ABSTRACT
We present the early UV and optical light curve of Type IIP supernova (SN) 2010aq at z = 0.0862, and compare it to analytical models for thermal emission following SN shock breakout in a red supergiant star. SN 2010aq was discovered in joint monitoring between the Galaxy Evolution Explorer (GALEX) Time Domain Survey (TDS) in the NUV and the Pan-STARRS1 Medium Deep Survey (PS1 MDS) in the g, r, i, and z bands. The GALEX and Pan-STARRS1 observations detect the SN less than 1 day after shock breakout, measure a diluted blackbody temperature of 31,000 ± 6,000 K 1 day later, and follow the rise in the UV/optical light curve over the next 2 days caused by the expansion and cooling of the SN ejecta. The high signal-to-noise ratio of the simultaneous UV and optical photometry allows us to fit for a progenitor star radius of 700 ± 200R⊙, the size of a red supergiant star. An excess in UV emission two weeks after shock breakout compared to SNe well fitted by model atmosphere-code synthetic spectra with solar metallicity, is best explained by suppressed line blanketing due to a lower metallicity progenitor star in SN 2010aq. Continued monitoring of PS1 MDS fields by the GALEX TDS will increase the sample of early UV detections of Type II SNe by an order of magnitude, and probe the diversity of SN progenitor star properties.

Subject headings: supernovae: individual (SN 2010aq) — ultraviolet: general — surveys

1. INTRODUCTION

Shock breakout in a core-collapse supernova (SN) marks the first escape of radiation from the blast wave that breaks through the surface of the star and launches the SN ejecta, heating it to temperatures of 10⁵ – 10⁶ K (Colgate 1974; Folk 1978; Klein & Chevalier 1978; Matzner & McKee 1999). The duration of this radiative precursor in the UV/X-rays is smeared out by light-travel time effects to \( t_{\text{lt}} = R_e/c \sim 2 \text{s} \) (\( R_e/R_\odot \)), where \( R_e \) is the pre-SN radius of the progenitor star. In the presence of a dense wind, or if the shock breakout is aspherical or very weak, the observed duration can be much longer (Campana et al. 2006; Chevalier & Fransson 2008; Couch et al. 2009; Dessart et al. 2010).

Following shock breakout, the early SN light curve is powered by radiation from the expanding and cooling SN ejecta. In hydrogen-rich Type II-plateau SNe (SNe IIP), a receding H recombination wave prolongs the optical brightness of the SN until radioactive heating plays a dominant role. The luminosity and temperature evolution of the early thermal expansion phase can be used as a diagnostic for the radius of the progenitor star, as well as the explosion energy to ejecta mass ratio (Waxman et al. 2007). This is an important tool, since the direct detection of SN progenitors is incredibly difficult, and has only been possible for a small number of nearby SNe with pre-explosion high resolution imaging (Smartt et al. 2009).

Recent observational advances have enabled the detection of early UV emission from core-collapse SNe from hours to a couple of days after explosion. The Swift satellite serendipitously detected luminous X-ray bursts with X-Ray Telescope (XRT) from Type Ib/c SNe 2006aj and 2008D, which were modeled by shock breakout in the dense wind surrounding a Wolf-Rayet (WR) star (Campana et al. 2006; Waxman et al. 2007; Soderberg et al. 2008), although alternative scenarios were also proposed that invoked the presence of relativistic jets (Ghisellini et al. 2007; Mazzali et al. 2008). The UV/optical counterparts detected in co-aligned Swift UVOT observations were well fitted by analytical models for emission from the expanding, cooling envelope of a progenitor with the radius of a WR star (Campana et al. 2006; Soderberg et al. 2008; Rabinak & Waxman 2010).
The wide-field UV survey capabilities of the Galaxy Evolution Explorer (GALEX) satellite serendipitously detected the onset within 7 hr of shock breakout of a UV-bright plateau lasting 2 d before fading away from Type IIP SN SNLS-04D2dc at $z = 0.185$, two weeks before its discovery in the optical Supernova Legacy Survey (SNLS) (Gezari et al. 2008; Schawinski et al. 2008). While the data were modeled both numerically and analytically with thermal emission following shock breakout in an RSG progenitor with $R_\star$, ranging from 800 to 1000$R_\odot$, and a variety of stellar envelope density structures (Gezari et al. 2008; Schawinski et al. 2008; Tomlinaga et al. 2009; Rabinak & Waxman 2010), the low signal-to-noise ratio of the detections ($S/N < 3$) and the lack of simultaneous optical data preclude one from fitting for the parameters of the RSG progenitor star.

