The Gravitational Path Integral for $N = 4$ BPS Black Holes from Black Hole Microstate Counting

Gabriel Lopes Cardoso, Abhiram Kidambi, Suresh Nampuri, Valentin Reys and Martí Rosselló

Abstract. We use the exact degeneracy formula of single-centred $\frac{1}{4}$ BPS dyonic black holes with unit torsion in 4D $N = 4$ toroidally compactified heterotic string theory to improve on the existing formulation of the corresponding quantum entropy function obtained using supersymmetric localization. The result takes the form of a sum over Euclidean backgrounds including orbifolds of the Euclidean AdS$_2 \times S^2$ attractor geometry. Using an $N = 2$ formalism, we determine the explicit form of the Abelian gauge potentials supporting these backgrounds. We further show how a rewriting of the degeneracy formula is amenable, at a semi-classical level, to a gravitational interpretation involving 2D Euclidean wormholes. This alternative picture is useful to elucidate different aspects of the gravitational path integral capturing the microstate degeneracies. We also comment on the relation between the associated 1D holographic models.

Understanding black hole entropy has served as a fecund nexus of diverse approaches to uncovering the fundamental principles of quantum gravity. In this note, we analyse some of these approaches and how they feed into each other in the context of obtaining the microstate degeneracies \( d(m, n, \ell) \) of single-centred \( \frac{1}{2} \) BPS black holes with unit torsion in toroidally compactified 4D \( N = 4 \) heterotic string theory. In this case, there are three distinct approaches to obtaining the corresponding degeneracies for these dyonic configurations:

1. The statistical approach, pioneered in [1] and used with spectacular success for certain classes of BPS black holes, identifies the statistical microscopic degeneracies as Fourier coefficients of automorphic forms. In the \( N = 4 \) case, \( d(m, n, \ell) \) are encoded in the Fourier coefficients of a particular meromorphic Siegel modular form, namely the reciprocal of the Igusa cusp form \( \Phi_{10} \) [2,3]. An exact expression for the microstate degeneracies \( d(m, n, \ell) \) has been given in [4,5] by resorting to a Rademacher-type expansion of the Fourier coefficients of \( 1/\Phi_{10} \), building on earlier work [6,7].

2. The quantum entropy function approach consists of extracting \( d(m, n, \ell) \) from a particular quantum gravity partition function [8]. In this approach, one is instructed to sum over gravitational space-time metrics that asymptote to Euclidean \( \text{AdS}_2 \times S^2 \). This a priori infinite-dimensional integral reduces to a finite-dimensional one via supersymmetric localization [9–12]. This drastic simplification enables explicit computations for the counting of BPS black hole microstates.

3. The holographic approach uses the \( \text{AdS}_2 / \text{CFT}_1 \) correspondence applied to the decoupled near-horizon geometry associated with asymptotically flat BPS black holes. Bulk fluctuations in \( \text{AdS}_2 \) are holographically encoded in a Lorentzian 1D DFF-type model [13–16]. This model has been shown to capture the semi-classical Wald entropy of BPS black holes [17].

The approaches just discussed are summarized on the left-hand side of Fig. 1. The statistical approach, which is at present the one formulated most rigorously, will be used as a starting point to connect to results obtained in the quantum entropy function approach. We will review the formulation of the quantum entropy function in an \( N = 2 \) language. To relate it to the expression
for \( d(m, n, \ell) \) given in [5] requires certain assumptions that we will spell out in due course.

Importantly, the expression for \( d(m, n, \ell) \) given in [5] can also be brought to a different but equivalent form whose significance is as follows. While the Rademacher form is naturally related to the quantum entropy function, which is constructed from an underlying action principle, the equivalent form presents features that are covariant under S-duality. We will show that this ‘covariant’ picture suggests a space-time interpretation of the microscopic result in terms of space-time geometries that, at the semi-classical level, involve the 2D Euclidean wormholes in AdS\(_2\) introduced in [18,19].

The wormhole interpretation admits a holographic dual description in terms of a 1D Liouville theory [19]. We will demonstrate that this model can be rewritten as a Lorentzian DFF-type model dual to the near-horizon AdS\(_2\) factor by means of an appropriate time reparametrization. This equivalence provides a suggestive first step in understanding the relation between the macroscopic quantum entropy function and 2D wormhole pictures introduced above. The alternative descriptions we propose in this paper, and their interrelations, are summarized on the right-hand side of Fig. 1.

2. Microstate Degeneracies of \( \frac{1}{4} \) BPS \( N = 4 \) Black Holes

The degeneracies \( d(m, n, \ell) \) of \( \frac{1}{4} \) BPS states with unit torsion in heterotic string theory compactified on a six-torus are given in terms of the Fourier coefficients of \( 1/\Phi_{10} \), where \( \Phi_{10} \) is the Igusa cusp Siegel modular form of weight 10 [2,20,21]. \( \Phi_{10} \) depends on 3 variables, here denoted by \( \rho, \sigma, v \), and the
degeneracies are extracted by integrating these variables over a contour $C$,

$$d(m, n, \ell) = (-1)^{\ell+1} \int_{C} d\sigma dv d\rho \frac{1}{\Phi_{10}(\rho, \sigma, v)} e^{-2\pi i(m\rho + n\sigma + \ell v)}. \quad (2.1)$$

Since $1/\Phi_{10}$ is a meromorphic Siegel modular form, the resulting expression for the Fourier coefficients $d(m, n, \ell)$ will depend on the choice of the integration contour $C$.

Here, we will focus on the degeneracies of single-centred dyonic $\frac{1}{4}$ BPS black holes. The microstate degeneracies $d(m, n, \ell)$ of these BPS black holes are determined in terms of charge bilinears $m, n, \ell$ satisfying $\Delta > 0$, where

$$\Delta = 4mn - \ell^2. \quad (2.2)$$

Following [3,22–24], we define the $R$-chamber by

$$\frac{\rho_2}{\sigma_2} \gg 1, \quad \frac{v_2}{\sigma_2} = -\frac{\ell}{2m}, \quad \frac{\ell}{2m} \in [0, 1), \quad (2.3)$$

where $\rho = \rho_1 + i\rho_2$, $\sigma = \sigma_1 + i\sigma_2$, and $v = v_1 + iv_2$. To extract the degeneracies of single-centred $\frac{1}{4}$ BPS black holes, we take the integration contour $C$ to be the one detailed in [5]. By first integrating over the variable $\rho$, one obtains an exact expression for the degeneracies $d(m, n, \ell)$ with $\Delta > 0$ in terms of a fine-grained Rademacher-type expansion that uses two distinct $SL(2, \mathbb{Z})$ subgroups of $Sp(4, \mathbb{Z})$. We refer to [5] for the exact but somewhat lengthy expression for $d(m, n, \ell)$.

When integrating over $\rho$, one obtains an expression that can be brought to the form [5]

$$d(m, n, \ell)_{\Delta > 0} = \sum_{P} \sum_{\Sigma \in \mathbb{Z}/a |a| \mathbb{Z}} (-1)^{\ell+1} \gamma(2a_c)^{13} \int_{C} \frac{d\tau \wedge d\bar{\tau}}{(\tau - \bar{\tau})^{13}} \left( \frac{m}{ac} E_2(\rho_0') + \frac{c}{a} E_2(\sigma_0') \right) \times \frac{1}{\eta^{24}(\rho_0') \eta^{24}(\sigma_0')} e^{-2\pi i \Lambda}, \quad (2.4)$$

where the set $P$ is defined by

$$P = \left\{ \left( \begin{array}{cc} a & b \\ c & d \end{array} \right), \left( \begin{array}{cc} \alpha & \beta \\ \gamma & \delta \end{array} \right) \in SL(2, \mathbb{Z}) \mid a, \gamma > 0, c < 0, \alpha, \delta \in \mathbb{Z}/\gamma \mathbb{Z}, b \in \mathbb{Z}/a \gamma \mathbb{Z} \right\}, \quad (2.5)$$

and where $\tau = \tau_1 + i\tau_2$, $\bar{\tau} = \tau_1 - i\tau_2$, and $|\tau|^2 = \tau \bar{\tau}$. The combinations $\rho_0'$ and $\sigma_0'$ are functions of $\tau$ and $\bar{\tau}$, while the exponent $\Lambda$ depends on $(\tau, \bar{\tau})$ as well as on the charge bilinears $(m, n, \ell)$. Their explicit expressions will be given in the next subsection, where we also discuss the contour $\hat{C}$. The subsequent evaluation of (2.4) results in the fine-grained Rademacher-type expansion mentioned above, which expresses the BPS degeneracies with $\Delta > 0$ in terms of the polar BPS degeneracies with $\Delta < 0$. We refer to [5] for more details.
Below, we will show that by adding a total derivative term to the integrand, we can bring the expression (2.4) to the following form,

\[
d(m, n, \ell)_{\Delta > 0} = \sum_{P \in \mathbb{Z}/|ac|\mathbb{Z}} \sum_{\Sigma \in \mathbb{Z}} e^{i\pi \varphi} \frac{(-1)^{\ell+1}}{2i\pi \gamma(ac)^{13}} \int_{\tilde{C}} d\tau \wedge d\bar{\tau} \times \left(26 + \frac{2\pi m}{n_2} \frac{|\tau|^2 + n - \ell \tau_1}{\tau_2} \right) \frac{1}{\eta^{24}(\rho') \eta^{24}(\sigma')} e^{\frac{\pi}{n_2} \frac{m|\tau|^2 + n - \ell \tau_1}{\tau_2}},
\]

where \(n_2 = -ac\gamma\) and \(\varphi\) depends on \((m, n, \ell)\). To write (2.6), we have dropped exponentially suppressed contributions associated with small BPS black holes that we will discuss in Sect. 2.2. As mentioned in the introduction, we will call (2.4) the Rademacher form of the microscopic degeneracy formula, and (2.6) the ‘covariant’ form. We will show that the total derivative term that relates the Rademacher and ‘covariant’ forms of the degeneracy formula does not contribute when integrated over the contour \(\tilde{C}\).

In the rest of the paper, we will explain how both (2.4) and (2.6) are amenable to a gravitational path integral interpretation in terms of a sum over gravitational backgrounds that include Euclidean orbifolds of AdS_2 spacetimes [9–12]. Furthermore, we will demonstrate that, at a semi-classical level, the ‘covariant’ form (2.6) is amenable to an alternative macroscopic description in terms of 2D wormholes introduced in [18,19].

As shown in [4,25], a detailed analysis of the Rademacher form (2.4) reveals that the degeneracies \(d(m, n, \ell)\) of \(1/4\) BPS states with \(\Delta > 0\) are encoded in the degeneracies of polar states, which are BPS states with \(\Delta < 0\). The degeneracies of the latter can be constructed from a continued fraction structure associated with the decay of two-centred \(1/4\) BPS bound states. Note that this bound state structure is not manifest in (2.6).

In the rest of this section, we first recall how the Rademacher form (2.4) arises. Subsequently, we show how (2.6) is related to (2.4).

