frac{1}{a^2} \frac{d^2 a}{dt^2},
\]

with \( k \) understood to be the comoving momentum. The comoving occupation number is given by

\[
f_k = |\beta_k|^2.
\]

### B. Condition for unitarity violation

As we mentioned, it is known that the mass induced from the target space curvature causes unitarity violation during preheating in Higgs inflation. On the other hand, although having a curved target space, unitarity violation is not observed in, e.g., \( \alpha \)-attractor inflation and Higgs-Palatini inflation in an explicit analysis of these models [15,40-42]. This indicates that a nontrivial target space curvature alone is not sufficient for unitarity violation. The purpose of this

\(^\text{10}\)This is because we assume that \( \tilde{\chi} \) does not have any background field value and hence the \( \mathbb{Z}_2 \) symmetry is not spontaneously broken.

\(^\text{11}\)Note that this holds even if \( \partial_\chi h_{\phi\phi} \neq 0 \) after substituting the background field configuration.
subsection is to derive a handy condition of when we expect unitarity violation from the target space curvature during preheating.

In this work, we assume that unitarity is violated during preheating if the momentum of the mode which contributes most dominantly to the energy density, \( k_{\text{max}} \), is larger than the unitarity cutoff scale. Thus, we estimate \( k_{\text{max}} \) of particle production from the target space curvature in a model-independent way in the following. Let \( \Lambda \) denote the typical mass scale of the target space curvature around the origin. Since scattering amplitudes of scalar fields depend on the target space curvature (see, e.g., Ref. [43] and references therein), this scale \( \Lambda \) corresponds to the (small field) cutoff scale of the theory at the same time\(^{12} \); we will comment on this point is not important for us hereafter. This model reduces to a chaotic inflation model in Ref. [38] that determines the cutoff scale. Practically, however, this point is not important for \( \Lambda \ll M_p \) as long as one works solely in the Einstein frame as we do in this paper.

\[ \mathbf{\hat{k}}^2 = \frac{1}{2c V(\Phi)} \frac{k^2 \Lambda^2}{V(\Phi)}, \]  

and hence the typical energy scale of the particle production is

\[ \left( \frac{k}{a_\ast} \right)_{\text{max}}^2 \sim \frac{V(\Phi)}{\Lambda^2}, \]

where we assumed that \( c \) is of order unity, and reinterpret \( k \) in Sec. II D as \( k/a_\ast \). Requiring that \( (k/a_\ast)_{\text{max}} \) is larger than \( \Lambda \), we arrive at the same condition.

Let us now comment on our choice of unitarity cutoff scale. Depending on the model, the cutoff scale can depend on the background field value, as is the case for Higgs inflation \([12,44]\). Although we evaluate the spectrum at the end point of the oscillation, particle number for the UV-modes is already well defined at \( |\phi| \sim \Lambda \). For this reason, we adopt the small-field value of the cutoff scale when we determine whether unitarity is violated.

In the following, we consider running kinetic inflation, Higgs inflation, \( \alpha \)-attractor inflation and Higgs-Palatini inflation, and study particle production and unitarity violation caused by the target space curvature. We will see that Eq. (3.21) is satisfied for the former two models, while it is violated for the latter two models, explaining the different unitarity structures of these models during preheating.

C. Analysis of specific inflation models

From now, we consider running kinetic inflation, Higgs inflation, \( \alpha \)-attractor inflation and Higgs-Palatini inflation in turn. We study the particle production and the unitarity structure of these models after one inflaton oscillation. It will turn out that the method we developed in Sec. II is a powerful tool to study the spectrum analytically. In contrast to Sec. II, we include the expansion of the universe in our computations for completeness, although it is unimportant for our main discussion.

1. Running kinetic inflation

First, we consider running kinetic inflation. We consider the following action

\[ S = \int d^4x \sqrt{-g} \left[ \frac{M_p^2}{2} R + \frac{1}{2} \left( \frac{\phi^2}{\Lambda^2} - c_K \frac{\chi^2}{\Lambda^2} \right) (\partial \phi)^2 + \frac{1}{2} (\partial \chi)^2 \right] + \left( 1 + \frac{c_V \chi^2}{\Lambda^2} \right) \lambda \phi^4 \],

where we put couplings between \( \phi \) and \( \chi \) just by hand, and assume that \( c_K, c_V > 0 \), since otherwise \( \chi \) can be tachyonic. If we instead identify the inflaton as, e.g., the Higgs and consider production of the Goldstone modes, the analysis would be closer to Higgs inflation which we discuss hereafter. This model reduces to a chaotic inflation model.
with a quadratic potential in the large field region, which is
now disfavored by the CMB observation. This can be
overcome however by taking the exponent of $\phi$ in the
prefactor of the kinetic term larger. Although our analysis,
in particular the argument in Sec. II, equally applies to such
difficulties with the method developed in Sec.II. The relevant
geometrical quantities are given by

$$R^I_{\phi\phi} = -\frac{c_K}{\Lambda^2}, \quad \nabla^i V_\chi = c_v \frac{\lambda \phi^4}{4 \Lambda^2},$$ (3.32)

and hence the effective mass is given by

$$m_\chi^2 = \frac{1}{\Lambda^2} \left[ c_K \dot{\phi}^2 + c_v \frac{\lambda \phi^4}{2} \right].$$ (3.33)

Numerically we can simply substitute this expression and
solve Eq. (3.15) with the background equations of motion.
The spectrum is then given by Eq. (3.17).