In this Letter, we present SN IIP 2010aq at $z = 0.0862$ discovered in joint monitoring observations in the UV by GALEX Time Domain Survey (TDS) and in the optical by the Pan-STARRS1 Medium Deep Survey (PS1 MDS). The UV and optical observations discover the SN less than 20.5 hr after shock breakout in the SN rest frame, and the high $S/N$ of the detections enable us to use model fits to the early light curve to place meaningful constraints on the radius of the RSG progenitor star for the first time.

2. OBSERVATIONS

From UT 2010 February 4 - March 22 (UT dates are used throughout this Letter) the GALEX TDS monitored the 7 deg$^2$ PS1 MDS field MD04 in the NUV with 7 pointings, each 1 deg$^2$, with a cadence of 2 days and with a limiting magnitude of $m_{AB} \sim 23$. Gaps in the regular monitoring occurred when the NUV detector was shut down for engineering tests. The GALEX science images were run through the difference imaging pipeline photpipe (Rest et al. 2005), and difference image detections were filtered through a series of selection criteria to remove false detections due to image-subtraction artifacts. The remaining detections were associated between epochs, and then cross-matched with the PS1 SN alerts from the MDS with a matching radius of 5$''$.

GALEX TDS detected a variable object on 2010 February 12 coincident with a PS1 SN candidate discovered at R.A.$=10^\mathrm{h}02^\mathrm{m}09.741$, decl.$=+01^\circ14'00''94$ (J2000) in daily imaging cycling through the $g, r, i$, and $z$ filters starting on 2010 February 12. The SN was confirmed with spectroscopy with the 4.2m William Herschel Telescope (WHT) with ISIS on 2010 February 23.08 to be a Type IIP SN at $z = 0.0862$ from its strong Balmer P-Cygni features (SN 2010aq, Valenti et al. 2010). We obtained additional epochs of spectroscopy with the Nordic Optical Telescope (NOT) with ALFOSC on 2010 February 24.98, the 6.5 m Magellan Telescope with IMACS on 2010 February 25.17, and with the 6.5m MMT with Hectospec on 2010 April 10.20. In Figure 1 we show the H\textsc{o} and H\textsc{\textbeta} features in our spectra, and the velocity drift of the absorption minimum of H\textsc{\textbeta} with time from the recession of the photosphere in mass.

In order to avoid systematic errors from residuals in the difference images, the GALEX photometry is measured on the science images with a 6$''$ radius aperture centered on the host galaxy, and the flux of the SN is determined by subtracting the flux of the host galaxy measured from pre-SN epochs ($NUV = 22.0 \pm 0.1$ mag). The 1\sigma error is measured empirically from the dispersion in magnitudes measured for sources detected in all epochs. The offset between the SN and the host galaxy centroid is 1.75 (1 pixel), for which we estimate an upper limit to systematic errors due to centering of the aperture $< 0.1$ mag. The GALEX photometry is in the AB system, has been aperture corrected ($\Delta m = -0.23$, Morrissey et al. 2007), and is corrected for Galactic extinction with $E(B - V) = 0.024$ mag.

The PS1 MDS images were reduced with the PS1 Image Processing Pipeline (Magnier 2006) including detecting, calibration, warping, and stacking. Difference imaging and transient alerting were performed using the photpipe pipeline on the stacked PS1 images (Rest et al. 2005). The SN photometry is measured by photpipe using forced point-spread function (PSF) photometry on the difference images at the position of the SN, and the zero point is measured from comparison with field stars in the SDSS catalog. The PS1 photometry is in the AB system, and is corrected for Galactic extinction.

Table 1 lists the GALEX and PS1 SN photometry, and Figure 2 shows the UV and optical SN light curve. We define the phase of the SN ($\phi$) to be days in the SN rest frame since the time of shock breakout ($t_{\mathrm{SBO}}$). Our observed constraint on $t_{\mathrm{SBO}}$ is the time between the last non-detection with GALEX in the NUV on MJD 55237.54, and the first detection with PS1 in the $z$-band on MJD 55238.47, which is a window of 20.5 h in the SN rest frame. We further constrain $t_{\mathrm{SBO}}$ using fits of shock breakout models to the early UV/optical light curve in §4 to be $t_{\mathrm{SBO}} = 55238.42 \pm 0.02$.