### 2.1. Integrating \(1/\Phi_{10}\) Over \(\rho\)

We first consider integrating (2.1) over \(\rho\). To do so we follow [5]. The integral over \(\rho\) is evaluated by summing over the residues in the \(\rho\)-plane associated with the quadratic poles of \(1/\Phi_{10}\). These poles are characterized by the 5 integers \(m_1, n_1, m_2, n_2 \in \mathbb{Z}, j \in 2\mathbb{Z} + 1\). One may take \(n_2 \geq 0\) without loss of generality. The poles with \(n_2 > 0\) are referred to as quadratic poles, while those with \(n_2 = 0\) are called linear poles. The poles are defined by the loci

\[
n_2(\rho \sigma - v^2) + jv + n_1 \sigma - m_1 \rho + m_2 = 0,
\]

in the Siegel upper half plane. The five integers \(m_1, n_1, m_2, n_2, j\) satisfy the constraint

\[
m_1 n_1 + m_2 n_2 = \frac{1}{4} \left(1 - j^2\right),
\]
and they can be parametrized in terms of 9 integers, 8 of which comprise the entries of the two $SL(2, \mathbb{Z})$ matrices in the set (2.5), as follows [5,26]

\begin{align}
n_2 &= -ac\gamma, \\
j &= ad + bc, \\
n_1 &= -bd\alpha - \gamma\Sigma, \\
m_1 &= ac\delta, \\
m_2 &= -bd\beta - \delta\Sigma.
\end{align}

(2.9)

Integrating over $\rho$ in this manner, one obtains the expression [5]

\[
d(m, n, \ell)\Delta > 0 = \sum_P \sum_{\Sigma \in \mathbb{Z}/|ac|\mathbb{Z}} (-1)^{\ell+1} \int_{\tilde{C}} d\sigma \wedge dv \left( \frac{(\gamma\sigma + \delta)^{10}}{ac} \right)
\]

\[
\times \left( \frac{m}{ac} + \frac{a}{c} E_2(\rho'_0) + \frac{c}{a} E_2(\sigma'_0) \right) \frac{1}{\eta^{24}(\rho'_0)} \frac{1}{\eta^{24}(\sigma'_0)} e^{-2\pi i \Lambda},
\]

(2.10)

which is encoded in the two distinct $SL(2, \mathbb{Z})$ subgroups that describe the set $P$ in (2.5). Here, $E_2$ is the Eisenstein series of weight two and $\tilde{C}$ denotes a particular contour in the $(\sigma, v)$-plane [5]. The variables $\rho'_0$ and $\sigma'_0$ are given in terms of $\sigma$ and $v$ as

\begin{align}
\rho'_0 &= -\frac{b}{c} \left( \frac{a\sigma + b}{\gamma\sigma + \delta} \right) + \frac{a}{c} \left( \frac{v}{\gamma\sigma + \delta} \right) - \frac{a}{c} \Sigma, \\
\sigma'_0 &= \frac{d}{a} \left( \frac{a\sigma + b}{\gamma\sigma + \delta} \right) - \frac{c}{a} \left( \frac{v}{\gamma\sigma + \delta} \right) - \frac{c}{a} \Sigma,
\end{align}

(2.11)

while the quantity $\Lambda$ is given by

\[
\Lambda(\sigma, v) = m \left[ \frac{\gamma v^2}{\gamma\sigma + \delta} - \frac{bd}{ac} \left( \frac{a\sigma + b}{\gamma\sigma + \delta} \right) + \frac{(ad + bc)}{ac} \frac{v}{\gamma\sigma + \delta} - \frac{1}{ac} \right] + n\sigma + \ell v.
\]

(2.12)

We now bring (2.10) to the form (2.4) by expressing

\[
\int_{\tilde{C}} d\sigma \wedge dv \left( \frac{(\gamma\sigma + \delta)^{10}}{ac} \right) = - \int_{\tilde{C}'} \frac{1}{\gamma^{13}} \left[ \frac{a}{\gamma} - \frac{a^2 r_0}{\gamma} + \frac{a^2 s_0}{\gamma} + \frac{2ac}{\gamma} \right]^{13},
\]

(2.13)

where the contour $\tilde{C}$ has been mapped to the contour $\tilde{C}'$ through (2.11). We then obtain for the exponent in (2.10),

\[
\Lambda = \frac{X_1}{X_2} - \frac{m}{ac} \Sigma.
\]

(2.14)
where
\[
X_1 = \frac{1}{\gamma} \left[ m \left( -\rho'_0 \sigma'_0 \gamma + \alpha d^2 \rho'_0 + \alpha b^2 \sigma'_0 \right) + n \left( -\beta + \delta A \right) + \ell \left( cd \rho'_0 + ab \sigma'_0 \right) \right] + \sum \left( -m \frac{A}{ac} + m \frac{\alpha (a^2 d^2 + b^2 c^2)}{ac} + 2n \frac{\delta}{\gamma ac} + \ell \frac{ad + bc}{\gamma} \right) - \Sigma^2 m, \\
X_2 = \frac{\alpha}{\gamma} - A - 2ac \Sigma, \\
\]
and where for later use we define the combinations
\[
A = c^2 \rho'_0 + a^2 \sigma'_0, \\
B = c^2 \rho'_0 - a^2 \sigma'_0, \\
\]
in terms of which
\[
\rho'_0 = \frac{A + B}{2ac}, \quad \sigma'_0 = \frac{A - B}{2a^2}. \\
\]

Next we change integration variables from \((\rho'_0, \sigma'_0)\) to \((\tau, \bar{\tau})\) using
\[
\rho'_0 = -\frac{a}{c} \frac{\tau}{\gamma} - \frac{b}{c} \frac{\alpha}{\gamma} - \frac{a}{c} \Sigma, \\
\sigma'_0 = \frac{c}{a} \frac{\bar{\tau}}{\gamma} + \frac{d}{a} \frac{\alpha}{\gamma} - \frac{c}{a} \Sigma, \\
\]
where we define \(\tau = \tau_1 + i \tau_2\), \(\bar{\tau} = \tau_1 - i \tau_2\), and \(|\tau|^2 = \tau \bar{\tau}\). Note that \(\tau_1\) and \(\tau_2\) are complex variables, since \(\rho'_0\) and \(\sigma'_0\) are complex. The quantities \(X_1\) and \(X_2\) are expressed in terms of \(\tau\) and \(\bar{\tau}\) as
\[
X_2 = \frac{ac}{\gamma} \left( \tau - \bar{\tau} \right) = 2i \frac{ac}{\gamma} \tau_2, \\
\]
\[
\gamma X_1 = m \left( \tau \bar{\tau} - \frac{\alpha}{\gamma} bd (\tau - \bar{\tau}) \right) + n \left( \frac{1}{\gamma} - \frac{\delta}{\gamma} ac (\tau - \bar{\tau}) \right) - \ell \frac{\tau_1}{\gamma} - i \ell \frac{\tau_2}{\gamma} (ad + bc), \\
\]
and hence we obtain for the combination (2.14),
\[
- 2\pi i \Lambda = \frac{\pi}{n_2} \left[ \frac{m |\tau|^2 + n - \ell \tau_1}{\tau_2} + 2i \left( -\frac{1}{2} j \ell - m_1 n + n_1 m \right) \right]. \\
\]

Then, (2.10) becomes
\[
d(m, n, \ell)_{\Delta > 0} = \sum_{P} \sum_{\Sigma \in \mathbb{Z}/|ac| \mathbb{Z}} \frac{(-1)^{\ell + 1}}{\gamma^2 (ac)^{13}} \int_{\hat{C}} \frac{d\tau \wedge d\bar{\tau}}{(\tau - \bar{\tau})^{13}} \left( \frac{m}{ac} E_2 (\rho'_0) + \frac{c}{a} E_2 (\sigma'_0) \right) \\
\times \frac{1}{\eta^{24} (\rho'_0)} \frac{1}{\eta^{24} (\sigma'_0)} e^{-2\pi i \Lambda}, \\
\]
with \(\rho'_0\), \(\sigma'_0\) and \(\Lambda\) expressed in terms of \(\tau\) and \(\bar{\tau}\) through (2.18) and (2.20), and where the contour \(\hat{C}\) has been mapped to the contour \(\hat{C}'\) through (2.18).
To describe the new contour $\hat{C}$, we first note the relations
\[ \tau = -\frac{\gamma(v + \frac{b}{\gamma})}{\gamma \sigma + \delta} = \tau_1 + i\tau_2 , \]
\[ \bar{\tau} = -\frac{\gamma(v + \frac{c}{\gamma})}{\gamma \sigma + \delta} = \tau_1 - i\tau_2 . \]
Then, using the relation (2.3) and the contours of integration over $\sigma$ and $v$ discussed in [5], it can be shown that $\hat{C}$ takes the following form in terms of the $(\tau_1, \tau_2)$ coordinates,
\[ \tau_1 : \frac{\ell}{2m} - i\tau_2 \rightarrow \frac{\ell}{2m} + i\tau_2 , \quad \tau_2 : \varepsilon - i\infty \rightarrow \varepsilon + i\infty , \] (2.23)
where $\varepsilon$ is a positive real number. We can set it to $\varepsilon = \frac{\sqrt{\Delta}}{2m}$ to guarantee that the contour passes through the attractor point, which is the tree-level saddle point value for $\tau$ given in (2.48). The contour (2.23) can be parametrized by
\[ \Gamma_1 : \tau_1 = \frac{\ell}{2m} + i\tau_2 (-1 + 2y) , \quad \delta \leq y \leq 1 - \delta , \]
\[ \Gamma_2 : \tau_2 = \varepsilon + it , \quad -\infty < t < \infty , \] (2.24)
where $\delta > 0$ is a regulator, whose presence ensures that the arguments of the $\eta$ functions in (2.21) satisfy $|e^{2\pi i \rho^*_0}| < 1$ and $|e^{2\pi i \sigma^*_0}| < 1$ on the contour.\(^1\) Indeed, on this contour we have
\[ \tau_1 + i\tau_2 = \frac{\ell}{2m} + 2i\tau_2 y = \frac{\ell}{2m} - 2ty + 2i\varepsilon y , \]
\[ \tau_1 - i\tau_2 = \frac{\ell}{2m} - 2i\tau_2 (1 - y) = \frac{\ell}{2m} + 2t(1 - y) - 2i\varepsilon (1 - y) , \] (2.25)
and hence, using (2.18), we infer that on the contour
\[ |e^{2\pi i \rho^*_0}| = e^{4\pi \frac{\partial}{\partial \rho^*_0}} \varepsilon y = e^{-4\pi \frac{\partial}{\partial \rho^*_0}} \varepsilon y < 1 , \]
\[ |e^{2\pi i \sigma^*_0}| = e^{4\pi \frac{\partial}{\partial \sigma^*_0}} \varepsilon (1 - y) = e^{-4\pi \frac{\partial}{\partial \sigma^*_0}} \varepsilon (1 - y) < 1 . \] (2.26)
Throughout the paper, when we write $\int_{\hat{C}} d\tau \wedge d\bar{\tau} f$, we will mean
\[ 2i \int_{\Gamma_2} d\tau_2 \left( \int_{\Gamma_1} d\tau_1 f \right) . \] (2.27)
In the next subsection, we will show how the Rademacher form (2.21) of the degeneracy formula can be brought into the ‘covariant’ form (2.6).

\[ \text{2.2. Adding a Total Derivative Term} \]
The Rademacher form (2.21) is obtained by performing the integration over the $\rho$ variable in (2.1). An alternative expression for the degeneracies can be obtained by first integrating over the $v$ variable. As shown in [9], the leading contribution to (2.1) coming from the residue at the pole $\rho \sigma - v^2 + v = 0$ takes the form of the integral entering (2.6). We now explain how to directly relate
\[ ^1\text{A similar contour was also used in [27,28].} \]
the degeneracies obtained from integrating over \( \rho \) and over \( v \) by the addition of a total derivative term.

