Deciphering *Clostridium* metabolism and its responses to bioreactor mass transfer during syngas fermentation

Ni Wan¹, Ashik Sathish², Le You³, Yinjie J. Tang³ & Zhiyou Wen⁴

This study used ¹³C tracers and dynamic labeling to reveal metabolic features (nutrients requirements, pathway delineation and metabolite turnover rates) of *Clostridium carboxidivorans* P7, a model strain for industrial syngas fermentation, and its implication with bioreactor mass transfer. P7 shows poor activity for synthesizing amino acids (e.g., phenylalanine) and thus, needs rich medium for cell growth. The strain has multiple carbon fixation routes (Wood-Ljungdahl pathway, pyruvate:ferredoxin oxidoreductase reaction and anaplerotic pathways) and *Re-citrate* synthase (Car.06155) was a key enzyme in its tricarboxylic acid cycle (TCA) pathway. High fluxes were observed in P7’s Wood-Ljungdahl pathway, right branch of TCA cycle, pyruvate synthesis, and sugar phosphate pathways, but the cells anabolic pathways were strikingly slow. In bioreactor culture, when syngas flowrate increased from 1 to 10 mL/min, P7 strain produced same amount of total extracellular products (acids and alcohols) but high flowrate favored alcohol accumulation. This observation was due to the mass transfer limitation influencing energy metabolism (CO/H₂ oxidation for cofactor generations) more prominently than carbon fixation. When syngas flowrate increased from 10 to 20 mL/min, the alcohol productivity was not improved and the labeling rate (~0.03 h⁻¹) of key metabolite acetyl-CoA reached to P7 strain’s metabolism limitation regime.

Biological utilization syngas such as CO₂ and CO becomes an important research field due to cheap feedstock and the concerns of global warming. Although photosynthesis cell factories can effective convert CO₂ into biomass, they do not have efficient native pathways for production of extracellular chemicals and thus sophisticated genetic modifications are necessary to develop photo-bioferries. Unlike photo-bioferinery, syngas fermentation uses native species to converts CO₂, CO and H₂ to diverse products such fuels and chemicals (e.g., ethanol, acetic acid, and butanol). Other advantages for syngas fermentation include bioprocess stability and tolerance to inhibitory compounds. Biocatalysts such as *Clostridium* sp. and *Acetobacterium woodii* naturally synthesize alcohol and organic acids and are commonly used in syngas fermentation¹,². Genetic improvements³ and syngas composition optimizations⁴⁻⁶ have been attempted to improve efficiency of product synthesis.

Currently, syngas fermentation is still facing challenges because the low solubility of gaseous substrates (CO and H₂) hinders the transport of gas molecules across the gas-liquid interface and diffusion into cells for bio-conversion⁷. The engineering challenges such as gas-to-liquid mass transfer are still restricting industrial syngas fermentation efficiency. Mass transfer can commonly be improved through increasing agitation or gas flowrate. Various reactor designs such as hollow fiber membrane reactor⁸, monolithic reactor⁹ and rotating packed bed biofilm reactor¹⁰ have also been developed to improve mass transfer in syngas fermentation.

In addition to mass transfer limitations, biotransformation of gaseous substrates into metabolites inside the cell can be another bottleneck in syngas fermentation. In general, the Wood-Ljungdahl pathway is the key pathway for converting CO/CO₂ into acetyl-CoA¹¹,¹². This pathway is much less effective in CO₂ fixation
than other pathway such as cyanobacterial CO₂ fixation. Synthetic biology tools can be used to enhance cell’s Wood–Ljungdahl pathway and oxidase activity. However, there has been a lack of complete knowledge of cell metabolism of syngas fermentation strains. Therefore, it is necessary to have a thorough investigation of the rate and routes of cell metabolism for conversion of acetyl-CoA into cascade metabolites during syngas fermentation.