In order to interpret the numerical results analytically, we
ignore $c_v$ and the Hubble parameter since they are expected
to be subdominant for the particle production. This simplifies the mass as

$$m_\chi^2 \approx \frac{c_K}{\Lambda^2} \frac{\phi^2}{\lambda^2}.$$ (3.34)

If we ignore the Hubble expansion, energy conservation
then tells us that

$$\dot{\phi}^2 \approx \frac{\lambda^2}{2 \lambda^2} \frac{\Phi^4}{1 + \phi^2/\Lambda^2},$$ (3.35)

where $\Phi = O(\sqrt{\Lambda/\Lambda})$ is the inflaton amplitude at the end
of inflation. These relations correspond to the first example
in Sec. II.D, and hence we can directly apply the analysis
there to this model. As a result, we estimate the occupation
number as

$$f_k \approx \frac{\pi^4}{4} \left[ -\sqrt{c_K} \left( 1 + \left( \frac{k}{k} \arctan(\bar{k}) \right) \right] \right. $$

$$\left. - \exp \left[ -\frac{\pi \sqrt{c_K} k^2 + 1}{2k} \right] \right)^2 .$$ (3.36)

where

$$\bar{k} = \frac{\Phi}{\lambda}, \quad \bar{k}^2 = \frac{2}{c_K} \frac{\Lambda^2}{\lambda \phi^4}.$$ (3.37)

In our semiclassical formula, we always take $\Phi$ as the
inflaton field value at the point $\epsilon = -\dot{H}/H^2 = 1$. Note also
that we use the scale factor at the first turning point $a_i$ in
the definition of $\bar{k}$. Since the argument in Sec. II does not
include the cosmic expansion, we have small uncertainties
related to the choice of $\Phi$ and $a_i$ here, which we cannot
resolve within our semiclassical analysis without including
the Hubble expansion.

In Fig. 4, we compare the numerical results with the
analytical estimate (3.36), choosing

$$\lambda = 10^{-10} \left( \frac{M_P}{\Lambda} \right)^2.$$ (3.38)

Note that we no longer rescale the physical momentum by
$\sqrt{2} \Lambda$, but just by the unitarity cutoff scale $\Lambda$, such that it is
easy to see if unitarity is violated. The result now depends
on what value is chosen for $\lambda$. We initialize the background

In our semiclassical formula, we always take $\Phi$ as the
inflaton field value at the point $\epsilon = -\dot{H}/H^2 = 1$. Note also
that we use the scale factor at the first turning point $a_i$ in
the definition of $\bar{k}$. Since the argument in Sec. II does not
include the cosmic expansion, we have small uncertainties
related to the choice of $\Phi$ and $a_i$ here, which we cannot
resolve within our semiclassical analysis without including
the Hubble expansion.

In Fig. 4, we compare the numerical results with the
analytical estimate (3.36), choosing

$$\lambda = 10^{-10} \left( \frac{M_P}{\Lambda} \right)^2.$$ (3.38)

Note that we no longer rescale the physical momentum by
$\sqrt{2} \Lambda$, but just by the unitarity cutoff scale $\Lambda$, such that it is
easy to see if unitarity is violated. The result now depends
on what value is chosen for $\lambda$. We initialize the background

In our semiclassical formula, we always take $\Phi$ as the
inflaton field value at the point $\epsilon = -\dot{H}/H^2 = 1$. Note also
that we use the scale factor at the first turning point $a_i$ in
the definition of $\bar{k}$. Since the argument in Sec. II does not
include the cosmic expansion, we have small uncertainties
related to the choice of $\Phi$ and $a_i$ here, which we cannot
resolve within our semiclassical analysis without including
the Hubble expansion.

In Fig. 4, we compare the numerical results with the
analytical estimate (3.36), choosing

$$\lambda = 10^{-10} \left( \frac{M_P}{\Lambda} \right)^2.$$ (3.38)

Note that we no longer rescale the physical momentum by
$\sqrt{2} \Lambda$, but just by the unitarity cutoff scale $\Lambda$, such that it is
easy to see if unitarity is violated. The result now depends
on what value is chosen for $\lambda$. We initialize the background

In our semiclassical formula, we always take $\Phi$ as the
inflaton field value at the point $\epsilon = -\dot{H}/H^2 = 1$. Note also
that we use the scale factor at the first turning point $a_i$ in
the definition of $\bar{k}$. Since the argument in Sec. II does not
include the cosmic expansion, we have small uncertainties
related to the choice of $\Phi$ and $a_i$ here, which we cannot
resolve within our semiclassical analysis without including
the Hubble expansion.

In Fig. 4, we compare the numerical results with the
analytical estimate (3.36), choosing

$$\lambda = 10^{-10} \left( \frac{M_P}{\Lambda} \right)^2.$$ (3.38)

Note that we no longer rescale the physical momentum by
$\sqrt{2} \Lambda$, but just by the unitarity cutoff scale $\Lambda$, such that it is
easy to see if unitarity is violated. The result now depends
on what value is chosen for $\lambda$. We initialize the background
equation sufficiently early, such that it follows the attractor solution toward the end of inflation (set by the slow roll parameter $\epsilon = 1$). We initialize the mode functions 2 $e$-folds before the end of inflation. At this point, all modes are adiabatic, i.e., $|\partial_\phi/\partial_k| \ll 1$, and particle number is well defined. The particle number and energy density shown in Fig. 4 are evaluated at $\phi = \phi_c$, when all modes are adiabatic again.\(^{13}\)

The left panel of Fig. 4 shows that the semiclassical result approximates the numerics reasonably well, although the correspondence is somewhat worse than we saw in Fig. 2 for the single pole case. Two factors cause the deviation. First, we expect some particle production from ordinary parametric resonance, which is not described by Eq. (3.36). This contribution increases with $c_K$ and would also have occurred in the single pole case if we had chosen a larger value of $c$. Second, the inflaton amplitude decreases due to Hubble expansion, and the conserved quantity as defined in Eq. (2.3) is only approximately conserved.

Nevertheless, the right panel of Fig. 4 shows that the semiclassical result gives an excellent estimate of $k_{\text{max}}$ and can thus be used to determine unitarity violation. Here the vertical axis is the physical energy density $\rho_k/a^4$ per log $k/a_s$, where $\rho_k \equiv k^3a_k f_k/2\pi^2$ is the comoving energy density. In the left panel of Fig. 5, we show the numerical results for the ratio of the maximum physical momentum $(k/a_s)_{\text{max}}$ and the cutoff scale. Assuming that unitarity is violated when this ratio is larger than 1, we find that unitarity is violated for $\Lambda \lesssim 2 \times 10^{-2} M_p$, consistent with our estimate of Eq. (3.31). We also note that the semiclassical formula is thus not only useful for the determination of the minimum value of $\Lambda$ to avoid unitarity violation, but also to study the spectrum in the case without unitarity violation.