We start from (2.21),

\[
d(m, n, \ell)_{\Delta > 0} = \sum_P \sum_{\Sigma \in \mathbb{Z}/|ac|\mathbb{Z}} e^{i\pi \varphi} \left( -1 \right)^{\ell+1} \frac{\gamma}{(ac)^{13}} \int \frac{d\tau \wedge d\bar{\tau}}{C(\tau - \bar{\tau})^{13}}
\times \left( \frac{m}{ac} + \frac{a}{c} E_2(\rho'_0) + \frac{c}{a} E_2(\sigma'_0) \right)
\times \frac{1}{\eta^{24}(\rho'_0)} \frac{1}{\eta^{24}(\sigma'_0)} e^{\frac{\pi}{n_2} \frac{m|\tau|^{2+n-\ell_{\tau_1}}}{\tau_2}},
\]

where the phase \( \varphi \) reads

\[
\varphi = \frac{2}{n_2} \left( -\frac{1}{2} j \ell - m_1 n + n_1 m \right).
\]

To this, we add the total derivative term

\[
\int_{\Gamma_2} d\tau_2 \frac{d}{d\tau_2} \left( \int_{\Gamma_1} d\tau_1 R(\tau_1, \tau_2) \right),
\]

with

\[
R(\tau_1, \tau_2) = \frac{i}{\pi} \sum_P \sum_{\Sigma \in \mathbb{Z}/|ac|\mathbb{Z}} e^{i\pi \varphi} \left( -1 \right)^{\ell+1} \frac{1}{\gamma (2iac)^{13}} \frac{1}{\tau_2^{13}} \frac{1}{\eta^{24}(\rho'_0)} \frac{1}{\eta^{24}(\sigma'_0)} e^{\frac{\pi}{n_2} \frac{m|\tau|^{2+n-\ell_{\tau_1}}}{\tau_2}},
\]

(2.30)

(2.31)

to obtain

\[
d(m, n, \ell)_{\Delta > 0} = \sum_P \sum_{\Sigma \in \mathbb{Z}/|ac|\mathbb{Z}} \left\{ e^{i\pi \varphi} \left( -1 \right)^{\ell+1} \frac{\gamma}{(ac)^{13}} \int \frac{d\tau \wedge d\bar{\tau}}{C(\tau - \bar{\tau})^{14}}
\times \left( 26 + \frac{2\pi}{n_2} \frac{m|\tau|^{2+n-\ell_{\tau_1}}}{\tau_2} \right)
\times \frac{1}{\eta^{24}(\rho'_0)} \frac{1}{\eta^{24}(\sigma'_0)} e^{\frac{\pi}{n_2} \frac{m|\tau|^{2+n-\ell_{\tau_1}}}{\tau_2}} \right\}
\]

\[
+i(1-2\delta) \int_{\Gamma_2} d\tau_2 R \left( \tau_1 = \frac{\ell}{2m} + i\tau_2(1-2\delta), \tau_2 \right)
\]

(2.32)

Next, let us analyse the last two terms in (2.32). We focus on the term

\[
\int_{\Gamma_2} d\tau_2 R \left( \tau_1 = \frac{\ell}{2m} + i\tau_2(1-2\delta), \tau_2 \right) = \frac{i}{\pi} \sum_P \sum_{\Sigma \in \mathbb{Z}/|ac|\mathbb{Z}} e^{i\pi \varphi} \left( -1 \right)^{\ell+1} \frac{\gamma}{(2iac)^{13}}
\times \int_{\Gamma_2} \frac{d\tau_2}{\tau_2^{1+\delta}} \frac{1}{\eta^{24}(\rho'_0)} \frac{1}{\eta^{24}(\sigma'_0)} e^{\frac{\pi}{n_2} \frac{\Delta_{\tau_2} + 4m\tau_2 \delta(1-\delta)}}
\]

(2.33)
\[ \rho_0' = -\frac{a}{c\gamma} \left( \frac{\ell}{2m} + 2i\tau_2(1-\delta) \right) - \frac{1}{c} \left( \frac{b\alpha}{\gamma} + a\Sigma \right), \]  
\[ \sigma_0' = \frac{c}{a\gamma} \left( \frac{\ell}{2m} - 2i\tau_2\delta \right) + \frac{1}{a} \left( \frac{d\alpha}{\gamma} - c\Sigma \right). \]

Let us perform a saddle point analysis of the integral in (2.33). Taking \( \text{Im}\, \tau_2 \) to be large, and using the approximation

\[ \frac{1}{\eta^{24}(\rho_0')} \frac{1}{\eta^{24}(\sigma_0')} \approx e^{-2\pi i (\rho_0' + \sigma_0')}, \]

we obtain for the saddle point value of \( \tau_2 \),

\[ \tau_{2\text{extr}} = \frac{\sqrt{\Delta}}{\sqrt{16m (|a|^2(1-\delta) + |c|^2\delta + m\delta(1-\delta))}}. \]

For the case \( n_2 = 1 \), and setting \( \delta = 0 \), this becomes

\[ \tau_{2\text{extr}} = \sqrt{\frac{\Delta}{16m}}, \]

which, when inserted back into (2.33), shows that the summand on the right-hand side behaves as \( e^{2\pi \sqrt{\Delta/m}} \) in a saddle point approximation. This is an exponentially suppressed contribution that can be dropped in the semi-classical expansion, as it does not scale with the charges. A similar argument applies to the last two terms of (2.32). Since in Sect. 2.3 we will be interested in the semi-classical analysis of dyonic single-centred BPS black holes whose classical entropy scales quadratically in the charges, we will ignore these terms in what follows.

Finally, let us show that the integrated total derivative term (2.30) vanishes,

\[ \int_{\Gamma_2} \frac{d}{d\tau_2} \left( \int_{\Gamma_1} d\tau_1 R(\tau_1, \tau_2) \right) = \frac{i}{\pi} \sum_{P} \sum_{\Sigma \in \mathbb{Z}/|ac|\mathbb{Z}} e^{i\pi \varphi \left( \frac{(-1)^{\ell+1}}{\gamma(2i\alpha c \gamma)_{13}} (G_{n_2}(\varepsilon + i\infty) - G_{n_2}(\varepsilon - i\infty)) \right)}, \]

where

\[ G_{n_2}(\tau_2) = \frac{2i}{\tau_{2\text{extr}}^2} e^{\frac{4\pi \Delta \tau_2}{\pi n_2\tau_{2\text{extr}} \sqrt{\varepsilon^2 + t^2}}} e^{\frac{\pi \varepsilon \tau_2}{\pi n_2}} e^{\frac{\pi \tau_2}{\pi n_2 \varepsilon^2}} M(t), \]

Let us estimate \( |G_{n_2}(\tau_2)| \) using Darboux’s inequality,

\[ |G_{n_2}(\varepsilon + it)| \leq \frac{2}{(\varepsilon^2 + t^2)^6} e^{\frac{\pi \Delta \tau_2}{\pi n_2 \sqrt{\varepsilon^2 + t^2}}} e^{\frac{\pi \varepsilon \tau_2}{\pi n_2}} M(t), \]

\[ M(t) = \int_{\delta}^{1-\delta} dy \left| \frac{1}{\eta^{24}(\rho_0')} \frac{1}{\eta^{24}(\sigma_0')} \right|. \]

Note that \( M(t) \) is finite due to the regulator \( \delta \), and that it stays finite for arbitrary values of \( t \), i.e. \( M(t) \leq M \ \forall t \in \mathbb{R} \). Therefore, \( |G_{n_2}(\varepsilon \pm i\infty)| = 0 \), and hence \( G_{n_2}(\varepsilon \pm i\infty) = 0 \). Thus, we have established the equivalence of the
Rademacher and ‘covariant’ forms (2.4) and (2.6), respectively, up to exponentially suppressed corrections. In Sect. 5, we will give a physical motivation for adding the total derivative term to (2.21) and working with the covariant expression of the degeneracies, which allows for an interpretation involving 2D Euclidean wormholes.

Note that in the ‘covariant’ expression (2.6) the measure factor
\[
26 + \frac{2\pi}{n_2^2} m|\tau|^2 + n -\ell \tau_1
\]
does not carry any dependence on \(\Sigma\), and that the dependence of the integrand on the \(SL(2, \mathbb{Z})\) parameters of (2.5) is solely contained in the combination \(n_2 = -ac\gamma\), cf. (2.9).

### 2.3. Semi-classical Expansions

We established that the expression for the microstate degeneracies (2.28) is equal to the expression (2.6) (up to the exponentially suppressed contributions just discussed) which we reproduce here for convenience,

\[
d(m, n, \ell)_{\Delta>0} = \sum_P \sum_{\Sigma \in \mathbb{Z}/|ac|\mathbb{Z}} \frac{e^{i\pi \varphi}}{2i\pi} \frac{(-1)^{\ell+1}}{\gamma (ac)^{13}} \int_C \frac{d\tau \wedge d\bar{\tau}}{(\tau - \bar{\tau})^{14}} \\
\times \left(26 + \frac{2\pi}{n_2^2} m|\tau|^2 + n -\ell \tau_1\right) \frac{1}{\eta^{24}(\rho'_0)} \frac{1}{\eta^{24}(\sigma'_0)} e^{\frac{\pi}{n_2} m|\tau|^2 + n -\ell \tau_1},
\]

where
\[
\rho'_0 = -a \frac{\tau}{c} - b \frac{\alpha}{\gamma} - a \frac{\Sigma}{c},
\]
\[
\sigma'_0 = c \frac{\bar{\tau}}{a} + d \frac{\alpha}{\gamma} + c \frac{\Sigma}{a}.\tag{2.42}
\]

Let us consider the integrand of (2.41). Both the measure and the exponent are given in terms of the combination
\[
\frac{\pi}{n_2^2} m|\tau|^2 + n -\ell \tau_1,
\]
which, upon substituting the tree-level saddle point value for \(\tau\), is equal to
\[
\frac{S_{\text{BH}}}{n_2} = \frac{\pi \sqrt{\Delta}}{n_2},
\]

where \(S_{\text{BH}}\) denotes the Bekenstein–Hawking entropy of a BPS black hole carrying charge bilinears \((m, n, \ell)\) at the two-derivative level. Note that despite the presence of the combination (2.43) in the measure of (2.41), no contribution proportional to \(\log S_{\text{BH}}\) arises when evaluating the integral (2.41) in saddle point approximation [9]. When \(n_2 = 1\), the associated quantum entropy function space-time background is \(\text{AdS}_2 \times S^2\), while when \(n_2 > 1\), the associated space-time background has been argued to be a freely acting \(\mathbb{Z}_{n_2}\) orbifold of an \(\text{AdS}_2 \times S^2\) background [9–12]. We note at this stage that the order \(n_2\) of the orbifold is a composite integer given by \(n_2 = -ac\gamma\). Moreover, the orbifold background is supported by electric and magnetic gauge potentials \((A_I^\theta, \tilde{A}_{\theta I})\) whose values depend on the integers introduced in (2.9). There are therefore several sectors in (2.41) that are labelled by different integers but have the
same order $n_2$. We will discuss these orbifold backgrounds in more detail in Sect. 3, in conjunction with S-duality.

To facilitate the discussion about the space-time interpretation of (2.28) and (2.41), it is useful to first infer semi-classical expressions for $\log d(m, n, \ell)$ by extremizing the integrand of either expressions. Both extremizations give identical results, and we will choose to extremize the latter since the analysis is less involved. We will first extremize the terms in the exponent of (2.41), and subsequently consider the extremization problem in the presence of the $\eta^{24}$ terms.