Isotope tracer technique has been used to determine the mass transport in bioreactors. This approach can also investigate cell metabolism by analyzing isotopomer of both proteinogenic amino acids and fast-turnover free metabolites. To investigate whether fermentation process is operated in a mass transfer limitation regime or a metabolism limitation regime, this study designs 13C-labeling experiments to delineate functional pathways and to identify metabolic rate limiting steps in Clostridium Carboxidivorans P7. P7 is a model syngas fermentation strain for producing fuel ethanol from CO/CO₂. This strain has been studied for its microbial physiology and metabolic characteristics as well as its performance in various bioreactor configurations. The aim of this work is to elucidate functional pathway for cell growth and syngas conversion under different bioreactor mass transfer scenarios. Via 13C-fingerprinting of proteinogenic amino acid and fast-turnover metabolites, this study tracks cell adsorption of sugars or syngas (CO/CO₂) from culture medium into its biosynthesis pathways. The labeling information deciphers cell product synthesis and metabolic responses to bio-availability of carbon substrate. In addition, this study reported a reverse-labelling approach following previous report to trace syngas metabolism. Since continuous flushing 13CO₂ and 13CO into bioreactor would be prohibitively expensive, an inverse labeling approach was designed. U-13C-glucose was used to grow P7 strain so its central metabolites became 13C-labeled. With organic labeled 13C glucose were consumed, unlabeled syngas was fed into the culture and time-course samples were taken to monitor un-labelled 13C entering cell metabolism. The dynamic labeling/un-labelling of metabolites provides new insights into functions of individual central pathway under different mass transfer conditions.

Materials and Methods

Stain, medium and culture preparation. C. carboxidivorans P7 (ATCC-624T) was stored as 1 mL frozen glycerol stocks at −80 °C. To recover the cells, the stock culture was inoculated into culture tubes (40 mL) containing 10 mL seed medium, which contained (per liter) 5 g/L glucose and 1 g/L yeast extract (YE) dissolved in solution, 10 mL of a trace metal solution, 1 mL resazurin sodium salt solution (1% w/v), 10 mL vitamin stock solution, and 10% inoculum ratio. The medium composition in the serum bottle culture was the basal medium supplemented with cysteine-sulfide) was prepared anaerobically and autoclaved at 121 °C for 20 min. Glucose stock solution was stored in −80 °C and the cysteine-sulfide stock solution was stored at room temperature. Stain, medium and culture preparation.

Syngas fermentation in serum bottle systems. Serum bottles were used to evaluate the necessity of yeast extract in the syngas fermentation of P7 strain and elucidate its central metabolism using 13C-labelling technology. The aim and design of each set of experiment were summarized in Table 1. Specifically, the seed culture in the mid/late exponential phase was inoculated into a 125 mL serum bottles containing 50 mL medium at a 10% inoculum ratio. The medium composition in the serum bottle culture was the basal medium supplemented with 1 g/L YE and different combinations of sugars (glucose or fructose) and/or NaHCO₃ (Table 1). In cases of 13-C labeling tests (Tests 2 and 3, Table 1), the seed was first inoculated into serum bottles which only contained basal medium (glucose-free). The bottles was incubated for 12 hours to ensure the residual unlabeled glucose in the inoculum was exhausted to avoid the interference of unlabeled glucose to the labeling results. Then, 13C-glucose or 13C-bicarbonate were injected into cultures before bottles were flushed and pressured with 15 psi syngas containing (v/v) 75% N₂, 20% CO, and 5% H₂ (Table 1). At the end of culture, samples (~15 mL) were harvested using falcon tubes then quickly cooled to 0 °C via liquid nitrogen bath. The cold samples (~0 °C) were centrifuged and the biomass pellets were frozen and stored for subsequent analyses.

Syngas fermentation in bioreactor systems. P7 fermentation were performed using Applikon MiniBio reactor systems. The bioreactor has 250 mL working volume (37 °C and 500 rpm agitation), and culture pH was controlled at 6.0 using 1 M NaOH solution. Since continuous flushing of 13CO₂ and 13CO into bioreactors is prohibitive expensive, we designed an inverse dynamic labeling approaches to reveal the metabolism of P7 cells under different flow rate. In brief, fully labeled 13C-glucose was first used as a carbon source for cell growth. During this stage, N₂ gas was flushed to the vessel and 13C-glucose was the major carbon source for labeling intracellular metabolites. The exhausting gas from the vessels was passed through a standard MiniBio system condenser then an ice-cold water trap submerged in an ice water bath to trap volatile products. The volumetric gas flow rates used for different sets of the bioreactor cultures were shown in Table 1. Once glucose was exhausted in bioreactor, culture was switched to syngas growth mode by switching flushing gas from N₂ to a gas mixture containing 50% CO, 37.5% CO₂, and 12.5% H₂ (v/v) with the same flow rate. After gas switching, pH control was stopped to minimize perturbations from NaOH feeding. To track dynamics of metabolite labeling of P7 cells, broth samples (~20 mL) were harvested at 0 s, 30 min, 5 hr, 24 hr, 48 hr, 65 hr, 88 hr and 120 hr, respectively. Each sample were placed in falcon tubes and immediately cooled to −0 °C by liquid N₂ bath for 10 s to stop cell metabolism (note: samples need be stirred during liquid N₂ bath to avoid being frozen). The quenched samples were then centrifuged (8,000 g) at 4 °C and biomass pellets were frozen for further analysis of free metabolites.