Now let us make a brief comment on possible UV completions of the present model. If unitarity is violated during the preheating stage as seen above, it is necessary to consider a UV-completed theory to discuss preheating. One example of the renormalizable action is something as

$$S = \int d^4x \sqrt{-g} \left[ \frac{M_p^2}{2} R + \frac{1}{2} (\partial \psi)^2 + \frac{1}{2} (\partial \phi)^2 + \frac{1}{2} (\partial \chi)^2 - \frac{1}{2} (m \psi - c_\phi \phi^2 - c_\chi \chi^2)^2 - V(\phi) \right],$$

(3.39)

where $\psi$, $\phi$, and $\chi$ are real scalar fields, $c_\phi$ and $c_\chi$ are constants assumed to be positive. We assume that $m$ is larger than any other scale appearing in $V(\phi)$. We may then integrate out $\psi$ by using the relation $m \psi = c_\phi \phi^2 + c_\chi \chi^2$ and the inflationary trajectory is taken to be $m \psi = c_\phi \phi^2$ with $\chi = 0$. Then the action reduces to the form of Eq. (3.24) with $\Lambda = m/(2c_\phi)$ and $c_K = c_\chi/(4c_\phi)$. Another example is

$$S = \int d^4x \sqrt{-g} \left[ \frac{M_p^2}{2} R + \frac{1}{2} (\partial \psi)^2 + \frac{1}{2} (\partial \phi)^2 + \frac{1}{2} (\partial \chi)^2 - \frac{1}{4} (m^2 - c_\psi \psi^2 + c_\phi \phi^2 + c_\chi \chi^2)^2 - V(\phi) \right],$$

(3.40)

where we assume that $c_\phi$ and $c_\psi$ are positive and satisfy $c_\phi \gg c_\psi$ and again $m$ is larger than any other scale appearing in $V(\phi)$. Then, for $|\dot{\phi}| \lesssim m/\sqrt{c_\phi}$, it reduces to the effective action (3.24) with $\Lambda = \sqrt{c_\psi m}/c_\phi$ and $c_K = c_\chi/c_\phi$ after eliminating $\psi$ with the use of the constraint $c_\psi \psi^2 = m^2 + c_\phi \phi^2 + c_\chi \chi^2$. Both models give the same

\[^{13}\text{Note that we can not choose } c_\psi \text{ too small, as otherwise adiabaticity is violated when } \dot{\phi} = 0 \text{ for the IR modes. This is not the case for our chosen value of } c_\psi.\]
effective theory (3.24) in a certain parameter range and field space, but phenomenological implications are quite different. In the model (3.39), one should take into account the production of the heavy mode that would have been integrated out in the effective theory, but it may not have significant phenomenological impact as far as it decays into lighter degrees of freedom or the Standard Model sector quickly. On the other hand, in the model (3.40), there is a possibility of domain wall formation if $V(\phi_{\text{ini}}) \gtrsim m^4$ due to the multifield scalar dynamics, since the action has a $Z_2$ symmetry under which $\phi$ and $\psi$ change their sign and the final vacuum expectation values $(\phi, \psi) = (0, \sqrt{\epsilon_{\psi} m})$ spontaneously break the $Z_2$ symmetry. The formation of domain walls during the preheating is a cosmological disaster unless there are some mechanisms to make the domain walls unstable. This inspection shows that one should be careful about the unitarity violation in the effective theory. Even if one can safely use the effective theory like (3.24) during slow-roll inflation, the validity of that theory may not always be guaranteed for the analysis of (p)reheating. Once unitarity violation is observed, one should go back to the UV-completed theory, and the phenomenological consequences are sensitive to the concrete model of UV completion.

2. Higgs inflation

Next we consider Higgs inflation. We start from the Jordan frame action

$$S = \int d^4x \sqrt{-g} \left[ \frac{M_p^2}{2} \Omega^2 R + \frac{1}{2} g^{\mu\nu} \partial_\mu \phi \partial_\nu \phi - V_J(\phi, \chi) \right],$$

(3.41)

where the subscripts “$J$” denote quantities in the Jordan frame, $\phi = \phi, \chi$, and we define

$$\Omega^2(\phi, \chi) = 1 + \frac{\xi_\phi \phi^2 + \xi_\chi \chi^2}{M_p^2},$$

(3.42)

and

$$V_J(\phi, \chi) = \frac{\lambda_\phi \phi^4}{4} + \frac{g^2}{2} \phi^2 \chi^2 + \frac{\lambda_\chi \chi^4}{4}.$$  

(3.43)

Here we have slightly generalized the model, and the case $\xi_\chi = \xi_\phi$ and $\lambda_\chi = \lambda_\phi = \lambda_\phi$ corresponds to the original (Abelian) Higgs inflation model.\(^{14}\) We always assume that $\xi_\phi$ and $\xi_\chi$ are of comparable order.

It is convenient to go to the Einstein frame by rescaling the metric as

$$g_{\mu\nu} \rightarrow \Omega^2 g_{\mu\nu},$$

(3.44)

resulting in

$$S = \int d^4x \sqrt{-g} \left[ \frac{M_p^2}{2} R + \frac{1}{2} h_{ab} g^{\mu\nu} \partial_\mu \phi_a \partial_\nu \phi_b - V(\phi, \chi) \right],$$

(3.45)

with the potential in the Einstein frame given by

$$V(\phi, \chi) = \frac{V_J(\phi, \chi)}{\Omega^4},$$

(3.46)

and the target space metric

\(^{14}\)The discussion below is the same for an SU(2) case as long as a linearized mode equation is concerned.
\[ h_{ab} = \frac{1}{\Omega^4} \left[ \Omega^2 \delta_{ab} + \frac{3}{2} \partial_a \Omega^2 \partial_b \Omega^2 \right] \]
\[ = \frac{1}{\Omega^4} \left( \frac{\Omega^2 + \frac{6 \xi^2 \phi^2}{M_p^2}}{M_p^2} \right) \left( \frac{6 \xi \phi \phi^2}{M_p^2} \right) \Omega^2 + \frac{6 \xi^2 \phi^2}{M_p^2} \right). \]  
(Eq. 3.47)

For generic initial conditions, this model does not display strong turning, so without loss of generality, we can take \( \phi \) to be the inflaton. The background value of \( \chi \) will remain zero (this was checked on the lattice for \( 1 < \xi_\phi < 100 \) [45,46]) as long as the parameters satisfy

\[ \frac{g^2}{\lambda_\phi} \geq \frac{\xi_\phi}{\xi_\phi}. \]  
(Eq. 3.48)

which we assume to be the case [see Eq. (3.56)]. This allows us to apply the argument of Sec. III A to this model.