For subsequent use, we recall that the evaluation of (2.28) results in an exact expression for the degeneracies $d(m, n, \ell)$ in terms of a fine-grained Rademacher expansion that involves Kloosterman sums and modified Bessel functions of the first kind [5]. This exact expression, given in equation (5.118) of [5], is rather lengthy and will not be reproduced here. For our semi-classical analysis it will be sufficient to focus on the first line of this result since, in the large $\Delta$ limit, the remaining terms are exponentially suppressed. Here, we simply recall that this part of the exact degeneracies involves modified Bessel functions $I_{23/2}(z)$, with $z = \pi \sqrt{\Delta |\tilde{\Delta}|/(\gamma m)}$, as well as the generalized Kloosterman sum

$$Kl\left(\frac{\Delta}{4m^2}, \frac{\tilde{\Delta}}{4m^2}, \gamma, \psi\right)_{\ell\tilde{\ell}} = \sum_{0 \leq -\delta < \gamma \atop (\delta, \gamma) = 1, \alpha \delta = 1 \mod \gamma} e^{2\pi i \left(\frac{\alpha \delta}{4m} + \frac{\delta}{4m}\right)} \tilde{\psi}(\Gamma)_{\ell\tilde{\ell}},$$

(2.45)

where

$$\Delta = 4mn - \ell^2 > 0, \quad \tilde{\Delta} = 4m\tilde{n} - \tilde{\ell}^2 < 0. \quad (2.46)$$

2.3.1. Extremization Without log $\eta$ Terms. Let us consider the terms in the exponent of (2.41),

$$f_0(\tau, \bar{\tau}) = \frac{\pi}{n_2} \frac{m|\tau|^2 + n - \ell \tau_1}{\tau_2} + i\pi \varphi, \quad (2.47)$$

where we recall that the phase $\varphi$ is given by (2.29). Extremizing with respect to $\tau$ yields

$$\tau_\ast = \frac{\ell}{2m} + i\frac{\sqrt{\Delta}}{2m}. \quad (2.48)$$

At this extremum, (2.47) takes the value

$$f_0(\tau_\ast, \bar{\tau}_\ast) = \pi \left[ \frac{\sqrt{\Delta}}{n_2} - \frac{i}{n_2} (ad + bc)\ell + 2i\frac{\delta}{\gamma} \frac{\delta}{\gamma} + 2i\frac{\alpha bd}{\gamma ac} m + 2im\frac{\Sigma}{ac} \right]. \quad (2.49)$$
which we can write as

$$f_0(\tau_*, \bar{\tau}_*) = \pi \left[ \frac{\sqrt{\Delta}}{n_2} + \frac{2i}{n_2} \left( -\frac{1}{2} j\ell - m_1 n + n_1 m \right) \right],$$

(2.50)

using (2.9). We thus reproduce the semi-classical result for \( \log d(m, n, \ell) \) obtained in [9,11,29] as expected.

Next, we determine the values of \((\rho, \sigma, v)\) at the extremum, which we will denote by \((\rho_*, \sigma_*, v_*)\). Using

$$\rho = \frac{\alpha}{\gamma} \left( d^2 \rho_0' + b^2 \sigma_0' + 2bd\Sigma \right) + \Sigma^2 - \rho_0' \sigma_0',$$

$$\sigma = -\frac{\delta}{\gamma} + \frac{1}{\gamma^2} X_2,$$

$$v = \frac{cd\rho_0' + ab\sigma_0' + (ad + bc)\Sigma}{\gamma X_2},$$

$$\gamma\sigma + \delta = \frac{1}{\gamma X_2},$$

as well as (2.18) and (2.48), we obtain

$$\rho_* = -\frac{n_1}{n_2} + i \frac{n}{n_2 \sqrt{\Delta}},$$

$$\sigma_* = \frac{m_1}{n_2} + i \frac{m}{n_2 \sqrt{\Delta}},$$

$$v_* = \frac{j}{2n_2} - i \frac{\ell}{n_2 \sqrt{\Delta}}.$$

(2.52)

This reproduces the result for \((\rho_*, \sigma_*, v_*)\) obtained in [11], apart from a sign difference in \(\text{Im } v_*\).

**2.3.2. Extremization with log \(\eta\) Terms.** Next, we consider the extremization of the terms in the exponent in (2.41), but this time also taking into account the \(\eta^{24}\) terms in (2.41). This will result in a change of the saddle point value of \(\tau\) given in (2.48).

We take the imaginary part of \(\tau\) to be large and use the approximation

$$\frac{1}{\eta^{24}(\rho_0')} \frac{1}{\eta^{24}(\sigma_0')} \approx e^{-2\pi i (\rho_0' + \sigma_0')}.$$

(2.53)

We thus extremize the function

$$f(\tau, \bar{\tau}) = -2\pi i (\rho_0' + \sigma_0') + \pi \frac{m|\tau|^2 + n - \ell \tau_1}{n_2 \tau_2} + i\pi \varphi$$

(2.54)

with respect to \(\tau\) and \(\bar{\tau}\) using the expressions (2.18). This results in the following two equations:

$$a^2(\tau - \bar{\tau})^2 + m\bar{\tau}^2 - \ell \bar{\tau} + n = 0,$$

$$c^2(\tau - \bar{\tau})^2 + m\tau^2 - \ell \tau + n = 0,$$

(2.55)
which are solved by
\[ \tau_{\text{extr}} = \frac{\ell}{2m} + i \frac{\sqrt{\Delta}}{2m} \frac{m + a^2 - c^2}{\sqrt{(m + (a - c)^2)(m + (a + c)^2)}}, \]
\[ \bar{\tau}_{\text{extr}} = \frac{\ell}{2m} - i \frac{\sqrt{\Delta}}{2m} \frac{m - a^2 + c^2}{\sqrt{(m + (a - c)^2)(m + (a + c)^2)}}, \]
where we choose the appropriate signs so that (2.56) reduces to (2.48) when switching off the terms proportional to \(a^2\) and \(c^2\). Note that when \(a^2 \neq c^2\), the saddle point values \(\tau_{\text{extr}}\) and \(\bar{\tau}_{\text{extr}}\) are not any longer complex conjugates of one another.

In the following, let us consider the case \(a = -c = 1, b = 0, d = 1\). The saddle point value is then
\[ \tau_{\text{extr}} = \frac{\ell}{2m} + i \frac{\sqrt{\Delta}}{2\sqrt{(m + 4)m}}, \]
which reproduces the \(R^2\)-corrected attractor value for \(\tau\) at leading order [30].

Next, we evaluate the value of (2.54) at the saddle point. Exponentiating the resulting expression gives
\[ e^{f(\tau_{\text{extr}}, \bar{\tau}_{\text{extr}})} = e^{2\pi i \left( \frac{n}{\gamma} - \frac{a}{\gamma} - \frac{\ell}{\gamma} \right) + \frac{\pi}{\gamma} \sqrt{\Delta \frac{\bar{\Delta} n^2}{4m}}}. \]
Comparing with (2.49), we note the presence of the additional \(R^2\) induced phase \(\alpha\) stemming from the terms (2.53).

We observe that the exponent in (2.58) corresponds to the term \(\tilde{n} = -1, \tilde{\ell} = m\) in the Rademacher expression given in (5.118) of [5], in which case \(\tilde{\Delta} = 4mn - \tilde{\ell}^2 = -m(4 + m)\). The real part of the exponent yields Wald’s \(R^2\) corrected entropy [30] divided by \(\gamma\). The imaginary part of the exponent matches the exponent in the Kloosterman sum (2.45)
\[ \frac{\delta}{\gamma} \frac{\Delta}{4m} + \frac{\alpha}{\gamma} \frac{\bar{\Delta}}{4m} + \frac{\alpha (\tilde{\ell} - 2mT)^2}{4m} - \frac{\ell(\tilde{\ell} - 2mT)}{2m\gamma} + \frac{\delta \ell^2}{4m} \]
\[ = \frac{\delta}{\gamma} n + \frac{\alpha}{\gamma} \left( \tilde{n} - \tilde{\ell}T + mT^2 \right) - \frac{\ell(\tilde{\ell} - 2mT)}{2m\gamma}, \]
for
\[ \tilde{n} = -1, \quad \tilde{\ell} = m, \quad T = 0. \]
Note that the \(R^2\) induced phase \(\alpha\) is crucial to obtain this matching.

As mentioned above, the exact expression for the microstate degeneracies \(d(m, n, \ell)\) involves modified Bessel functions \(I_{23/2}(z)\), with \(z = \pi \sqrt{\Delta|\bar{\Delta}|/(\gamma m)}\). Note that \(z\) has a dependency on \(1/\gamma\), not on \(1/n_2\). On the other hand, the saddle point result (2.50), when exponentiated, gives an expression whose modulus is \(e^{\pi \sqrt{\Delta}/n_2}\). One may then wonder how these two seemingly differently looking expressions are related. To do so, we proceed as follows. The quantity \(\Delta\) in (2.46) can be expressed in terms of integers \(M, N\) as [5]
\[ \Delta = \frac{1}{a^2 c^2} \left[ -(a^2 M - c^2 N)^2 - (m^2 - 2m(a^2 M + c^2 N)) \right], \]
where $M, N$ satisfy the bounds
\[ -m < a^2 M - c^2 N \leq m, \quad a^2 M + c^2 N \leq m. \] (2.62)
Taking $m$ to be large, and restricting to integers $M, N$ such that the following holds:
\[ |a^2 M - c^2 N| \ll m, \quad |a^2 M + c^2 N| \ll m, \] (2.63)
we find that $\tilde{\Delta}$ is approximately given by
\[ |\tilde{\Delta}| \approx \frac{m^2}{(ac)^2}, \] (2.64)
in which case $z$ becomes
\[ z = \frac{\pi \sqrt{\Delta}}{n_2}, \] (2.65)
so that to leading order,
\[ I_{23/2}(z) \approx e^{\frac{\pi \sqrt{\Delta}}{n_2}}. \] (2.66)
Note that the set of integers $M, N$ satisfying (2.63) is finite. This is a consequence of demanding that $\tilde{\Delta} < 0$ as well as of the continued fraction condition stated in [5].

3. Orbifolds of AdS$_2$ and S-Duality

The microscopic result (2.41) suggests that its semi-classical interpretation in terms of sums over space-time backgrounds involves freely acting $\mathbb{Z}_{n_2}$ orbifolds of an AdS$_2 \times S^2$ background [9,11,12,31], as we mentioned in Sect. 2.3.

In Euclidean space-time, a freely acting $\mathbb{Z}_{n_2}$ orbifold background is described by the following Euclidean line element [9,11,12,31]:
\[ ds^2 = v_*( (r^2 - 1)d\theta^2 + \frac{dr^2}{r^2 - 1} + d\psi^2 + \sin^2 \psi \, d\phi^2 ) + \frac{2\pi}{n_2}, \quad \phi \approx \phi + \frac{2\pi}{n_2}, \] (3.1)
and by gauge potentials $A_I^\theta$ that acquire a constant real part when orbifolding,
\[ A_I^\theta = -ie_\ast^I (r - 1) \, d\theta + \text{Re} A_I^\theta. \] (3.2)
Likewise, the dual gauge potentials $\tilde{A}_{\theta I}$ also acquire a constant real part when orbifolding.

In the following, we will determine the real part of the gauge potentials that support these orbifolds in the context of $N = 2$ theories, by resorting to S-duality and viewing it as a symplectic transformation acting on the symplectic vector that comprises the gauge potentials in these $N = 2$ theories. We will thereby show that $(\text{Re} A_I^\theta, \text{Re} \tilde{A}_{\theta I})$ depend on the integers $m_1, n_1, j$ introduced in (2.9). Recall that the order of the orbifold is given by $n_2 = -ac\gamma$. Hence, we slightly abuse the notation when denoting these orbifolds as $\mathbb{Z}_{n_2}$ and it
is important to keep in mind that the geometry and the supporting gauge potentials depend on the integers \(m_1, n_1\) and \(j\) in addition to \(n_2\).

We obtained the saddle point action (2.50) by extremizing the combination (2.47) that appears in the exponent of (2.41). Following [9, 11, 12, 31], we will regard (2.50) as the saddle point action of a \(\mathbb{Z}_{n_2}\) orbifold background. If we write this action as

\[
\pi \left[ \sqrt{\Delta} + i \left( q \cdot \text{Re} A_\theta - p \cdot \text{Re} \tilde{A}_\theta \right) \right],
\]

(3.3)

then the question is what are the constant real parts of the gauge potentials \((A_\theta, \tilde{A}_\theta)\) that support the orbifold background.

To address this question, we will use an \(N = 2\) language, label the gauge potentials as \((A_I^{\theta}, \tilde{A}_I^{\theta})\), where \(I = 0, 1, \ldots, n\), and consider a specific \(N = 2\) model.