3. HOST GALAXY

We measure the host galaxy redshift of $z = 0.0862$ from nebular emission lines that are superimposed on the SN spectrum, and adopt a distance modulus, $DM=38.0$. The narrow Balmer lines have a Galactic-extinction corrected H\textsc{\textalpha}/H\textsc{\textbeta} ratio of 3.28 $\pm$ 0.15, corresponding to an internal extinction of $E(B - V) = 0.12 \pm 0.04$ mag (Calzetti 2001). We use the semiempirical relation between metallicity and the measured nebular emission line ratios, $[\mathrm{N II}]/\mathrm{H\alpha} < 0.1$, $[\mathrm{O III}]/\lambda 5007/\mathrm{H\beta} = 3.6 \pm 0.2$, and $\log(R_{23}) = [(\mathrm{[O III]})/\lambda 3727 + (\mathrm{[O III]})/\lambda 5007 + 4959]/\mathrm{H\beta} = 0.89 \pm 0.05$, to measure a low oxygen abundance of $12+\log(O/H) = 8.2 - 8.5$ (McGaugh 1991; van Zee et al. 1998; Pettini & Pagel 2004), which is consistent with the low metallicity expected from the luminosity-metallicity relation from Tremonti et al. (2004) given the dwarf host galaxy of SN 2010aq with an internal extinction and K-corrected rest-frame absolute magnitude of $M_B = -17.3$ mag.

4. COMPARISON WITH ANALYTICAL MODELS

We compare the early ($\phi < 3$ d) UV/optical light curve to analytical models for shock breakout and its immediate aftermath in a RSG star, the progenitors of Type IIP SNe. The analytical model presented by Nakar & Sari (2010) (NS10), follows the photon-gas coupling to determine the location of the photosphere, and takes into account photon diffusion from inner layers below the photosphere. The analytical relations presented by Rabinak & Waxman (2010) (RW10) neglect the effects of photon diffusion, but do include opacity from electron scatter-
ing and its effect on the emitted spectrum. Although the pre-SN stellar structure and detailed physics are better treated in numerical radiation hydrodynamics models, these models are computing-time intensive, and analytical models are more practical to use for fitting for the parameters of the progenitor star. We rely on the analytical scaling relations from NS10 to constrain \( R_{500} \) and \( E_{51}/M_{15} \), where \( R_{500} \) is \( R_*/500R_\odot \), \( M_{15} = M/15M_\odot \), and \( E_{51} = E/10^{51} \) ergs. Here \( E \) is the energy of the explosion, and \( M \) refers to the mass of the ejecta, and does not include the 1.44 \( M_\odot \) from the neutron star core or mass lost from winds during the lifetime of the star.

In the spherical expansion phase (when \( \nu_{ph} \approx \nu_{ph,t} \)), the NUV light curve rises to a maximum when the ejecta expands and cools until the peak energy of the emission is \( 3kT = h\nu_{NUV}(1+z) \), or when \( T = 1.94 \) eV. Using \( T(\phi) \) for a RSG from NS10, this translates to \( \phi_{peak} = 2.2 \) d \( M_{15}^{0.23} R_{500}^{0.68} E_{51}^{0.20} \). For a blue supergiant star (BSG) with \( R = 20 - 70R_\odot \), \( \phi_{peak} \) in the NUV occurs much earlier (\( \phi_{peak} < 0.6 \) d), which is incompatible with the observed light curve of SN 2010aq. If we use our observed limits on \( t_{ph} = \) MJD 55238.0 \pm 0.5, and conservatively estimate \( \phi_{peak} \) to be within 1 day of the second GALEX detection on MJD 55241.5, then in the SN rest-frame \( \phi_{peak} = 3 \pm 1 \) d, and this results in \( M_{15}^{−0.23} R_{500}^{0.68} E_{51}^{0.20} \approx 1.4 \pm 0.5 \).

The first detection in the NUV (\( \phi_1 \)) on MJD 55239.30, as well as on MJD 55239.46 in the \( g \) and \( r \) bands, places a tight constraint on \( T(\phi_1) \). In the first couple of days after shock breakout, the spectrum of the bands is well approximated by a diluted blackbody (Gezari et al. 2008; Tomimaga et al. 2009). Assuming that the \( g \) and \( r \) data points are \( \sim 0.2 \) mag fainter on MJD 55239.30, the UV/optical photometry is fitted with \( E(B-V) = 0.11 \pm 0.01 \) mag and \( T_{ph} = 2.7 \pm 0.5 \) eV, in excellent agreement with \( E(B-V) \) derived from the Balmer decrement. Note that the observed diluted blackbody temperature is hotter than the photospheric temperature by a factor of \( \approx 1.2 \) as a result of electron scattering (RW10).