Determination of kLa of bioreactor. Mass transfer coefficient (kLa) of the MiniBio system was determined based on the dynamic method using oxygen as the model gas species. In brief, nitrogen was sparged into the reactor to remove dissolved oxygen (DO) until DO level reached to almost zero; air was then sparged...
into the reactor and the DO level was recorded every minute. The DO concentration change and \( k_{La} \) follow the relationship as:

\[
\frac{dC}{dt} = k_{La}(C^* - C)
\]

(1)

where \( C \) is the instant DO concentration at time \( t \), \( C^* \) is the saturated DO concentration. \( k_{La} \) can be determined from the slope of the following integrated equation:

\[
k_{La} = -\frac{\ln(C^* - C)}{t}
\]

(2)

In this work, \( k_{La} \) was determined under three flow rates (1, 10, and 20 mL/min), with other operation conditions being the same as the syngas fermentation experiments (37 °C, 500 rpm agitation, and 250 mL working volume).

Isotopomer analysis. Analysis of free metabolites followed a previous protocol. Briefly, cell pellet was suspended in 1 mL methanol/chloroform solution (7:3 v/v) and shake at 150 rpm at 4 °C. Water was added to the cell-solvent mix to extract cell metabolites. The aqueous phase was filtered through an Amicon Ultra centrifuge filter (3000 Da; EMD Millipore, Billerica, MA), lyophilized, and dissolved in acetonitrile and water (6:4, v/v) solution for LC-MS measurement (Agilent Technologies 1200 Series equipped with a ScQuant Zic-pHILIC column;
LC-MS analysis was performed at Lawrence Berkeley National Laboratory. MS distributions of the metabolite were determined based on the ratio of the integrated peak area of the chosen isotopeomer to the sum of integrated peak areas of all isotopomers.

The proteinogenic amino acids was measured by GC-MS followed previous protocols.24 Cell biomass was hydrolyzed with 6 M HCl at 105 °C, air-dried and then derivatized with N-tert-butyldimethylsilyl-N-methyl trifluoroacetamide for GC-MS analysis. MS data [M−15]1 and [M−57]1 represent entire amino acid, and [M−159]1 or [M−85]1 represents amino acid losing carboxyl group. For leucine and isoleucine, their [M−57]1 signal was overlapped by other peaks and [M−15]1 was analyzed. All MS data were corrected to remove the noise from natural isotopes using published algorithms25. Labeling fractions (M0, M1, M2...) represent MS fragments with 0, 1, 2 labeled carbons.

Determination of glucose, alcohol and acid productions. The broth was filtered through a 0.22-μ filter and diluted with deionized water. A Thermo Scientific Dionex ICS-5000 ion chromatograph (IC) with an electo-chemical detector (AgCl electrode) was used to determine glucose concentration. Ethanol, butanol, acetic acid, and butyric acid were determined using a Varian 450 gas chromatograph (GC) with an FID detector. A Zebron 1701 column (60 m × 0.25 mm × 0.25 μm) couple to a Zebron guard column (5 m × 0.25 mm) was used for separation. The details of product measurement has been described in our recent papers.8,9.

Data availability statement. The datasets generated during and/or analysed during the current study are available from the corresponding authors on reasonable request.