### 3.1. Gauge Potentials and S-Duality

We consider the following \(N = 2\) model,

\[
F(Y) = -Y^1 Y^a \eta_{ab} Y^b / Y^0, \quad a = 2, \ldots, n
\]

(3.5)

where \(\eta_{ab}\) is a constant symmetric matrix. For the moment, we work with a type II tree-level prepotential and will discuss the effect of adding loop corrections below. We denote the electric–magnetic charges in the type IIA basis by \((q_I, p_I),\) while in the heterotic basis they will be denoted by \(Q_I, P_I\). Both sets are related as follows:

\[
Q_I = (q_0, p_1^I, q_a), \quad P_I = (p_0^I, -q_0^I, p_a^I).
\]

(3.6)

The charge bilinears \((m, n, \ell)\) are expressed as follows in terms of the charges [30],

\[
m = P_I O_{IJ} P^J = p_0^I q_1 + p_a^I \eta_{ab} p_b^I,
\]

\[
n = Q_I M^{IJ} Q_J = -q_0^I p_1 + 1/4 q_a^I \eta_{ab} q_b^I,
\]

\[
\ell = Q_I P^I = q_0^I p_0^I - q_1^I p_1^I + q_a p_a^I,
\]

(3.7)

where we introduced the constant matrices

\[
M^{IJ} = \begin{pmatrix} 0 & -1/2 & -1/2 \\ -1/2 & 0 & 1/2 \eta_{ab} \\ 1/2 & 0 & \eta_{ab} \end{pmatrix}, \quad O_{IJ} = \begin{pmatrix} 0 & -1/2 & -1/2 \\ -1/2 & 0 & \eta_{ab} \\ 0 & \eta_{ab} & 0 \end{pmatrix}.
\]

(3.8)

In the following, we work in the type IIA basis, and we define the constant real parts of the gauge potentials \((A_I^{\theta}, \tilde{A}_I^{\theta})\) to be

\[
\text{Re} A_0^{\theta} = 2m_1 p_1^I - j p_0^I,
\]

\[
\text{Re} A_1^{\theta} = 2n_1 p_0^I + j p_1^I,
\]

\[
\text{Re} A_a^{\theta} = -1/2 m_1 \eta_{ab} q_b^I - 1/2 j p_a^I.
\]
\[ \begin{align*}
\text{Re} \tilde{A}_{\theta} &= 0 , \\
\text{Re} \tilde{A}_{\theta 1} &= 0 , \\
\text{Re} \tilde{A}_{\theta a} &= -2n_1 \eta_{ab} p^b + \frac{1}{2} jq_a .
\end{align*} \tag{3.9} \]

Note that these expressions depend on the integers \((m_1, n_1, j)\), but not on the integers \(n_2\) and \(m_2\). One readily verifies that

\[ q_I \text{Re} A^I_{\theta} - p^I \text{Re} \tilde{A}_{\theta I} = -j \ell - 2m_1 n + 2n_1 m , \tag{3.10} \]

in accordance with the saddle point expression (3.4).

We claim that the gauge potentials \((A^I_{\theta}, \tilde{A}^I_{\theta})\) defined by (3.9) transform as a symplectic vector under S-duality. Let us first consider the action of the T-generator of S-duality on the charges \((q_I, p^I)\), which is represented by the \(SL(2, \mathbb{Z})\) matrix

\[ \begin{pmatrix} 1 & s \\ 0 & 1 \end{pmatrix} , \quad s \in \mathbb{Z} , \tag{3.11} \]

and results in the transformation law (see, for instance, Eq. 3.6 in [32])

\[ \begin{align*}
p^0 &\to p^0 , \\
p^1 &\to p^1 + sp^0 , \\
p^a &\to p^a , \\
q_0 &\to q_0 - sq_1 , \\
q_1 &\to q_1 , \\
q_a &\to q_a - 2s \eta_{ab} p^b .
\end{align*} \tag{3.12} \]

The gauge potentials \((A^I_{\theta}, \tilde{A}^I_{\theta})\) defined by (3.9) should transform precisely in the same manner as the charges \((q_I, p^I)\), i.e.

\[ \begin{align*}
\text{Re} A^0_{\theta} &\to \text{Re} A^0_{\theta} , \\
\text{Re} A^1_{\theta} &\to \text{Re} A^1_{\theta} + s \text{Re} A^0_{\theta} , \\
\text{Re} \tilde{A}_{\theta 0} &\to \text{Re} \tilde{A}_{\theta 0} - s \text{Re} \tilde{A}_{\theta 1} , \\
\text{Re} \tilde{A}_{\theta 1} &\to \text{Re} \tilde{A}_{\theta 1} , \\
\text{Re} \tilde{A}_{\theta a} &\to \text{Re} \tilde{A}_{\theta a} - 2s \eta_{ab} \text{Re} A^b_{\theta} .
\end{align*} \tag{3.13} \]

To verify the transformation behaviour (3.13) under the action of the T-generator of S-duality, we need to determine the transformation behaviour of the quantities that enter in (3.13). The charge bilinears \((m, n, \ell)\) transform as follows:

\[ \begin{align*}
m &\to m , \\
n &\to n - s \ell + s^2 m , \\
\ell &\to \ell - 2s m .
\end{align*} \tag{3.14} \]

The invariance of the microscopic result (2.41) under the transformation (3.14) is implemented by demanding the following transformation of the integers \((m_1, n_1, m_2, n_2, j)\):

\[ \begin{align*}
m_1 &\to m_1 , \\
n_1 &\to n_1 - sj - s^2 m_1 , \\
j &\to j + 2sm_1 , \\
m_2 &\to m_2 , \\
n_2 &\to n_2 .
\end{align*} \tag{3.15} \]

With this at hand, it is straightforward to check that the real parts of the gauge potentials (3.9) indeed transform as in (3.13). Owing to the symplectic product structure, this immediately implies that (3.3) is invariant under (3.14) and (3.15). Note that the transformation (3.15) leaves the locus (2.7) invariant.
when supplemented by the action\(^2\) of the T-generator on the triplet \((\rho, \sigma, v)\). We will return to the invariance of the microscopic result (2.41) under the action of the T-generator below.

Next, let us consider the action of the S-generator of S-duality on the charges \((q_I, p^I)\), which is represented by the \(SL(2, \mathbb{Z})\) matrix

\[
\begin{pmatrix}
0 & 1 \\
-1 & 0
\end{pmatrix},
\]

(3.16)

and results in (see, for instance, Eq. 3.6 in [32])

\[
\begin{align*}
p^0 & \rightarrow -p^1, \quad p^1 \rightarrow p^0, \quad p^a \rightarrow \frac{1}{2} \eta^{ab} q_b, \\
q_0 & \rightarrow -q_1, \quad q_1 \rightarrow q_0, \quad q_a \rightarrow -2 \eta_{ab} p^b.
\end{align*}
\]

(3.17)

The gauge potentials \((A^I_\theta, \tilde{A}_{\theta I})\) defined by (3.9) should transform precisely in the same manner as the charges \((q_I, p^I)\), i.e.

\[
\begin{align*}
\text{Re} A^0_\theta & \rightarrow -\text{Re} A^1_\theta, \quad \text{Re} A^1_\theta \rightarrow \text{Re} A^0_\theta, \quad \text{Re} A^a_\theta \rightarrow \frac{1}{2} \eta^{ab} \text{Re} \tilde{A}_{\theta b}, \\
\text{Re} \tilde{A}_{\theta 0} & \rightarrow -\text{Re} \tilde{A}_{\theta 1}, \quad \text{Re} \tilde{A}_{\theta 1} \rightarrow \text{Re} \tilde{A}_{\theta 0}, \quad \text{Re} \tilde{A}_{\theta a} \rightarrow -2 \eta_{ab} \text{Re} A^b_\theta.
\end{align*}
\]

(3.18)

To verify the transformation behaviour (3.18) under the action of the S-generator of S-duality, we need to determine the transformation behaviour of the quantities that enter in (3.18). The charge bilinears \((m, n, \ell)\) transform as follows:

\[
\begin{align*}
m & \rightarrow n, \quad n \rightarrow m, \quad \ell \rightarrow -\ell.
\end{align*}
\]

(3.19)

Demanding that the integers \((m_1, n_1, j)\) transform as

\[
\begin{align*}
m_1 & \leftrightarrow -n_1, \quad j \rightarrow -j,
\end{align*}
\]

(3.20)

we establish the transformation behaviour (3.18) under the action of the S-generator of S-duality. Observe that if we further supplement (3.19) with the transformation law

\[
\begin{align*}
m_2 & \rightarrow m_2, \quad n_2 \rightarrow n_2,
\end{align*}
\]

(3.21)

then the combined transformation (3.20) and (3.21) leaves the locus (2.7) invariant, provided also that \(\rho \leftrightarrow \sigma\) and \(v \rightarrow -v\). The latter correctly implements the action of the S-generator on the triplet \((\rho, \sigma, v)\), cf. footnote 2.

Thus, we have shown that the real parts of the gauge potentials \((A^I_\theta, \tilde{A}_{\theta I})\) given in (3.9) transform as a symplectic vector under S-duality, and that their symplectic product with the charge vector \((q_I, p^I)\) yields the correct invariant expected from the saddle point expression (3.4).

\(^2\)Under an S-duality transformation \((a b \quad c d) \in SL(2, \mathbb{Z})\), the vector \(\begin{pmatrix} v \\ \sigma \end{pmatrix}\) transforms as

\[
\begin{pmatrix} v \\ \sigma \end{pmatrix} \rightarrow M \begin{pmatrix} v \\ \sigma \end{pmatrix}, \quad \text{where} \quad M = \begin{pmatrix}
ad + bc & -bd & -ac \\
-2cd & a^2 & c^2 \\
-2ab & b^2 & a^2
\end{pmatrix}.
\]
Finally, let us display the expressions for the gauge potentials (3.9) for the case when $a = 1, c = -1, d = 1, b = 0, \Sigma = 0$, in which case the parameters $(m_1, n_1, m_2, n_2, j)$ given in (2.9) take the values $(-\delta, 0, 0, \gamma, 1)$. Then,

\[
\begin{align*}
\text{Re} A^0_\theta &= -2\delta p^1 - p^0, \\
\text{Re} A^1_\theta &= p^1, \\
\text{Re} A^a_\theta &= \frac{1}{2} \delta \eta^{ab} q_b - \frac{1}{2} p^a, \\
\text{Re} \tilde{A}_{\theta 0} &= 0, \\
\text{Re} \tilde{A}_{\theta 1} &= 0, \\
\text{Re} \tilde{A}_{\theta a} &= \frac{1}{2} q_a,
\end{align*}
\]

and (3.4) is given by

\[
q \cdot \text{Re} A_\theta - p \cdot \text{Re} \tilde{A}_\theta = -\ell + 2\delta n. \tag{3.23}
\]

Including loop corrections to the $N = 2$ prepotential (3.5) does not modify the discussion of S-duality above. It will, however, affect the result of the extremization (3.3). If we include a one-loop correction of the form

\[
F(Y) = -\frac{Y^1 Y^a \eta_{ab} Y^b}{Y^0} - \frac{i}{2\pi} \log \eta^{24} \left(\frac{Y^1 Y^0}{Y^0}\right), \tag{3.24}
\]

then the value of (3.3) will be modified according to Sect. 2.3.2. For the case when $a = 1, c = -1, d = 1, b = 0, \Sigma = 0$, the loop corrections to (3.3) will read

\[
\frac{\pi}{\gamma} \left[ \sqrt{\frac{m + 4}{m}} \sqrt{\Delta} + i \left( q \cdot \text{Re} A_\theta - p \cdot \text{Re} \tilde{A}_\theta \right) - 2i\alpha \right]. \tag{3.25}
\]

Comparing with the extremization result (2.58) that was obtained by taking into account the presence of the $\eta^{24}$ terms in (2.41), we see that the saddle point value receives contributions from the symplectic product of the real parts of the gauge potentials with the charge vector (3.23), and from the loop corrections to the $N = 2$ prepotential.