In the single-field limit, the background equation of the inflaton field is

\[ 0 = \dot{\phi} + 3H \phi \]
\[ + \left( \frac{\xi_\phi(1 + 6 \xi_\phi) \phi}{1 + \xi_\phi(1 + 6 \xi_\phi) \phi^2/M_p^2} - \frac{2 \xi_\phi \phi^2}{1 + \xi_\phi \phi^2/M_p^2} \right) \frac{\dot{\phi}^2}{M_p^2} \]
\[ + \frac{\lambda_\phi \phi^3}{(1 + \xi_\phi \phi^2/M_p^2)(1 + \xi_\phi(1 + 6 \xi_\phi) \phi^2/M_p^2)}, \]  
(Eq. 3.49)

and the Friedmann equations are

\[ H^2 = \frac{1}{3M_p^2} \left( \frac{1 + \xi_\phi(1 + 6 \xi_\phi) \phi^2/M_p^2}{2(1 + \xi_\phi \phi^2/M_p^2)^2} - \frac{\lambda_\phi \phi^4}{4(1 + \xi_\phi \phi^2/M_p^2)^2} \right), \]  
(Eq. 3.50)

\[ \dot{H} = - \frac{(1 + \xi_\phi(1 + 6 \xi_\phi) \phi^2/M_p^2) \dot{\phi}^2}{2(1 + \xi_\phi \phi^2/M_p^2)} \frac{M_p^2}{M_p^2}. \]  
(Eq. 3.51)

Higgs inflation is well known to be consistent with the CMB observation [5], and the CMB normalization requires that

\[ \frac{g^2}{\lambda_\phi} \approx 2 \times 10^9. \]  
(Eq. 3.52)

This indicates that \( \xi_\phi \gg 1 \) unless \( \lambda_\phi \) is tiny at the inflationary scale. This large value of \( \xi_\phi \) is an active subject of discussion. A notable consequence is that the cutoff scale of the theory becomes as low as \( \Lambda \sim M_p/\xi_\phi \) [8–11].\(^\text{15}\) This is called the unitarity issue of Higgs inflation, and different viewpoints on this issue are discussed at the end of this subsection. Our point in this paper is that, even if the analysis during inflation is not spoiled due to the field-dependence of the cutoff [12,44], unitarity can still be violated after inflation [1]. The preheating dynamics of Higgs inflation was studied in great detail in Refs. [7,45,46].

Now we apply the condition (3.21) to this model. Inflation happens for \( \phi \gtrsim M_p/\sqrt{\xi_\phi} \), and hence the height of the inflaton potential at the end of inflation is given by

\[ V(\Phi) \sim \frac{\lambda_\phi M_p^4}{\xi_\phi^2}, \]  
(Eq. 3.53)

Since the cutoff scale of this theory is \( \Lambda \sim M_p/\xi_\phi \), we obtain

\[ \frac{V(\Phi)}{\Lambda^4} \sim \frac{\lambda_\phi \xi_\phi^2}{\xi_\phi^2} \times 10^{-9} \xi_\phi^4, \]  
(Eq. 3.54)

where we used Eq. (3.52) in the second similarity. The ratio can be larger than unity for large \( \xi_\phi \), and thus the condition (3.21) indeed signals unitarity violation in this model.

We now study the spectrum of the produced particles in detail with the method developed in Sec. II, confirming the above estimation. The relevant geometrical quantities are given by

\[ R^{\gamma} \phi_{\gamma'} = - \frac{1}{6M_p^2 \Omega^2 (\Omega^2 + 6 \xi_\phi \phi^2/M_p^2)} \]
\[ \times \left[ \Omega^2(1 + 6 \xi_\phi)(1 + 6 \xi_\phi) - \left( \Omega^2 + 6 \xi_\phi \phi^2/M_p^2 \right)^2 \right], \]
(Eq. 3.55)

\[ \nabla^\gamma V_\gamma = \frac{\phi^2}{\Omega^2} \left[ -\lambda_\phi \phi^2 \Omega^2 + g^2 \Omega^2 - \frac{\lambda_\phi \phi^2(1 + 6 \xi_\phi) \phi^2/M_p^2}{\Omega^2 + 6 \xi_\phi \phi^2/M_p^2} \right], \]
(Eq. 3.56)

where \( \chi \) is set to zero in \( \Omega \) in these expressions, and hence the effective mass is given by

\[ m_\chi^2 = \frac{\phi^2}{6M_p^2 \Omega^2 (\Omega^2 + 6 \xi_\phi \phi^2/M_p^2)} \]
\[ \times \left[ \Omega^2(1 + 6 \xi_\phi)(1 + 6 \xi_\phi) - \left( \Omega^2 + 6 \xi_\phi \phi^2/M_p^2 \right)^2 \right] \]
\[ + \frac{\phi^2}{\Omega^2} \left[ -\lambda_\phi \phi^2 \Omega^2 + g^2 \Omega^2 - \frac{\lambda_\phi \phi^2(1 + 6 \xi_\phi) \phi^2/M_p^2}{\Omega^2 + 6 \xi_\phi \phi^2/M_p^2} \right]. \]
(Eq. 3.57)

It is now numerically straightforward to solve Eq. (3.15) with the background equations of motion and obtain the spectrum (3.17).\(^\text{15}\)