Results and Discussion

Importance of yeast extract for P7 growth. The first task is to examine the necessity of medium nutrient, particularly yeast extract (YE), on P7 growth (Test 1, Table 1). The information will inform us the influence of rich medium on labelling test and metabolic flux quantifications. This is because the complex carbon nutrients (i.e., amino acids) in YE can incorporate into biomass, and thus, interfere with a quantitative flux analysis. As shown in Fig. 1, P7 barely grew in YE-free medium even carbon sources (glucose (GLU) or fructose (FRU)) were provided. This result was similar to previous report that P7 syngas fermentation in YE-free medium experienced a very long lag phase (5 days) with minimal cell density achieved over 600 hours.26 YE addition, even without sugars, improved cell growth significantly (p < 0.01, Fig. 1). Such a benefit effect of YE on cell growth indicates that YE can be used in the initial stage of P7 culture to promote rapid cell growth before implementing syngas fermentation stage. Thus, it shortens the syngas fermentation stage and save the gas pumping cost. The cell growth was further improved when sugars (glucose or fructose) were provided. However, supplementation of syngas in the YE- and sugar-containing medium did not further promote cell growth, indicating sugar was the preferred carbon source for P7 cells.

To further investigate the role of YE for P7 growth, a glucose- or NaHCO3- labelling test were performed. Figure 2 shows amino acid labeling results when 13C-glucose (either 1-13C glucose or 1,2-13C glucose) and NaH13CO3 were used in the medium (Test 2, Table 1). As shown in Fig. 2, all amino acids had a significant un-labelled isotopeomer, indicating that a large portion of those amino acids were not de novo synthesized but rather taken from YE. The labelled aspartate and glutamate were significant higher than other labelled amino acids because of 13C flux through the TCA metabolites (p < 0.05, Fig. 3). Figure 2 also shows that for all amino acids except methionine, addition of symgas CO and H2 into 13C-glucose culture (either 1-13C glucose or 1,2-13C glucose) did not change labeling of those proteinogenic amino acids (Fig. 2a–j). This observation can be interpreted that Clostridium species demonstrate the hierarchy of nutrient utilization (i.e., utilize a preferred carbon source in multiple-substrate medium).27 For methionine, presence of CO and H2 resulted in ~10% more labelled methionine molecules (note: oxaloacetate (OAA) and 5,10-methyltetrahydrofolate (C1) are its precursors), supporting the fact that CO and H2 as electron donors facilitate labeled CO2, which released from NaH13CO3 during acidogenesis phase of syngas fermentation, to enter methyl branch of the Wood-Ljungdahl pathway. Collectively, the results in Fig. 2 indicate that P7 has a relatively weak capability for de novo synthesizing several key amino acids although its genome contains complete annotations of all amino acid pathways. It is therefore necessary to use rich nutrient (e.g., YE) to support biomass growth and reduce P7 fermentation duration. As a result, a pathway delineations rather than quantitative flux analysis of the P7 cells were performed in this work.

Analysis of functional pathways in P7. The central pathways of P7 were delineated via NaH13CO3 and unlabeled CO and H2 in the serum bottle cultures (Test 3, Table 1). The labeling of metabolites in central pathways was deduced from isotopomer analysis of proteinogenic amino acid. As shown in Fig. 3, most leucine was found unlabeled, indicating most of its precursor, Acetyl-CoA, was almost unlabeled. Furthermore, alanine was mainly labeled in its first position (i.e., the loss of carboxyl group of alanine resulted in unlabeled fragment), indicating C2 and C3 carbons of pyruvate (the precursor of alanine) were mostly unlabeled (Fig. 3). Oxaloacetate (precursor of aspartate) was labeled with one (39%) and two carbons (15%), while ketoglutarate (precursor of glutamate) was mainly labeled with one carbon (56%). The labeling of pyruvate and oxaloacetate/4-ketoglutarate confirmed that labeled carbon from NaH13CO3 was fixed via pyruvate:ferredoxin oxidoreductase (Ccar_01615) and carboxylase mainly labeled with one carbon (56%). The labeling of pyruvate and oxaloacetate/ketoglutarate confirmed that the TCA cycle was active in P7. Aspartate (the precursor of alanine) was labeled with one carbon (39%) and two carbons (15%), while ketoglutarate (precursor of glutamate) was labeled with one carbon (39%) and two carbons (15%). The labeling of pyruvate and oxaloacetate/ketoglutarate confirmed that labeled carbon from NaH13CO3 was fixed via pyruvate:ferredoxin oxidoreductase (Ccar_01615) and carboxylase (Ccar_01615), while little amount of 1-13C formed Acetyl-CoA. This observation can be interpreted by preferred uptake of CO2 instead of bicarbonate by the Wood-Ljungdahl pathway.28,29 (note: autotrophic microbes such as algae can use both bicarbonate and gaseous CO2).