\subsection*{3.2. Invariance Under the T-Generator}

Let us now show that the microscopic result (2.32) is invariant under the T-transformation (3.14) of the charge bilinears $(m, n, \ell)$. Using (2.29), the exponents in (2.32) are invariant under the combined transformation (3.14) and (3.15) when supplemented by the transformation

\[
\tau \rightarrow \tau - s, \tag{3.26}
\]

which is the reflection of the T-generator action on the variables $\rho, \sigma, v$ after we have integrated over $\rho$ by residue. The transformation (3.26) also leaves the $\tau$-contour of integration (2.23) invariant, since the shift

\[
\frac{\ell}{2m} \rightarrow \frac{\ell}{2m} - s \tag{3.27}
\]
induced by (3.14) gets compensated by the shift in \( \tau_1 \). The invariance of the contour arises from our initial choice of a charge-dependent contour (2.3), as in [23].

Since (2.32) involves a sum over the integers in the set (2.5) as well as over \( \Sigma \), we also need their transformation properties under the action of the T-generator. Their transformation properties should be such that, when using the expressions (2.9), they result in the transformation (3.15). The following set of transformations achieves this: the Greek entries \( \alpha, \beta, \gamma, \delta \) are inert under the action of the T-generator, while the Latin entries \( a, b, c, d \) transform as

\[
\begin{pmatrix} a & b \\ c & d \end{pmatrix} \rightarrow \begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} 1 & \delta s \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} a & b + a\delta s \\ c & d + c\delta s \end{pmatrix},
\]

(3.28)

and \( \Sigma \) transforms as

\[
\Sigma \rightarrow \Sigma - \beta(ad + bc)s - \beta\delta acs^2.
\]

(3.29)

Using these expressions as well as (2.18), we obtain for the transformation behaviour of \( \rho'_0 \) and \( \sigma'_0 \),

\[
\rho'_0 \rightarrow \rho'_0 + 2ab\beta s + a^2\beta\delta s^2,
\]

\[
\sigma'_0 \rightarrow \sigma'_0 + 2cd\beta s + c^2\beta\delta s^2,
\]

(3.30)

where the shifts are integer valued, so that

\[
\eta^{24}(\rho'_0) \eta^{24}(\sigma'_0) \rightarrow \eta^{24}(\rho'_0) \eta^{24}(\sigma'_0).
\]

(3.31)

Note that \( a, c \) and the Greek entries \( \alpha, \beta, \gamma, \delta \) are inert under the action of the T-generator. Now consider a fixed sector \( (a, c, \alpha, \beta, \gamma, \delta) \): the only independent integers that transform are \( b \in \mathbb{Z} \) and \( \Sigma \in \mathbb{Z} / |ac| \mathbb{Z} \). For a given \( s \), the integer \( b \) transforms by a uniform shift \( a\delta s \), and hence we have a bijection from \( \mathbb{Z} \) into \( \mathbb{Z} \) in a given sector \( (a, c, \alpha, \beta, \gamma, \delta) \). The transformation law of \( \Sigma \) is also an integer shift which also depends on \( b \). The prescribed order of summation [5], first \( \Sigma \) then \( b \), implies that the transformation of \( \Sigma \) is 1-to-1 and therefore the sum is invariant.

More generally, we may infer the transformation law of the 9 integers \( \alpha, \beta, \gamma, \delta, a, b, c, d, \Sigma \) under general S-duality transformations from the transformation law of the 5 integers \( m_1, n_1, m_2, n_2, j \) under the T-generator and the S-generator by ‘inverting’ the relations (2.9), as follows. Recall that \( a > 0, c < 0, \gamma > 0 \). We use the following gcd rules,

\[
gcd(n_2, 0) = n_2 > 0, \quad \gcd(-ac, -a) = a > 0, \quad \gcd(-ac, c) = -c > 0.
\]

(3.32)

Since \( n_2 \neq 0 \), we have \( \gcd(n_2, -m_1) \neq 0 \). Using the expressions (2.9) and recalling that \( \gcd(\gamma, \delta) = 1 \), we infer the relations

\[
-ac = \gcd(n_2, -m_1),
\]

(3.33)
as well as

\[ \gamma = \frac{n_2}{\gcd(n_2, -m_1)}, \]
\[ \delta = -\frac{m_1}{\gcd(n_2, -m_1)}. \]  

(3.34)

Since \( \alpha \in \mathbb{Z}/\gamma \mathbb{Z} \), (3.34) uniquely specifies \( \alpha \) and \( \beta \) in terms of \( n_2 \) and \( m_1 \) via the relation \( \alpha \delta - \beta \gamma = 1 \).

Using (3.33), and recalling the relation \( j = 1 + 2bc \), we obtain

\[ c = -\gcd\left( \frac{\gcd(n_2, -m_1), \frac{j - 1}{2}}{2} \right), \]  

(3.35)

as well as

\[ a = \frac{\gcd(n_2, -m_1)}{\gcd(\gcd(n_2, -m_1), \frac{j - 1}{2})}. \]  

(3.36)

Using the relation (2.8) together with \( j = 1 + 2bc = 2ad - 1 \), we infer that \( m_1 n_1 + m_2 n_2 = abcd \), and hence

\[ bd = \frac{1 - j^2}{4 \gcd(n_2, -m_1)}, \]  

(3.37)

from which it follows that

\[ d = \gcd\left(\frac{1 - j^2}{4 \gcd(n_2, -m_1)}, \frac{j + 1}{2}\right), \]  

(3.38)

and hence

\[ b = \frac{1 - j^2}{4 \gcd(n_2, -m_1)} \cdot \frac{1 - j^2}{4 \gcd(n_2, -m_1)}, \]  

(3.39)

Finally, coming back to (2.9), \( \Sigma \) can be expressed as

\[ \Sigma = -\frac{n_1 + bd\alpha}{\gamma}. \]  

(3.40)

Using the map worked out above, this shows that \( \Sigma \) can be written in terms of the 4 integers \( n_1, m_1, n_2 \) and \( j \). Thus, the 9 integers \( \alpha, \beta, \gamma, \delta, a, b, c, d, \Sigma \) can be expressed purely in terms of \( m_1, n_1, n_2, j \). Note that this map does not involve the fifth integer \( m_2 \). This observation will be relevant for the analysis of the quantum entropy function below.

Let us then verify that the T-transformation (3.15), when combined with (3.29), reproduces the transformation law (3.28) and keeps the Greek entries \( \alpha, \beta, \gamma, \delta \) inert. It follows immediately from (3.34), (3.33) and (3.37) that

\[ \gamma \rightarrow \gamma, \quad \delta \rightarrow \delta, \quad \alpha \rightarrow \alpha, \]
\[ \beta \rightarrow \beta, \quad ac \rightarrow ac, \quad bd \rightarrow bd + j \delta s + ac s^2. \]  

(3.41)
Thus, the Greek entries $\alpha, \beta, \gamma, \delta$ are indeed invariant under the T-transformation. Introducing the notation
\[
q = \gcd\left(\gcd(n_2, -m_1), \frac{j - 1}{2}\right),
\]
\[
q' = \gcd\left(\gcd(n_2, -m_1), \frac{j - 1}{2} + m_1 s\right),
\]
we obtain that under the T-transformation,
\[
a = \frac{\gcd(n_2, -m_1)}{q} \rightarrow a' = \frac{\gcd(n_2, -m_1)}{q'} = a\frac{q}{q'},
\]
i.e. $aq = a'q'$. From (3.42), any prime factor of $q$ divides $\gcd(n_2, -m_1)$ and $\frac{j - 1}{2}$ and therefore is a prime factor of $q'$. Similarly, every prime factor of $q'$ divides $q$, and hence $q = q'$. This shows that $a$ does not transform. It then follows from $ac \rightarrow ac$ that also $c$ is invariant.

Next, using that under the T-transformation,
\[
ad = \frac{1}{2}(j + 1) \rightarrow ad + m_1 s,
\]
and dividing by $a > 0$, we obtain
\[
d \rightarrow d + \frac{m_1}{a}s = d + c\delta s.
\]
Likewise, using (3.44), we infer
\[
bc = j - ad \rightarrow bc + m_1 s,
\]
and dividing by $c$, we obtain
\[
b \rightarrow b + m_1 c s = d + a\delta s.
\]
This reproduces the transformation of the Latin entries given in (3.28). We also observe that, using $n_1 + \gamma \Sigma = -bd\alpha$ and $m_2 + \delta \Sigma = -bd\beta$, the integer $\Sigma$ can be written as
\[
\Sigma = n_1 \beta - m_2 \alpha,
\]
which shows that the T-transformation of $n_1$ induces the transformation given in (3.29).

We do not test the invariance of the microscopic expression (2.32) under the S-generator of the S-duality group, because the microscopic expression (2.32) is guaranteed to equal the $\frac{1}{4}$ BPS single-centred degeneracy only for $n \geq m$ [3].

4. The Quantum Entropy Function
In this section, we relate the quantum entropy function for single-centred four-dimensional $\frac{1}{4}$ BPS black holes in toroidally compactified string theory to the microscopic degeneracy formula (2.4). To do so, we set up the quantum entropy function in the $N = 2$ formalism, review some of its salient features, and then we specialize to the $N = 4$ case.
We consider $N = 2$ supergravity theories in four dimensions, describing the coupling of $n_V$ $N = 2$ vector multiplets and of $n_H$ $N = 2$ hypermultiplets to $N = 2$ supergravity in the presence of Weyl square interactions. For later use, we introduce
\[ \chi = 2(n_V - n_H + 1). \] (4.1)

The quantum entropy function $W$ is defined [8,33] as a path integral with a Wilson line insertion in a class of four-dimensional Euclidean backgrounds $B$. Thus, $W = \sum_B W_B$ where $W_B$ denotes the functional integral, with suitable boundary conditions imposed, over all fields in string theory in the space-time background $B$. The backgrounds in question are backgrounds that asymptote to a specific AdS$_2 \times$ S$^2$ solution fixed by the attractor mechanism [34–36]. The latter is supported by Abelian gauge fields as well as constant scalar fields. The class of backgrounds we will consider comprises Euclidean AdS$_2 \times$ S$^2$ space-times and orbifolds thereof [9,11,12,31]. Further, the fields in the functional integral are required to asymptote to values consistent with the specific attractor AdS$_2 \times$ S$^2$ background in question.

For four-dimensional BPS black holes in the $N = 2$ supergravity theories mentioned above, supersymmetric localization reduces the $N = 2$ quantum entropy function $W_1(q,p)$ to a finite-dimensional integral of the form [9,37–39]
\[ W_1(q,p) = N \int_C d\phi \mu(\phi,p) Z_{1-\text{loop}}(\phi) e^{\pi[4 \text{Im}F(\phi+ip) - q \cdot \phi]}, \] (4.2)
where $q \cdot \phi = q_I \phi^I$, with $I = 0, \ldots, n_V$. The normalization $N$ is not fixed by localization but should be determined by either computing the expectation value of the identity operator, i.e. without the Wilson line insertion, or by comparison with the microscopic degeneracies. Here, $W_1$ denotes the functional integral over all fields in string theory in an Euclidean background described by an AdS$_2 \times$ S$^2$ space-time, with the fields subjected to the boundary conditions mentioned above. The localization manifold is labelled by $n_V + 1$ parameters $\{\phi^I\}$. Note that the integral in (4.2) requires specifying a contour $C$. The measure $\mu(\phi)$ arises as a result of the localization procedure implemented on the field configuration space. The term $Z_{1-\text{loop}}(\phi)$ denotes the one-loop determinant over non-BPS directions orthogonal to the localization locus and receives contributions from bulk modes as well as large diffeomorphisms [40]. The function $F$ entering in (4.2) is the holomorphic function $F(Y, \Upsilon)$ that defines the $N = 2$ Wilsonian effective action. It depends on complex scalar fields $Y^I$ and $\Upsilon$. The latter resides in a scalar chiral multiplet associated with the Weyl multiplet. $F(\phi + ip)$ and $F(Y, \Upsilon)$ are related by
\[ F(\phi + ip) = F\left( Y = \frac{1}{2}(\phi + ip), \Upsilon = -64 \right). \] (4.3)
For later use, we define the quantity
\[ e^{-\mathcal{K}} = i \left( \bar{Y}^I F_I - Y^I \bar{F}_I \right), \] (4.4)
where $F_I = \partial F(Y, \Upsilon)/\partial Y^I$.