\(^{15}\)As we mentioned above, we assume that \( \xi_\phi \) and \( \xi_\phi \) are comparable in this paper. The cutoff scales as \( M_p/\sqrt{\xi_\phi} \) for \( \xi_\phi \gg 1 \) when \( \xi_\phi \) and \( \xi_\phi \) are not comparable, as can be seen in Eq. (3.55). This is related to the fact that \( \xi_\phi \) is physical only when \( \chi \) is present (without the inflaton potential) [11].
In order to understand the numerical results analytically, we focus on the leading order terms in the large $\xi_\phi$ and $\xi_\chi$ limit, since they are expected to dominantly contribute to the particle production. This simplifies the mass to

$$m_*^2 \approx \frac{\xi_\phi}{\xi_\phi M_p \left(1 + 6\xi_\phi^2 \phi^4 / M_p^2\right)}.$$  

(3.58)

If we ignore the Hubble expansion, the energy density is conserved, which in our case leads to

$$\dot{\phi}^2 \approx \frac{\lambda_\phi}{2 + 6\xi_\phi^2 \phi^2 / M_p^2},$$

$$\Phi^4 = \frac{\Phi^4}{(1 + \xi_\phi \Phi^2 / M_p^2)^2},$$

(3.59)

where $\Phi = O(M_p / \sqrt{\xi_\phi})$ is the inflaton amplitude at the end of inflation. Here we again kept only the leading-order terms in $\xi_\phi$. Now these equations correspond to the second example in Sec. II D, and hence we can directly apply the analysis there. As a result, we estimate the spectrum as

$$f_k \approx \frac{\pi^2}{4} \left[ -2 \sqrt{\frac{\xi_\phi}{\xi_\phi}} \int_0^{\phi_\star} d\phi \sqrt{F} \right] + \left[ -2 \sqrt{\frac{\xi_\phi}{\xi_\phi}} \int_0^{\phi_\star} d\phi \sqrt{F} \right]^2,$$

$$- 2 \exp \left[ -2 \left( \frac{\xi_\phi}{\xi_\phi} \int_0^{\phi_\star} d\phi \sqrt{F} \right)^2 \right],$$

(3.60)

where

$$\tilde{F} = \frac{\xi_\phi \Phi^2}{\sqrt{6} M_p^2},$$

$$\tilde{k}^2 = \frac{\xi_\chi}{32 \xi_\phi^2} \tilde{\Phi}^4,$$

$$F = \sqrt{k^2 (1 - \tilde{k}^2) + \frac{1}{1 - \tilde{k}^2}},$$

$$\tilde{\phi}_\pm = \sqrt{1 \pm \frac{i}{k}}.$$  

(3.61)

We again take $\Phi$ as the inflaton field value at the point $c = 1$, and use the scale factor at the first turning point $a_i$, in the definition of $\tilde{k}$ in these expressions.

In Fig. 6, we compare the numerical results with the analytical estimate (3.60). We take

$$g^2 = \lambda_\phi \left( \frac{\xi_\chi}{\xi_\phi} + 0.2 \right),$$

(3.62)

and fix $\lambda_\phi$ by Eq. (3.52). We again initialize the background field such that it follows the attractor solution in the region where we solve the mode equation. We initialize the mode functions $2 e$-folds before the end of inflation and we evaluate the particle number and energy density at $\phi_\star$.

The left panel of Fig. 6 shows the particle number spectrum for $\xi_\phi = 100$ and $\xi_\chi = 100$, 300, 500. The physical momenta have been rescaled by $M_p / \sqrt{\xi_\phi}$, which roughly corresponds to the UV cutoff scale, which scales as $\Lambda \sim M_p / \sqrt{\xi_\phi \xi_\chi}$. For $\xi_\chi = 300$, 500 the particle number is smaller than 1 and the Born approximation is expected to be valid. The semiclassical approximation captures the UV part of the spectrum very well, even in the case where we include the expansion of the universe. For $\xi_\chi = 100$ the produced particle number is larger than 1 and the Born approximation is thus less powerful in the IR. Yet, the UV-tail is practically the most relevant, as can be seen in the right panel of Fig. 6, where the contribution to the energy density is shown for $\xi_\phi = 10^2$, $10^3$, $10^4$ and $\xi_\chi = \xi_\phi$. Even in this case, where the Born approximation breaks down in

FIG. 6. Particle number and energy density for Higgs inflation. Solid lines show the numerical solution of the mode equation and the dashed lines the results from the semiclassical approximation. Left: particle number density for Higgs inflation with $\xi_\phi = 100$ and $\xi_\chi = 100$, 300, 500 (blue, orange, green, respectively). Right: energy density for Higgs inflation with $\xi_\phi = 10^2$, $10^3$, $10^4$ (blue, orange, green, respectively) and $\xi_\chi = \xi_\phi$. 103536-14
the IR, as the particle number exceeds 1 for all three cases, the approximation works well at the peak of the energy density. The value of $(k/a_\star)_{\text{max}}$ is reproduced up to a factor 2. This also becomes clear in the right panel of Fig. 5, where the ratio of $(k/a_\star)_{\text{max}}$ over the cutoff scale (taken to be $M_p/\xi_\phi$) is plotted as a function of $\xi_\phi$. According to our numerical solution, unitarity is violated for $\xi_\phi \gtrsim 300$ and this value is reasonably reproduced by the semiclassical result. We also emphasize that the semiclassical formula works well even for $\xi_\phi = 10^2$, for which unitarity is not violated.

Let us make a brief comment on possible UV completions of Higgs inflation. For this case, some UV completions have been suggested in the literature [47–52]. In the large-$N$ limit, a healing mechanism arises [53–55], which restores unitarity, where $N$ denotes the number of real scalar fields ($N = 4$ for the Standard Model Higgs). This healing mechanism is now understood in the language of (frame-independent) nonlinear sigma model with the scalaron corresponding to the $\sigma$-meson [38]. These UV completions can greatly alter the preheating dynamics, as was demonstrated in Refs. [56–60].

3. $\alpha$-attractor inflation

Next we consider $\alpha$-attractor inflation. We consider the following action

$$S = \int d^4x \sqrt{-g} \left[ \frac{M_p^2}{2} R + \frac{(\partial \phi^a)^2}{2(1 - \phi^a \phi^a / \Lambda^2)^2} - \frac{\lambda}{4} (\phi^a \phi^a)^2 \right].$$

(3.63)

where $\phi^a = \phi_\chi$. This complex scalar field version of $\alpha$-attractor inflation is discussed, e.g., in Ref. [40].