P7 genome contains an incomplete TCA cycle, missing malate dehydrogenase (catalyze malate → oxaloacetate), succinate-CoA ligase, and ketoglutarate dehydrogenase. In serum bottle cultures with NaH13CO3, Fig. 4 shows lack of labeling in malate and succinate. A weak TCA cycle is common for anaerobic bacteria. Interestingly,
P7 genome lacks \textit{Si}-citrate synthase, the starting point of the TCA cycle. However, manual search of \textit{Re}-citrate synthase indicates a gene 2-isopropylmalate synthase (Ccar_06155) identical to the reported \textit{Re}-citrate synthase (amino acid sequence similarity ~79%). This alternative citrate synthase gene was confirmed by labeling data (Fig. 3): $\alpha$-carboxyl group of glutamate was unlabeled concurrently with carboxyl group of pyruvate\textsuperscript{30}. Such labeling signature highlights the existence of \textit{Re}-citrate synthase that causes $^{13}$C atom transitions to $\beta$-carboxyl group of glutamate (Fig. 3). In some anaerobic bacteria, citramalate synthase often co-exists with \textit{Re}-citrate synthase to involve atypical isoleucine synthesis from acetyl-CoA \textsuperscript{31}. However, BLAST search showed no gene candidate for citramalate synthase and P7 contained a normal threonine dependent isoleucine pathway. This view is supported by isotopic tracing that showed isoleucine was from oxaloacetate and had different labeling patterns from acetyl-CoA derived leucine\textsuperscript{32} (Fig. 3).

**P7 growth and bio-production during syngas fermentation.** In a typical syngas fermentation process, CO, CO\textsubscript{2}, and H\textsubscript{2} must move across the gas-liquid interface and be accessible to microbe cells. Once absorbed, the substrates must be converted into the desired products (such as ethanol) using an efficient metabolic pathway. During “substrate (CO, CO\textsubscript{2} and H\textsubscript{2}) $\rightarrow$ product (ethanol)” conversion process, a series of sequential transport phenomena occurred, including physical bulk gas-to-liquid mass transfer, the substrate moving across the cell membrane, and enzymatic conversion of the substrate molecules into various metabolites. In
general, syngas fermentation is operated in one of two regimes, a gas-liquid mass transfer limitation or a kinetics/metabolism limitation, depending on the bioreactor operational conditions and the cell intrinsic characteristics. Here, syngas fermentation was performed under three gas flow rate scenarios to determine whether the cells are in a mass transfer limitation regime or metabolism regime (Test 5, Table 1). Using oxygen as the model gas species, mass transfer coefficient (k La) of the bioreactor under the three gas flow rates were determined as 9.86 hr⁻¹ (20 mL/min); 6.29 hr⁻¹ (10 mL/min), and 0.86 hr⁻¹ (1 mL/min). As shown in Fig. 5, glucose was first used as a substrate to grow biomass in a YE-containing medium; the cell growth increased rapidly within the first 12 hours. After glucose was exhausted, the cells ceased growth and the culture was switched to syngas flushing mode. The culture experienced ~24 h lag phase for adapting new substrates (syngas). During this stage, cell acidogenesis ceased and culture pH maintained at around 6.0. After lag phase, the culture resumed its growth and entered acidogenesis phase. This triggers pH drops to ~5.5 and consequently solventogenesis to produce butanol and ethanol (Fig. 5). This growth pattern was also reported elsewhere. Table 2 summarizes the production of extracellular metabolites from 120h-syngas fermentation. The culture with 1 mL/min flow rate accumulated more acid which resulted in lower pH (Fig. 5). The flow rate of 10 mL/min increased alcohol ratios in the final products, but the titers of total final products (i.e. the sum of ethanol, acetic acid, butanol and butyric acid) were not differed. This observation indicates carbon fixation fluxes were not enhanced by higher flowrate syngas. On the other hand, CO was a major component (60%) in the syngas. CO was also a main energy source (NAD(P)H/ATPs) due to its inhibitory to hydrogenase. High flow rate facilitated CO oxidation to generate cofactors for alcohol synthesis, while low flow rate (1 mL/min) acetic acid and C4 (butyric acid) production, this was probably due to that high acetic acid inhibits its synthesis pathway, thereby redirecting Acetyl-CoA towards longer carbon chain (i.e., C4) pathway. When flowrate was further increased to 20 mL/min, neither alcohol or acetate productions was improved at the end of fermentation. Collectively, P7 energy metabolism was clearly under mass transfer limitation regime when gas flow rate was around 1 mL/min. If the gas flowrate was raised above 10 mL/min, cell productivity was mainly limited by the intrinsic metabolic capability.