In Figure 3 we plot the NS10 model for an RSG with \( M_{15} = R_{500} = E_{51} = 1 \), fitted for \( E(B-V) = 0.03 \) mag and \( t_{ph} = \) MJD 55238.42 \pm 0.02, with an offset of \( -1.5 \) mag and a K correction to transform the NS10 models from the rest-frame to the observed frame of SN 2010aq. The NS10 model is in good agreement with the data until \( \phi = 3 \) d. The tight constraint on \( t_{ph} \) is from the fit to the earliest detection in the \( z \)-band on MJD 0.03 \pm 0.02 d, and does not include the much larger uncertainties at very early phases (\( \phi \lesssim 1.5 \) d for a RSG) introduced by the simplistic approximations in the analytical models (RW10). While the NS10 \( M_{15} = R_{500} = E_{51} = 1 \) model is fitted to the data with a small amount of reddening, if we require that \( E(B-V) = 0.12 \pm 0.04 \) mag, then one gets the same fit at \( \phi_1 \) to a model with a factor of \( 1.4^{+0.4}_{-0.2} \) times higher temperature, and thus with \( M_{15}^{−0.13} R_{500}^{0.38} E_{51}^{0.11} = 1.4^{+0.4}_{-0.2} \). Given the offset in luminosity required to fit the model, and \( L(\phi) \) for a RSG from NS10, one gets an additional constraint of \( M_{15}^{−0.87} R_{500}^{0.59} E_{51}^{0.96} \approx 4 \).

When combining all of the constraints above, an extinction of \( E(B-V) \) \( < 0.12 \) mag is required for the allowed parameters from \( \phi_{peak} \) to converge with those from \( T(\phi_1) \). If we assume the best fit value for the reddening from \( T(\phi_1) \) of \( E(B-V) = 0.11 \pm 0.01 \) mag, which is in agreement with this upper limit, then for different values of \( E_{51} \), one then gets the following solutions, \( (E_{51}, M_{15}, R_{500}) = (0.5, 0.09 - 0.15, 1.0 - 1.5), (1.0, 0.23 - 0.38, 1.1 - 1.8), \) and \( (1.5, 0.37 - 0.62, 1.1 - 1.8) \), thus placing the strongest constraint on the radius of the RSG progenitor, \( R_{500} = 1.4 \pm 0.4 \). For this value of \( R_*, \) stellar evolutionary models of core-collapse SN progenitor stars with solar to half-solar metallicities have \( M_{15} \approx 0.45 - 0.90 \) (Eldridge & Chugai 2004), and hydrodynamical simulations of SNe IIP have even larger model ejecta masses (\( M_{15} > 1 \)) (Utrobin & Chugai 2008), thus favoring the solutions with \( E_{51} = 1 \).
Figure 9, Dessart & Hillier 2005). However, one must be cautious with this interpretation, since the UV spectral range is difficult to model. Even in the case of SN 1987A, where the metallicity, BSG progenitor, and explosion energy of the SN are well constrained, the most sophisticated time-dependent non-LTE radiative transfer models, while in excellent agreement with the optical observations (at the level of 10%), are in much worse agreement in the UV (only to the 30 – 50% level) (Dessart & Hillier 2010). However, given the low metallicity of the dwarf host galaxy of SN 2010aq, a subsolar metallicity progenitor star is the most natural explanation for the UV excess at late times.

6. CONCLUSIONS

Although the duration of the radiative precursor from shock breakout is too short to be resolved by rolling SN surveys, the thermal expansion phase in the days following can be studied in detail. In this Letter, we have shown that with daily cadence UV and optical imaging we can use analytical models to fit for the radius of the pre-SN progenitor star, and even use the evolution of the UV light curve to directly probe its metallicity. UV observations are also critical for constraining the time of shock breakout in distant SNe ($t_{\text{peak}} - t_{\text{SHO}}$ is only 2 days in the NUV compared to 2 weeks in the r band), and can improve the accuracy of using Type II-P SNe as distance indicators (Schmidt et al. 1992; Dessart et al. 2008; Kasen & Woosley 2009).