We now see that this model does not violate unitarity during preheating by using the condition (3.21). In this model, inflation happens when the inflaton field is close to the pole of its kinetic term, $\phi \sim \Lambda$, and hence the height of the inflaton potential at the end of inflation is given by

$$V(\Phi) \sim \lambda \Lambda^4.$$  

(3.64)

Since the cutoff scale of this theory is of order $\Lambda$, we obtain

$$\frac{V(\Phi)}{\Lambda^4} \sim \lambda \lesssim \mathcal{O}(1),$$

(3.65)

where we assume that $\lambda$ is less than order one by perturbativity constraints. Then, according to the discussion in Sec. III B, we expect that unitarity is preserved during preheating in this model. Indeed no unitarity violation during preheating is observed in the literature.

In this model, the geometrical quantities are given by

$$R^\chi_{\phi\chi} = \frac{4}{\Lambda^2} \frac{1}{(1 - \phi^2 / \Lambda^2)^2},$$

$$\nabla^\chi V_\chi = \dot{\lambda} \phi^2 \left( 1 - \frac{\phi^4}{\Lambda^4} \right).$$

(3.66)

and hence the mass term is given by

$$m_\chi^2 = -\frac{4}{\Lambda^2} \frac{\dot{\phi}^2}{(1 - \phi^2 / \Lambda^2)^2} + \lambda \phi^2 \left( 1 - \frac{\phi^4}{\Lambda^4} \right).$$

(3.67)

In particular, the contribution from the target space curvature is tachyonic. This requires a separate treatment and we cannot straightforwardly apply our semiclassical method in Sec. II. Therefore we do not discuss particle production of this model any further. See Refs. [40–42] for more on the preheating dynamics of this model.

4. Higgs-Palatini inflation

Finally we consider Higgs-Palatini inflation. The action in the Jordan frame is given by

$$S = \int d^4x \sqrt{-\bar{g}}$$

$$\times \left[ \frac{M_p^2}{2} \Omega^2 R_J(\Gamma) + \frac{1}{2} g^{\mu\nu} \partial_\mu \phi^a \partial_\nu \phi^a - \frac{\lambda}{4} (\phi^a \phi^a)^2 \right],$$

(3.68)

where the subscripts “$J$” again denote quantities in the Jordan frame, $\phi^a = \phi_\chi$, and we defined

$$\Omega^2 = 1 + \frac{\xi \phi^a \phi^a}{M_p^2}.$$  

(3.69)

This form of the action is the same as Eq. (3.41), but an essential point of the Palatini formulation is that one takes the spin connection independent of the vierbein at the level of the action, and it is given as a solution of the equation of motion (which results in a constraint equation). Since the equation of motion is of first order in derivatives, it is sometimes called the first order formalism [61].

It is again convenient to go to the Einstein frame by rescaling the metric as

$$g_{\mu\nu} \rightarrow g_{\mu\nu} = \Omega^2 g_{\mu\nu},$$

(3.70)

resulting in

$$S = \int d^4x \sqrt{-g}$$

$$\times \left[ \frac{M_p^2}{2} R + \frac{1}{2\Omega^2} g^{\mu\nu} \partial_\mu \phi^a \partial_\nu \phi^a - \frac{\lambda}{4} (\phi^a \phi^a)^2 \right].$$

(3.71)

Note that the target space metric is different from that of Higgs inflation because the Ricci scalar transforms
 differently under the Weyl transformation in the metric and Palatini formalisms. In the Einstein frame, the equation of motion tells us that the spin connection is given in terms of the vierbein in the standard form, and hence we can equally think of it as the metric theory.

We now apply the condition (3.21) to this model. In this model, inflation happens for \( \phi \gtrsim M_p/\sqrt{\xi} \) where the additional term in the target space metric becomes important, and hence the height of the inflaton potential at the end of inflation is given by

\[
V(\Phi) \sim \frac{\lambda M_p^4}{\xi^2}. \tag{3.72}
\]

Since the cutoff scale of this theory is \( \Lambda \sim M_p/\sqrt{\xi} \), we obtain

\[
\frac{V(\Phi)}{\Lambda^4} \sim \lambda \lesssim \mathcal{O}(1), \tag{3.73}
\]

where we again assume that \( \lambda \) is less than order one, from the perturbativity requirement. Thus, according to the discussion in Sec. III B, we expect that unitarity is preserved during preheating in this model. This is in contrast to Higgs inflation in the metric formalism, where the ratio can be greater than unity for large enough \( \xi \) [see Eq. (3.54)]. An essential difference is that the height of the inflaton potential and the cutoff scale depend on the different scales, \( M_p/\sqrt{\xi} \) and \( M_p/\xi \), in Higgs inflation, while they depend on the common scale \( M_p/\sqrt{\xi} \) in Higgs-Palatini inflation. Indeed no unitarity violation during preheating is observed in the literature.

In this model, the inflaton amplitude at the end of inflation is given by \( \Phi \sim (M_p/\sqrt{\xi}) \ln \xi \) [13]. Since the CMB requires \( \xi \sim 10^{10} \lambda \), the logarithmic term in \( \Phi \) can be sizeable, \( \ln \xi \sim \mathcal{O}(10) \), unless \( \lambda \) is tiny. This causes a scale separation between \( \Phi \) and \( \Lambda \sim M_p/\sqrt{\xi} \) that may justify the approximation \( \Phi \to \infty \) in Eq. (2.17). Since the effective mass term and the conserved quantities are not in the form discussed in Sec. II D, we need a separate analysis in this model. Therefore, although it would be interesting, we leave a detailed semiclassical study of this model as a future work. See also Ref. [15] for more on the preheating dynamics of this model.

5. Comments on the unitarity issue of Higgs inflation

Before closing this subsection, let us clarify our attitude on the unitarity issue of (metric) Higgs inflation in this paper, since different points of view are taken on this issue in the literature.