Figure 3. Major metabolic pathways (the Wood-Ljungdahl pathway, the TCA cycle, the pyruvate metabolism) and carbon transition identified in P7 strain. The cells were grown in basal medium containing NaHCO₃ with syngas (Test 3, Table 1). Cells were harvested at day 6 and subjected to proteinogenic amino acids labelling analysis. Re-citrate synthase (marked as brown), pyruvate carboxylase (marked as blue), fumarate hydratase (Marked as green), and malate dehydrogenase (marked as red, malate → pyruvate + CO₂) were annotated as the key enzymes for the TCA pathway. Embden-Meyerhof-Parnas pathway (EMP); phosphoenolpyruvate (PEP); ribulose 5-phosphate (Ru5P).
P7 metabolism during syngas fermentation under different gas flow rates. An inverse dynamic $^{13}$C-labelling experiment was conducted in P7 syngas fermentation to delineate the dynamic metabolism of free metabolites and proteinogenic amino acids (Tests 6 & 7, Table 1). In this inverse labelling test, labelled glucose was used for the initial culture to label the cell metabolites. Upon glucose depletion, un-labelled syngas was used for the cell culture to dilute the labeled metabolites and determine the speed of syngas carbons percolating metabolic network. Figure 6 shows the relative abundance of labelled and un-labelled key metabolites of P7 cells in inverse dynamic labelling tests. After the cultures were switched to unlabeled syngas (flowrate = 10 or 20 mL/min), $^{13}$C acetyl-CoA decreased without lag phase (Fig. 6a). However, other central metabolites such as free alanine (Fig. 6b) had longer lag phase before the unlabeled compound accumulated. The continued change of unlabeled-acetyl-CoA confirmed that the Wood-Ljungdahl pathway has fast responses to gaseous substrates. However, carbons are trapped in acetyl-coA node and require much longer time for cell re-organize its fluxes percolating through downstream pathways. After a lag phase, the fixed carbons in acetyl-CoA began actively...
Figure 6 shows that TCA metabolites and progression of syngas fermentation, supporting Fig. 3 that unlabeled CO/CO$_2$ flew from acetyl-CoA fluxes even under high flowrate syngas. Interestingly, fermentation with low flowrate (1 mL/min) had total 5.3 g/L of TCA cycle, and pyruvate synthesis showed relatively fast rates, while other biosynthesis pathways have low total products (from ~15% to 50%) with the progression of syngas fermentation, supporting Fig. 3 that unlabeled CO/CO$_2$ flew from acetyl-CoA fluxes even under high flowrate syngas. The low conversion from labeled to unlabeled malate (Fig. 6e) supports that P7 operates an incomplete TCA cycle.

Figure 6 demonstrates a faster synthesis of key metabolites (e.g., glutamate and malate) in central metabolism under higher flow rate. On the other hand, high flowrate fermentation did increase alcohol ratio in the extracellular products (sum of acids and alcohols) that were not lower than the total products from the fermentations under higher flow rate. While the mass transfer strongly influences energy efficiency and better bioavailability of syngas substrates. Moreover, the increase of the un-labelled proteinogenic amino acid proportion after un-labelled syngas flushing for 105 h was also determined. As shown in Fig. 7, all amino acid species demonstrated low increment of its un-labelled fractions. For example, serine, alanine, and aspartate had 20~35% increment of un-labelled fractions. This observation indicates that syngas carbons were minimally used for anabolism and thus P7 protein (Fig. 7) had very slow turnover rates even at high flowrate syngas.