Based on the detection efficiency of GALEX for detecting UV emission from Type II SNe measured from serendipitous observations of SNLS SN candidates, Gezari et al. (2008) predict a detection rate for GALEX TDS, which monitors one PS1 MD field per month, of $\approx 1$ month$^{-1}$. Given the actual detections of two SNe IIP in effectively 2 months of operations of GALEX TDS in coordination with PS1, luminous SN 2009kf at $z = 0.182$ (Botticella et al. 2010) and SN 2010aq, our detection rate appears to be right on the mark. Continued GALEX TDS and PS1 MDS monitoring will yield an exciting data set to probe the diversity of progenitors of core-collapse SNe, and approach a better understanding of the mapping from stellar evolution to stellar death.

S. G. thanks I. Rabinak and E. Nakar for kindly providing their models in the GALEX and PS1 filters, L. Dessart for helpful discussions, and the anonymous referee for useful comments. S. G. was supported by NASA through Hubble Fellowship grant HST-HF-01219.01-A awarded by the Space Telescope Science Institute, which is operated by AURA, Inc., for NASA, under contract NAS 5-26555. The PS1 Surveys have been made possible through the combinations of the Institute for Astronomy at the University of Hawaii, The PanSTARRS Project Office, the Max-Planck Society and its participating institutes, the Max Planck Institute for Astronomy, Heidelberg, and the Max Planck Institute for Extraterrestrial Physics, Garching, The Johns Hopkins University, the University of Durham, the University of Edinburgh, the Queen’s University of Belfast, the Harvard-Smithsonian Center for Astrophysics, the Las Cumbres Observatory Global Network, and the National Central University of Taiwan. We gratefully acknowledge NASA’s support for construction, operation, and science analysis for the GALEX mission, developed in cooperation with CNES of France and the Korean MOST.

Fig. 1.— Strong Hα and Hβ P-Cygni features in SN 2010aq, with the velocity of the Hβ absorption minimum (which shifts from 14,000 km s$^{-1}$ to 6,000 km s$^{-1}$ between φ = 10.7 and 53.2 d) marked with a dotted line. Also shown is the φ = 12.0 d and φ = 57.9 d spectrum for SN 2006bp from Dessart et al. (2008) and Quimby et al. (2007) which have been multiplied by a factor of 0.013 and 0.002, respectively, and have an Hβ absorption minimum at 10,160 km s$^{-1}$ and 7,000 km s$^{-1}$, respectively. The spectra have been binned in wavelength when necessary to improve the S/N, and offset in flux for clarity.
Fig. 2.— GALEX NUV and PS1 $g, r, i,$ and $z$ light curve of SN 2010aq. The flux of the host galaxy has been removed, and the magnitudes are in the AB system, corrected for Galactic extinction, and subtracted by the distance modulus (DM=38.0). Solid and dashed lines show the light curves of well-studied Type IIP SNe 2005cs and 2006bp from Dessart et al. (2008), and $K$-corrected to the observed frame of SN 2010aq. SN 2005cs was reddened by 0.02 mag and SN 2006bp was dereddened by 0.24 mag to remain with a net internal reddening of $E(B-V) = 0.11 \pm 0.05$ mag and offset by $-1.9$ and $-0.3$ mag, respectively.
Fig. 3.— Zoom in of the early UV/optical light curve of SN 2010aq in comparison to the best fitting analytical model from Nakar & Sari (2010) (NS10) with $E_{51} = 1$, $M_{15} = 1$, and $R_{500} = 1$ (thick solid line), and the analytical model from Rabinak & Waxman (2010) (RW10) with $E_{51} = 1.44$, $M_{15} = 0.59$, and $R_{500} = 1.73$ (dashed-dotted line). The models have been K-corrected into the observed frame of SN 2010aq and applied with a reddening of $E(B - V) = 0.03$ mag. The NS10 model has been offset by $-1.5$ mag.
### Table 1: GALEX and PS1 Photometry

| Filter | Date (MJD) | φ (d) | mag       | 1σ       |
|--------|------------|-------|-----------|----------|
| NUV    | 55235.42   | −2.8  | (22.69)   |          |
| NUV    | 55237.54   | −0.8  | (22.68)   |          |
| NUV    | 55239.32   | 0.8   | 21.06     | 0.18     |
| NUV    | 55241.52   | 2.8   | 20.64     | 0.09     |

---

*a* Days since MJD 55238.4 in the SN rest-frame.

*b* AB magnitudes corrected for a Galactic extinction of $E(B-V)=0.024$ and the host galaxy contribution removed. Upper limits are given in parentheses.