It is well known that the cutoff scale of Higgs inflation for large \( \xi \) is given by \( M_p/\xi (\ll M_p) \) in the vacuum [8–12], referred to as the unitarity issue of Higgs inflation. Reference [12] pointed out that the cutoff scale increases as the Higgs gets a large vacuum expectation value, and hence the unitarity issue does not necessarily spoil the inflationary prediction of Higgs inflation. However, we are aware of two types of arguments that cast doubt on the validity of Higgs inflation, besides unitarity violation during preheating.

Reference [49] constructed an explicit UV completion of Higgs inflation by adding an additional scalar field to the theory. The authors found that it is the additional scalar field, and not the Higgs, that dominantly drives inflation, and hence the model ceases to be “Higgs inflation” after the UV completion. They expect that this situation is generic and the inflationary prediction in general depends on the specific form of UV completion.

References [62,63] take a slightly different point of view. The main concern of the authors is on the relation between the parameters such as \( \lambda \), or more generally the shape of the Higgs potential, at the electroweak scale and the inflationary prediction. According to their argument, even if one assumes the existence of a UV theory in which inflation is described by the Higgs field only (this itself may be a strong assumption based on Ref. [49]), one has to introduce a “threshold correction” that parametrizes one’s ignorance of the connection between low and high energy physics. This prohibits one to relate the parameters at the electroweak scale with the inflationary prediction, to say the least. The threshold correction may even push \( \lambda \) negative, making Higgs inflation impossible.

In our discussion of unitarity violation of Higgs inflation during preheating above, we simply ignore these arguments, e.g., by assuming that a UV completion does not alter the inflationary dynamics of the Higgs, and taking \( \lambda \) positive without caring about its relation to the value at the electroweak scale. Our point is that, even if we put aside the points raised here, Higgs inflation still causes an issue during preheating, and an explicit UV completion is anyway unavoidable for \( \xi \gtrsim \mathcal{O}(100) \). In other words, we have served yet another argument that demands an explicit UV completion of Higgs inflation. Although not widely discussed in the literature, the same line of argument should apply to running kinetic inflation.

D. Application to scalar dynamics other than inflaton

So far we have considered particle production induced by the inflaton motion. In theories beyond the Standard Model, there often appear scalar fields other than the inflaton that exhibit coherent motion in the field space and lead to particle production in the early universe. In supergravity, for example, the scalar potential often has many flat directions along which the potential energy is zero in the supersymmetric limit. Such flat directions may be called moduli and their impacts significantly depend on their masses and interaction strengths.

Here we consider one explicit example, the dynamics of the saxion in supergravity [64–74]. The saxion is a scalar
partner of the axion that solves the strong CP problem in quantum chromodynamics [75,76]. The flatness of the saxion potential is ensured by the holomorphy of the superpotential combined with the Peccei-Quinn (PQ) global U(1) symmetry in the supersymmetric limit. The action of a supersymmetric axion model is given by

\[ S = \int d^4x \sqrt{-g} \left[ \frac{M_p^2}{2} R + \left| \partial \psi_1 \right|^2 + \left| \partial \psi_2 \right|^2 - V(\psi_1, \psi_2) \right]. \]  

(3.74)

\[ V(\psi_1, \psi_2) = \lambda^2 \left| \psi_1 \psi_2 - \Lambda^2 \right|^2 + m_1^2 \left| \psi_1 \right|^2 + m_2^2 \left| \psi_2 \right|^2. \]  

(3.75)

where \( \psi_1 \) and \( \psi_2 \) are complex scalars and we assume \( m_1^2 \approx m_2^2 (= m^2) \ll \Lambda^2 \). The action is invariant under the global U(1) symmetry, \( \psi_1 \rightarrow e^{i\theta} \psi_1 \) and \( \psi_2 \rightarrow e^{-i\theta} \psi_2 \) with a real parameter \( \theta \). Among four real degrees of freedom, two obtain masses of order \( \Lambda \), one obtains a mass of order \( m \) corresponding to the saxion, and the last one is massless, which is regarded as the axion.

Let us suppose that we can integrate out the heavy modes of mass \( \sim \Lambda \) to consider the saxion dynamics. By using the constraint \( \psi_1 \psi_2 = \Lambda^2 \) and decomposing \( \psi_1 \) as \( \psi_1 = (\phi/\sqrt{2}) e^{i\theta/\phi} \), we obtain the effective action for the saxion \( \phi \) and axion \( \chi \) as

\[ S = \int d^4x \sqrt{-g} \left[ \frac{M_p^2}{2} R + \frac{1}{2} h_{ab} g^{\rho\sigma} \partial_{\rho} \phi^a \partial_{\sigma} \phi^b - V(\phi) \right]. \]  

(3.76)

where we defined the vector \( \phi^a = (\phi, \chi) \) and

\[ h_{ab} = \left( 1 + \frac{4\Lambda^4}{\phi^4} \right) \left( \begin{array}{cc} 1 + \frac{2}{\phi^2} & -\frac{1}{\phi} \\ -\frac{1}{\phi} & 1 \end{array} \right), \]

\[ V(\phi) = \frac{m^2}{2} \left( 1 + \frac{4\Lambda^4}{\phi^4} \right) \phi^2. \]  

(3.77)

Thus we obtained a curved target space with typical curvature scale \( \Lambda \) as an induced metric. It has been pointed out in Ref. [74] that the effective mass of the axion in this setup shows a spiky behavior and the axion particle production from the saxion dynamics is very different from the standard scenario.