Overall, the inverse dynamic labelling test of P7 cells indicates that increasing flow rate from 10 to 20 mL/min did not significantly (P value > 0.05) increase the production of free metabolites and proteinogenic amino acids (Figs 6 and 7). The results, together with the cell growth performance in Fig. 5, demonstrate that the P7 strain was not limited by mass transfer under this flow rate range (10–20 mL/min); instead, P7 intrinsic metabolic capability limited substrate utilization and bio-production. In contrast to photoautotrophic metabolism cyanobacteria whose CO$_2$ fixation rate and flux through central pathways are in the order of minutes$^{36}$, P7 metabolic conversion rate (in the order of hours) is much slower under syngas conditions: the Wood-Ljungdahl pathway, right branch of TCA cycle, and pyruvate synthesis showed relatively fast rates, while other biosynthesis pathways have low fluxes even under high flowrate syngas. Interestingly, fermentation with low flowrate (1 mL/min) had total 5.3 g/L extracellular products (sum of acids and alcohols) that were not lower than the total products from the fermentations under higher flow rate. On the other hand, high flowrate fermentation did increase alcohol ratio in the total products (from ~15% to >60%, Table 2). Since solventogenesis consumes significantly more NAD(P)H than aciogenic metabolism, high syngas mass transfer is necessary for cell membrane to obtain electrons from H$_2$ and CO for alcohol production and biosynthesis$^{37}$. This leads to conclusion that the energy metabolism rather than carbon metabolism was more influenced by mass transfer limitations in our experiments.

### Conclusion

This study is first to elucidate metabolic pathways and mass transfer under syngas fermentation conditions via $^{13}$C labeling using P7 cells as model strain. The outcomes offer novel insights. First, complex nutrients (such as yeast extract) are essential for P7 cell growth. Also, the presence of organic carbon (such as sugars) repress syngas utilizations by P7 strain. Second, P7 cells can utilize CO$_2$ through the Wood-Ljungdahl pathway$^{36}$, pyruvate:ferredoxin oxidoreductase, and anaplerotic pathways. Third, P7 strain contains a novel Re-citrate synthase (Ccar$_{06155}$). Fourth, only a few pathways in P7 cells are highly active under syngas metabolism with minimal fluxes through protein synthesis. Fifth, bioreactor tests inferred that mass transfer strongly influences energy metabolism (syngas oxidation), which benefits alcohol production and reduces acid production. Sixth, the Wood-Ljungdahl pathway can quickly take C1 substrates after culture switching from glucose medium to syngas conditions, but downstream pathways require much longer time for flux adjustment. In summary, this study bridges the gap between cell metabolisms and bioprocess conditions, which offers broad impact on gas fermentation applications.

Table 2. Accumulation of carboxylic acids and alcohols during P7 syngas fermentation under different flow rates (Test 5, Table 1). Data are presented as mean ± SD of two duplicates.
Figure 6. Relative abundance of labeled and un-labelled key metabolites of P7 cell in inverse dynamic labeling tests (Tests 6 & 7, Table 1). 13C-glucose was used for the culture in the first 12 h when N2 gas was aerated into the reactor, unlabeled syngas was aerated when 13C-glucose was depleted. Two flow rates were used (low flowrate = 10 mL/min; high flowrate = 20 mL/min). Data were means of three replicates and error bars represent standard deviations. Legends: □: M0 labeling under low flowrate; △: M0 labeling under high flowrate, ■ 13C enrichment under low flowrate; ▲ 13C enrichment under high flowrate. Solid line: data from high flow rate samples; dash line: data from low flow rate samples. Note: The Wood-Ljungdahl pathway mainly turnover the acetyl group of acetyl-CoA. Thus, the labeling of acetyl group was also estimated in Fig. 6a: 13C enrichment in the acetyl group under high (●) and low (◆) flowrates. kLF and kHL are rate coefficients calculated by simulation for acetyl group labeling under low flowrate and high flowrate, respectively. 95% confidence interval was shown in parentheses.

Figure 7. Enrichment of the un-labelled proteinogenic amino acids in the inverse dynamic labelling syngas fermentation. Two gas flow rates were used (Test 6 & 7, Table 1). Cells were inoculated with 13C-glucose and grew until glucose used up, then unlabeled syngas was aerated. Enrichment was defined as the difference between the un-labelled amino acids at beginning of unlabeled syngas aeration (0 hr) and the end of the fermentation (105 hr). Error bars represent the standard deviation of duplicated experimental data.

Acknowledgements

This work was supported by NSF (CBET 1438042). We are also thankful for Mary Abernathy, Lian He and Di Liu at Washington University and Edward Baidoo from Lawrence Berkeley National Lab for helping with LC-MS analysis.
Author Contributions
The project is initiated and designed by Y.J.T. W.Z. A.S. and N.W. performed fermentation experiments and analyses. N.W. and L.Y. performed labeled experiments. A.S. and N.W. performed the syngas fermentation. All authors reviewed the manuscript.