The 1-loop determinant factor $Z_{1-\text{loop}}$ around localizing backgrounds consisting of $Z_{n_2}$ orbifolds of AdS$_2 \times$ S$^2$ has been determined very recently
in [40] and shown to receive contributions from both bulk modes as well as large diffeomorphisms. For $N = 2$ supergravity theories based on $n_V$ vector multiplets and $n_H$ hypermultiplets, the contribution to $Z_{1\text{-loop}}$ from the bulk modes is given by

$$Z_{N=2 \text{bulk}}^{N=2} = e^{-\frac{n_2 \chi}{24} (i\pi - 2\log n_2 - 24\zeta'(-1))} e^{-(1 - n_2 \chi) K},$$

(4.5)

while the contribution from large diffeomorphisms is

$$Z_{N=2 \text{bdry}}^{N=2} = \frac{1}{n_2} e^{-K}.$$

(4.6)

Thus, we infer that in $N = 2$ supergravity theories, $Z_{1\text{-loop}}$ is given by

$$Z_{N=2}^{1\text{-loop}} = \frac{1}{n_2} e^{-\frac{n_2 \chi}{24} (i\pi - 2\log n_2 - 24\zeta'(-1))} e^{-(2 - n_2 \chi) K}.$$

(4.7)

When $n_2 = 1$, which corresponds to the unorbifolded case, $Z_{1\text{-loop}}$ takes the form given earlier in [41–43] (up to the pure constant that can be absorbed in the normalization of the path integral). On the other hand, for $N = 4$ supergravity theories with $N_V = 4$ vector multiplets, the contribution to $Z_{1\text{-loop}}$ from the bulk modes is given by [40]

$$Z_{N=4 \text{bulk}}^{N=4} = e^K,$$

(4.8)

which is independent of the number of $N = 4$ vector multiplets, while the contribution from large diffeomorphisms is the same as in $N = 2$ theories and given by

$$Z_{N=4 \text{bdry}}^{N=4} = \frac{1}{n_2} e^{-K}.$$

(4.9)

Thus, for $N = 4$ supergravity theories, $Z_{1\text{-loop}}$ is given by

$$Z_{N=4}^{1\text{-loop}} = \frac{1}{n_2} e^{-\chi K}.$$

(4.10)

Finally, for $N = 8$ supergravity, $Z_{1\text{-loop}}$ is given by [40]

$$Z_{N=8}^{1\text{-loop}} = \frac{1}{n_2} e^{4K}.$$

(4.11)

We note that, if we set $n_2 = 1$ and if we evaluate $K$ on the BPS attractor at the two-derivative level, in which case $e^{-K}|_* = \frac{A}{4\pi G_N}$, the exponent in $Z_{1\text{-loop}}$ precisely yields the logarithmic area correction to the BPS black hole entropy [44,45],

$$S = \frac{A}{4G_N} + \# \log \frac{A}{G_N},$$

(4.12)

where

$$\# = \begin{cases} 
-4 & N = 8, \\
0 & N = 4, \\
2 - \frac{\chi}{24} & N = 2.
\end{cases} \quad (4.13)
$$

Let us now turn to the measure $\mu$ in (4.2). A proposal for the approximate form of the measure $\mu$ was given in [32,46] using arguments based on symplectic covariance. A different argument in favour of this proposal was given in [47]
and is related to the logarithmic corrections (4.13), as follows. Let us denote the exponent in (4.2) by
\[
H(\phi, p, q) = 4 \text{Im} F(\phi + ip) - q \cdot \phi ,
\]
and consider its extremization,
\[
\frac{\partial H(\phi, p, q)}{\partial \phi^I} = 0 .
\] (4.15)

Let us assume that for a given set of black hole charges \((q_I, p^I)\) there exists only one non-inflective critical point \(\phi^*\), corresponding to BPS attractor values such that \(H(\phi^*, p, q) > 0\). Expanding \(H(\phi, p, q)\) around the critical point \(\phi^*\), we obtain
\[
H(\phi, p, q) = H(\phi^*, p, q) + \frac{1}{2} \frac{\partial^2 H}{\partial \phi^I \partial \phi^J} \bigg|_{\phi^*} \delta \phi^I \delta \phi^J + \mathcal{O}((\delta \phi)^3) ,
\]
\[
= H(\phi^*, p, q) + \frac{1}{2} \frac{\partial^2 (4 \text{Im} F)}{\partial \phi^I \partial \phi^J} \bigg|_{\phi^*} \delta \phi^I \delta \phi^J + \mathcal{O}((\delta \phi)^3) .
\] (4.16)

This equals
\[
H(\phi, p, q) = H(\phi^*, p, q) + \frac{1}{2} \text{Im} F_{IJ} \bigg|_{\phi^*} \delta \phi^I \delta \phi^J + \mathcal{O}((\delta \phi)^3) ,
\]
\[
= H(\phi^*, p, q) + \frac{1}{2} \text{Im} F_{IJ} \bigg|_{\phi^*} \delta \phi^I \delta \phi^J + \mathcal{O}((\delta \phi)^3) .
\] (4.17)

where \(F_{IJ} = \partial^2 F/\partial Y^I \partial Y^J\). Next, we evaluate (4.2) by taking \(\mu Z_{1-\text{loop}}\) at the attractor point (4.15) and by integrating over the fluctuations \(\delta \phi^I \in \mathbb{C}\) in Gaussian approximation,
\[
W_1(q, p) \approx N \left( \frac{\mu Z_{1-\text{loop}}}{\sqrt{\det \text{Im} F_{KL}}} \right) \bigg|_{\phi^*} e^{\pi H(\phi^*, p, q)} .
\] (4.18)

For this to reproduce the logarithmic corrections in (4.13), \(\mu\) has to be proportional to \(\sqrt{\det \text{Im} F_{KL}}\).

The proposal
\[
\mu = \sqrt{\det \text{Im} F_{KL}} ,
\]
(4.19)
is based on the \(N = 2\) Wilsonian action, which is encoded in a holomorphic function \(F\). However, as also discussed in \([32,46]\), one needs to allow for the inclusion of non-holomorphic terms that are necessary to ensure that quantities such as \(H\) in (4.14) are invariant under duality symmetries. A systematic way to incorporate these non-holomorphic terms is provided by the framework of deformed special geometry \([48]\), which is based on a non-holomorphic function \(\hat{F}(Y, \bar{Y}, T, \bar{T}) = F(Y, \bar{Y}) + 2i \Omega(Y, \bar{Y}, T, \bar{T})\), where \(\Omega\) is a real function that is homogeneous of second degree. The non-holomorphic terms are encoded in \(\Omega\). The presence of \(\Omega\) leads to various modifications of (4.19), as discussed in \([32,46]\) and reviewed in \([47]\). One such modification is that (4.19) becomes multiplied by \(e^{4\pi \Omega}\). Based on these arguments, we will take \(\sqrt{\det \text{Im} F_{KL}} e^{4\pi \Omega}\) as a candidate for the measure in the quantum entropy function for \(1\) BPS black holes in \(N = 4\) heterotic string theory below. Note that the proposal for the measure in \([46]\) (cf. (4.6) in that paper) involves additional terms that we will drop in the \(N = 4\) context.
Let us now discuss the $N = 4$ supergravity theory obtained from compactifying heterotic string theory on a six-dimensional torus. The resulting supergravity theory is based on the $N = 4$ gravity multiplet as well as on $N_V = 22$ $N = 4$ vector multiplets. The $N = 4$ gravity multiplet contains 6 Abelian gauge fields as well as 2 real scalar fields that make up the axio-dilaton, while each of the $22 N = 4$ vector multiplets contains 1 Abelian gauge field as well as 6 real scalar fields. There are thus $28 = 6 + 22$ Abelian gauge fields in total. We will use an $N = 2$ description of this $N = 4$ supergravity theory and discuss the quantum entropy function for this theory using an $N = 2$ language. As emphasized in [40], all the $N = 2$ multiplets that arise in the decomposition of the $N = 4$ multiplets have to be taken into account when determining $Z_{\text{1-loop}}$. An $N = 4$ vector multiplet is decomposed into one $N = 2$ vector multiplet and one $N = 2$ hypermultiplet. In the context of BPS black holes, the complex scalar fields residing in the $N = 2$ vector multiplets are subjected to the attractor mechanism, while those residing in the hypermultiplets are set to arbitrary constant values. On the localizing manifold, the former give rise to the coordinates $\{\phi^a, a = 2, \ldots, 23\}$, while the latter remain fixed to a constant off-shell and do not affect the localization locus. The $N = 4$ gravity multiplet decomposes into the $N = 2$ gravity multiplet, two $N = 2$ spin-$\tfrac{3}{2}$ multiplets and one $N = 2$ vector multiplet. An $N = 2$ spin-$\tfrac{3}{2}$ multiplet contains 2 Abelian gauge fields. We will switch off the charges associated with the 4 Abelian gauge fields residing in the $N = 2$ spin-$\tfrac{3}{2}$ multiplets, that is, we will only retain the electric–magnetic charges $(q_I, p^I)$ where $I = 0, \ldots, 23$, associated to the 24 Abelian gauge fields that reside in the $N = 2$ gravity multiplet and in the $N_V + 1 = 23$ $N = 2$ vector multiplets that arise in the above decomposition. Likewise, we will retain the 24 complex scalar fields $Y^I$ that reside in the $N = 2$ vector multiplets and that are subjected to the attractor mechanism. The associated $N = 2$ holomorphic function $F(Y, \Upsilon)$ takes the form

$$F(Y, \Upsilon) = F^{(0)}(Y) + 2i \omega(Y, \Upsilon),$$

$$F^{(0)}(Y) = - \frac{Y^1 Y^a \eta_{ab} Y^b}{Y^0}, \quad \omega(Y, \Upsilon) = \frac{1}{256\pi} \Upsilon \log \eta^{24}(iS), \quad S = -i \frac{Y^1}{Y^0},$$

(4.20)

where $a = 2, \ldots, 23$ and $\eta_{ab}$ is a constant symmetric matrix. On the other hand, the real function $\Omega$ takes the form

$$4\pi \Omega(Y, \bar{Y}) = - \log(S + \bar{S})^{12}.$$  

(4.21)

Evaluating the candidate measure using, for example, (4.11) in [46] gives

$$\sqrt{|\det \text{Im} F_{KL}}| e^{4\pi \Omega} = \sqrt{|\det [-\eta_{ab}]|} \frac{\sqrt{e^{-2\kappa} - 4|\eta^{24}(iS)|}}{2|Y^0|^2 (S + \bar{S})^2} \sqrt{e^{-2\kappa} - 4|\eta^{24}(iS)|} D_S \partial_S \Omega|_{\text{2}}^2,$$

(4.22)

where $D_S \partial_S \Omega = \partial_S^2 \Omega + 2(S + \bar{S})^{-1} \partial_S \Omega$. In [46], this candidate measure was derived starting from a symplectic invariant measure and further imposing the magnetic attractor equations to change variables as $dY^I d\bar{F}_I \rightarrow \ldots$
\[ dY^I \sqrt{|\det \text{Im} F_{K,L}|} e^{4\pi \Omega}. \] However, the choice of this measure is only defined up to a symplectic invariant function. In order to match with the microscopic counting, we should choose an appropriate such function whose net effect is to produce a measure that retains only the first term under the square root in (4.22). Hence, our proposal for the measure \( \mu \) in the quantum entropy function of \( \frac{1}{4} \) BPS black holes in toroidally compactified heterotic string theory is

\[
\mu = \frac{\sqrt{|\det[-\eta_{ab}]|}}{2|Y^0|^2(S + \bar{S})^2} e^{-\kappa}, \tag{4.23}
\]

where we are instructed to set \( Y^I = \frac{1}{2}(\phi^I + i p^I) \) and \( Y = -64 \).

