**ABSTRACT**

We herein describe a 34-year-old woman with a persistent left superior vena cava (PLSVC) impinging on the posterior wall of the left atrium, subdivided by a membrane at the distal part of the impingement. In this patient, a much dilated coronary sinus due to the PLSVC resulted in a membrane-like structure in the posterior wall of the left atrium with the appearance of the cor triatriatum in transthoracic echocardiography (ie, a pseudo cor triatriatum). Although the PLSVC is a common malformation of the superior systemic vein, its aforementioned presentation is rare.

**Keywords:** Persistent Left Superior Vena Cava, Cor Triatriatum, Coronary Sinus, Left Atrial Function

**Introduction**

The Cor triatriatum is a rare congenital abnormality found incidentally in asymptomatic patients during echocardiography or evaluations for pulmonary arterial hypertension (1). The main feature of this abnormality is a fibrous membrane inside the left atrium (LA), dividing it into 2 posterosuperior and inferoanterior cavities. The upper cavity receives pulmonary venous drainage, and the lower one contains the LA appendage (2). These cavities are connected at the orifice, and the severity of the resulting stenosis and symptoms depends on the size of the orifice between the 2 LA parts (3). When the diameter exceeds 10 mm, patients are generally asymptomatic (4). The supramitral ring and the cor triatriatum may resemble each other in transthoracic echocardiography (TTE) and computed tomography. The difference, however, lies in the fact that in the cor triatriatum, the pulmonary veins are in the posterosuperior chamber and the LA appendage and the mitral valve are in the inferoanterior chamber, whereas in the supravitreal ring, the LA appendage and the pulmonary veins are in the posterosuperior chamber and the mitral valve is in the inferoanterior chamber (1).

The supramitral ring is a subcategory of stenotic mitral valve lesions and may be associated with such other abnormalities as the ventricular septal defect, subaortic valve stenosis, parachute mitral valves, the cor triatriatum, and the persistent left superior vena cava (PLSVC) (5), with the latter being the most common congenital cardiac anomaly of them all.

The visualization of a dilated coronary sinus (CS) by TTE should place the PLSVC at the forefront of the likely diagnoses, although it is asymptomatic in most cases (2).

The concurrence of the aforementioned congenital diseases constitutes a rare condition, which makes our case scintillating. Furthermore, our case differs from the rare reported instances of the conventional association between these congenital anomalies insofar as in our patient, not only did a markedly dilated CS due to a PLSVC mimic the clinical and echocardiographic features of a cor triatriatum sinistrum (1, 2), but also the supravitreal ring appeared as a nonobstructive ring attached to the atrial side of the mitral valve.
Case Report

A 34-year-old woman presented to our center with dyspnea and palpitation.

TTE, performed to evaluate possible structural heart diseases, revealed a left ventricular (LV) ejection fraction of 55% with a normal LV global function, a mild-to-moderate mitral insufficiency, and an enlarged LA (52 mL/m²) (Figure 1). Additionally, a thin, small indentation from the atrial side of the anterior mitral valve leaflet was visualized, suggesting a supramitral ring (Figure 2).

There was also a severely dilated CS, indicating the drainage of a PLSVC into the CS with turbulent flow across its length. The huge CS was responsible for the obstruction of the LV inflow tract, with a mean gradient of 3 mm Hg and the narrowest diameter of 9.3 mm. Injection of microbubbles intravenously in the left arm disclosed CS opacification, immediately followed by right-sided heart opacification, which confirmed the presence of the PLSVC and the dilated CS (Figure 3).

Transoesophageal echocardiography confirmed the findings of the TTE study. Computed tomography angiography showed a dilated LA, which contained a membrane-like structure, dividing it into proximal and distal chambers (Figure 4).

Discussion

This report describes our experience of an unusual case of a young woman whose echocardiographic examination in the parasternal long-axis and 4-chamber views showed LV inflow obstruction by a pseudo cor triatriatum sinistrum resulting from a PLSVC draining into a huge CS. Saline contrast echocardiography and cardiac computed tomography angiography confirmed the presence of the PLSVC draining into the giant CS.

The PLSVC is the commonest of the superior systemic vein malformations, occurring in about 0.4% of the general population and 4.3% of those affected by congenital heart diseases (6). The PLSVC drains mainly into the CS (62%) and less commonly into the LA (21%) or a common atrium (17%). In situs solitus, the PLSVC almost always drains into the CS. Drainage to a common atrium occurs with situs ambiguous and right isomerism. Most PLSVC cases with drainage into
the CS are asymptomatic and usually found incidentally during surgery, invasive cardiovascular procedures, or cardiovascular imaging. Nevertheless, in the presence of an atrial septal defect, a partial LV inflow obstruction may lead to LA return diversion and, thus, left-to-right shunts and exacerbated clinical symptoms. Moreover, studies have reported a higher incidence of cardiac arrhythmias and conduction defects in patients with the PLSVC, which might be secondary to the stretching and fibrosis of the atrioventricular node or the His bundle by the dilated CS or the dysfunction of the associated sinus node (1, 2, 7).

Another diagnostic challenge is that a markedly dilated CS due to a PLSVC can sometimes mimic the clinical and echocardiographic features of a supramitral ring or a cor triatriatum, as was the case in our patient. A significantly dilated CS may even produce LV inflow obstruction and heart failure and, consequently, give rise to pulmonary hypertension; it should, therefore, be considered in the differential diagnosis of pulmonary hypertension in infants (2, 7).

**Conclusion**

We herein presented a case of a PLSVC draining into the CS, causing its severe dilation. The huge CS, in turn, led to the obstruction of the LV inflow tract, with a mean gradient of 3 mm Hg and the narrowest diameter of 9.3 mm. Furthermore, the patient also had a supramitral ring, which appeared as a nonobstructive ring attached to the atrial side of the mitral valve. These findings can explain the etiology of the patient’s symptoms and the echocardiographic appearance of a pseudo cor triatriatum sinistrum. The echocardiographic findings were subsequently confirmed by cardiac computed tomography angiography.

Since our patient was symptomatic, we planned to surgically direct the PLSVC into the right SVC, repair the excessively dilated CS and the enlarged LA, and excise the supramitral ring.