The general arguments in Secs. III A and III B can be equally applied to this case. The relevant geometrical quantities are given by

\[ R^\rho_{\rho\sigma\tau} \phi^\sigma = \frac{2\phi^2}{\Lambda^4} \left( \frac{1}{1 + \phi^4/4\Lambda^4} \right)^2, \]

\[ \nabla^\rho V_\rho = m^2 \left( \frac{1 - \phi^4/4\Lambda^4}{1 + \phi^4/4\Lambda^4} \right)^2. \]  

(3.78)

and hence the effective mass of the canonical axion field is given by

\[ m_x^2 = \frac{2\phi^2}{\Lambda^4} \left( \frac{\phi^2}{1 + \phi^4/4\Lambda^4} \right)^2 + m^2 \left( \frac{1 - \phi^4/4\Lambda^4}{1 + \phi^4/4\Lambda^4} \right)^2. \]  

(3.79)

The first term that originates from the target space curvature shows the spiky behavior around \( |\phi| \ll \Lambda \). Assuming that the initial saxion field value satisfies \( \Phi \ll \Lambda \), the typical energy scale of the produced particles is given by

\[ \left( \frac{k}{a_\Lambda} \right)^2 \sim \frac{V(\Phi)}{\Lambda^2}, \]  

(3.80)

where \( a_\Lambda \) is the scale factor at the first turning point of the saxion. If we require that it should be below the cutoff scale \( \Lambda \), we again obtain the same condition as in the preheating analysis, \( V(\Phi) \ll \Lambda^4 \). If this condition is violated, integrating out the heavy fields and the use of the effective action may not be justified. For a large enough initial field value, \( \Phi \gtrsim \Lambda^2/m \), we must use the original renormalizable action (3.74) for the analysis of particle production. Actually for such a large initial saxion field value, the field trajectory significantly deviates from the flat direction and passes through the region \( \psi_1 = 0 \) or \( \psi_2 = 0 \), which may lead to nonthermal symmetry restoration and formation of topological defects [73,77,78]. Thus the cosmological effects of the saxion dynamics are completely different depending on whether the condition \( V(\Phi) \ll \Lambda^4 \) is satisfied or not.

This particular example demonstrates the phenomenological importance of the unitarity violation condition beyond the context of inflation. Once the low energy description breaks down, one must go back to a UV completed model. In the UV model, however, the dynamics should include heavy modes and they can have drastic effects on cosmology. The formation of topological defects, as seen in the saxion case, is an example of possible dangerous effects. Another possible dangerous effect is production of heavy particles that are stable against decay or charged under some (approximate) symmetry.

Here is a general remark on the moduli cosmology. In the context of string theory, the size and geometry of the compactified extra dimensions may be characterized by the moduli fields from the four-dimensional viewpoint, and their interactions are often suppressed by some high energy scale, leading to the notorious cosmological moduli problem [79,80]. Usually the moduli potential is assumed to be a simple quadratic form, but in general the flat directions may have a complicated structure in field space. In such a case particle production by the moduli and its cosmological consequences can be much different from the naive analysis.
IV. SUMMARY

In this paper, we have studied particle production and unitarity violation in inflationary models with multiple scalar fields and a curved target space during preheating after inflation. In these models the curvature of the target space causes a spiky feature in the mass of the other scalar particle(s) that couple to the inflaton. This feature results in efficient particle production and possibly in unitarity violation.

In Sec. II we demonstrate how the particle number spectrum after the first burst of particle production can be estimated in a semiclassical analysis, relying on the Born approximation ($|\alpha_i|^2 \sim 1, |\beta_i|^2 \ll 1$). Instead of $t$, we use the inflaton field $\phi$ as the time variable, hence referring to it as an analysis in (scalar) field space. This is possible since the inflaton field is a monotonic function of time between the end of inflation and its first turning point. We replace the finite integration range, from $\Phi$ to $-\Phi$ to an integration over the entire $\phi$-axis, where $\Phi$ is the inflaton oscillation amplitude. Upon using Cauchy’s residue formula, the spectrum can then be expressed as a sum over poles. We demonstrate this procedure for two example mass terms, with poles in $\phi$ of order one and two, by making use of the potential energy at the end of inflation as a conserved quantity. The semiclassical formula for the occupation number shows an excellent agreement with the numerical results for the two given examples.

In Sec. III C the analytical expressions are put to the test for two inflationary models: running kinetic inflation and Higgs inflation, which are similar to the pole of order one and two, by making use of the potential energy at the end of inflation as a conserved quantity. The semiclassical formula for the occupation number explicitly shows the limit of using effective theory during (p)reheating in the presence of unitarity violation.

J. was supported by Grants-in-Aid for JSPS Overseas Research Fellow (No. 201960698). This work was also supported by JSPS KAKENHI Grant (Nos. 18K03609 [KN] and 17H06359 [KN]). We thank Marieke Postma for useful comments.

In Sec. III B we provide a simple criterion for unitarity violation during reheating

$$V(\Phi) \gtrsim \Lambda^4.$$

that is, unitarity is violated if the inflaton potential at the end of inflation $V(\Phi)$ is larger than the fourth power of $\Lambda$, where $\Lambda$ is the curvature of the target space as well as the UV cutoff scale of the theory. The criterion immediately indicates that, for couplings consistent with the CMB normalization, unitarity can be violated for running kinetic inflation and Higgs inflation. This is also confirmed in our semiclassical analysis and numerical computations in Sec. III C, confirming that unitarity is violated for $\Lambda \lesssim 10^{-2} M_P$ for running kinetic inflation and for $\zeta_\phi \gtrsim 100$ for Higgs inflation. According to our condition, unitarity is not violated for $\alpha$-attractor models and Higgs-Palatini inflation, as is consistent with the literature [15,40–42].

Furthermore, we point out that particle production due to a curved target space is not exclusive to the preheating phase. As an example, we show in Sec. III D how integrating out the heavy field in a supersymmetric axion model results in an effective theory for the axion and the saxion with a curved target space. The saxion has a spikelike mass and unitarity violation is again possible, implying that the effective theory is not valid. The case of unitarity violation actually corresponds to the formation of topological defects in the original theory.

Unitarity violation is of great phenomenological importance, as it calls for a UV completion of the theory. If one starts from a UV-complete theory, as in the case of the saxion, one can simply go back to the original UV-complete theory. If one starts from low energy theories as in the cases of running kinetic inflation and Higgs inflation, however, this is a nontrivial requirement. We discuss several implications of the UV completion of running kinetic inflation and Higgs inflation in Sec. III C. For running kinetic inflation, it is shown that phenomenological consequences, possibly including domain wall formation, crucially depend on the concrete model of UV completion. This explicitly shows the limit of using effective theory during (p)reheating in the presence of unitarity violation.