Using the \( N = 4, n_2 = 1 \) result \( Z_{1\text{-loop}} = 1 \) given in (4.10), we obtain

\[
W_1(q,p) = \mathcal{N} \int_C d\phi \tilde{\mu}_1 e^{\pi[4 \text{Im} F^{(0)}(\phi + ip) - q \cdot \phi]}, \tag{4.24}
\]

where

\[
\tilde{\mu}_1 = \frac{\sqrt{|\det[-\eta_{ab}]|}}{2|Y^0|^2(S + \bar{S})^2} e^{-\kappa} \frac{1}{\eta^{24}(iS)\eta^{24}(i\bar{S})}. \tag{4.25}
\]

Note that the exponent in (4.24) is given in terms of \( F^{(0)} \), so that we regard the \( \eta^{24} \) terms as being part of the measure. This point of view will be justified below when we consider the dependence of the integrand in (4.24) on the axio-dilaton \( S \).

The exponent in (4.24) admits an immediate generalization to the case when the background is a \( \mathbb{Z}_{n_2} \) orbifold of the AdS_2 \times S^2 space-time described by the Euclidean metric (3.1). On the orbifold, we expect

\[
4 \text{Im} F^{(0)}(\phi + ip) - q \cdot \phi \rightarrow \frac{1}{n_2} \left[ 4 \text{Im} F^{(0)}(\phi + ip) - q \cdot \phi + i \left( q \cdot \text{Re} A_\theta - p \cdot \text{Re} \tilde{A}_\theta \right) \right], \tag{4.26}
\]

where \( (\text{Re} A_\theta, \text{Re} \tilde{A}_\theta) \) denote the constant real parts of the gauge potentials \( (A_\theta, \tilde{A}_\theta) \) that are induced by the orbifold action, as described in Sect. 3. The orbifold action will also affect the one-loop determinant and the measure factor, cf. (4.10). The net effect will be a change of \( \tilde{\mu}_1 \) in (4.24) to a new measure

\[
\tilde{\mu}_1 \rightarrow \tilde{\mu}_{n_2}, \tag{4.27}
\]

whose form will be inferred from the microscopic expression (2.41) shortly. Now recall that a \( \mathbb{Z}_{n_2} \) orbifold is supported by gauge potentials (3.9) that depend on the integers \( m_1, n_1, j \). The orbifold is therefore labelled by the 4 integers \( m_1, n_1, n_2, j \), and we will denote its contribution to the quantum entropy function by \( W_{n_2;m_1,n_1,j}(q,p) \) with

\[
W_{n_2;m_1,n_1,j}(q,p) = (-1)^j \mathcal{N} \int_C d\phi \tilde{\mu}_{n_2} e^{\pi^2 [4 \text{Im} F^{(0)}(\phi + ip) - q \cdot \phi + i(q \cdot \text{Re} A_\theta - p \cdot \text{Re} \tilde{A}_\theta)]}, \tag{4.28}
\]

Our chosen normalization ensures that the unorbifolded case corresponding to \( n_2 = 1, m_1 = n_1 = 0, j = 1 \) reduces to (4.24), i.e. \( W_{1;0,0,1} = W_1 \). Once the
orbifold contributions are computed, one should sum over all $W_{n_2;m_1,n_1,j}$ to obtain the degeneracies from the quantum entropy function.

We now proceed with the evaluation of $W_{n_2;m_1,n_1,j}$ by integrating out the scalar fields $\phi^a$. We will first focus on $W_1$ given in (4.24). Since the factor $e^{-K}$ in $\tilde{\mu}_1$ depends on these scalar fields, the integration cannot be performed exactly. We approximate the result by evaluating $e^{-K}$ on the saddle point values for the $\phi^a$, obtained by extremizing the exponent in (4.24).

4.1. The Quantum Entropy Function on $\text{AdS}_2 \times S^2$

The saddle point values of the $\phi^I$ are obtained by solving the attractor equations

$$4 \frac{\partial}{\partial \phi^I} \text{Im} F^{(0)}(\phi + ip) = q_I.$$  (4.29)

Solving for $\phi^a$ with $a = 2, \ldots, 23$ we obtain the following saddle point values:

$$\phi^a_* = \frac{1}{S + \bar{S}} (\eta^{ab} q_b + i(S - \bar{S}) p^a),$$  (4.30)

where $\eta^{ab} \eta_{bc} = \delta^a_c$. This yields the saddle point values $Y^a_* = \frac{1}{2} (\phi^a_* + ip^a)$. Hence, we obtain

$$e^{-K}|_* = \frac{1}{|Y^0|^2(S + \bar{S})} \left( (p^0)^2 n + (p^1)^2 m + p^0 p^1 \ell \right)$$

$$+ 2|Y^0|^2(S + \bar{S}) \left( \frac{\partial_S \omega}{(Y^0)^2} + \frac{\partial_{\bar{S}} \bar{\omega}}{(Y^0)^2} \right),$$  (4.31)

where the charge bilinears are given by (3.7).

Next, we rewrite $Y^0$ as [46]

$$Y^0 = \frac{1}{2} (\phi^0 + ip^0) = \frac{p^1 + i\bar{S} p^0}{S + \bar{S}},$$  (4.32)

so that

$$e^{-K}|_* = \frac{(S + \bar{S})}{|p^1 + i\bar{S} p^0|^2} \left( (p^0)^2 n + (p^1)^2 m + p^0 p^1 \ell \right)$$

$$+ 2|p^1 + i\bar{S} p^0|^2(S + \bar{S}) \left( \frac{\partial_S \omega}{(p^1 + i\bar{S} p^0)^2} + \frac{\partial_{\bar{S}} \bar{\omega}}{(p^1 - i\bar{S} p^0)^2} \right).$$  (4.33)

From now on, to simplify the resulting expressions, we set

$$p^0 = 0.$$  (4.34)

We will therefore work with the following saddle point expressions:

$$e^{-K}|_* = (S + \bar{S}) \left( m + 2 \partial_S \omega + 2 \partial_{\bar{S}} \bar{\omega} \right),$$

$$\tilde{\mu}_1|_* = \sqrt{\left| \det[-\eta_{ab}] \right|} \frac{m + 2 \partial_S \omega + 2 \partial_{\bar{S}} \bar{\omega}}{2|Y^0|^2(S + \bar{S}) \eta^{24}(iS) \eta^{24}(i\bar{S})}.$$  (4.35)

Then, setting $\tau = i\bar{S} = \tau_1 + i\tau_2$ and changing variables as

$$d\phi^0 \wedge d\phi^1 = -2i \frac{|Y^0|^2}{\tau_2} d\tau \wedge d\bar{\tau},$$  (4.36)
we obtain
\[ d\phi^0 \wedge d\phi^1 \mid_{\tau} = -\frac{i}{\sqrt{2}} d\tau \wedge d\bar{\tau} \sqrt{|\det[\eta]_{ab}|} \frac{m + E_2(\tau) + E_2(-\bar{\tau})}{\eta^{24}(\tau) \eta^{24}(-\bar{\tau})}, \quad (4.37) \]

where
\[ E_2(\tau) = \frac{1}{2\pi i} \frac{d}{d\tau} \log \eta^{24}(\tau). \quad (4.38) \]

Note that the dependence on \(|Y^0|^2\) has cancelled out, and hence so has the dependence on \(p^1\). Under this change of variables, the contour \(C\) also changes, but for notational simplicity we will denote the new contour also by \(C\).

Thus, using the approximate expression (4.35) for the measure, we obtain the following approximate expression for the quantum entropy function contribution \(W_1\) in the \(N = 4\) setting,
\[ W_1(q, p) = -N \frac{i}{2} \sqrt{|\det[\eta]_{ab}|} \int_C d\phi^a \frac{m + E_2(\tau) + E_2(-\bar{\tau})}{\eta^{24}(\tau) \eta^{24}(-\bar{\tau})} e^{\pi[4 \Im F^{(0)}(\phi + ip) - q \cdot \phi]}. \quad (4.39) \]

Next, using the expression for \(F^{(0)}\) given in (4.20), we integrate out the \(\phi^a\) in (4.39) \((a = 2, \ldots, 23)\), which are Gaussian integrals. Each \(\phi^a\) integral yields a factor
\[ \frac{1}{\sqrt{\tau_2}}, \quad (4.40) \]

and we obtain
\[ W_1(q, p) = 2^{12} N \int_C d\tau \wedge d\bar{\tau} \frac{m + E_2(\tau) + E_2(-\bar{\tau})}{\eta^{24}(\tau) \eta^{24}(-\bar{\tau})} e^{\frac{\pi}{\tau_2}(n - \ell \tau_1 + m|\tau|^2)} \quad (4.41) \]

where the contour \(C\) now describes a contour in \((\tau_1, \tau_2)\)-space.

We now compare (4.41) with the microscopic result \((2.21)\). The condition \(n_2 = 1\) implies \(a = -c = d = 1, b = 0, -\beta = \gamma = 1, \alpha = \delta = 0, \Sigma = 0\) (cf. \((2.5)\)), and hence \(m_1 = n_1 = m_2 = 0, j = 1\). Both expressions agree provided we set \(N = 2^{-12}\), as already observed in [28].

This agreement is remarkable, for the following reason. The \(N = 2\) measure (4.22) was obtained in [46] from a symplectic principle and imposing the magnetic attractor equations. We then further approximate 24 of the remaining integrals by setting 22 scalars at their saddle point values, which leads us to the measure (4.35) depending only on \(S\) and \(\bar{S}\). It would be very interesting to understand how such a measure arises from first principles in an \(N = 4\) setting.

By comparison, the contour \(C\) in (4.41) is determined to be the contour \(\hat{C}\) which then microscopically specifies a complex integration contour for \((\phi^0, \phi^1)\). This microscopic data have not been determined directly by the supergravity localization procedure, and it would be valuable to do so in the future. On this contour, \(W_1\) can be brought to the form (2.41) by adding a total derivative term, as discussed in Sect. 2.2. Neglecting the exponentially suppressed
contributions that are encoded in \( R \), cf. (2.32), the resulting expression reads

\[
W_1(q,p) = \frac{1}{2\pi i} \frac{1}{2^{12}} \int \frac{d\tau \wedge d\bar{\tau}}{(\tau - \bar{\tau})^2} \left( 26 + 2\pi \frac{m|\tau|^2 + n - \ell_1}{\tau_2} \right) e^{\pi i[4\text{Im}\hat{F}(\phi + ip) - q \cdot \phi]|_{\phi_0^2}},
\]

(4.42)

where the \( \phi^a \) are evaluated on the attractor value (4.30), and where we introduced the non-holomorphic function [49]

\[
\hat{F}(Y, \bar{Y}) = -\frac{Y^1 Y^a \eta_{ab} Y^b}{Y^0} - \frac{3i}{\pi} \log \left( |\eta^2(\tau)|^2 \tau_2 \right), \quad \tau = \frac{Y^1}{Y^0}.
\]

(4.43)

This corresponds to a deformation of \( F^{(0)} \) by a non-holomorphic term \( \Psi(\tau, \bar{\tau}) = \log \left( |\eta^2(\tau)|^2 \tau_2 \right) \) and is an example of deformed special geometry [48].

The saddle point evaluation of (4.42) yields the semi-classical entropy

\[
\left[ \pi \left( 4 \text{Im} F^{(0)}(\phi + ip) - q \cdot \phi \right) - 12 \log \left( |\eta^2(\tau)|^2 \tau_2 \right) \right]_*,
\]

(4.44)

which is the Wald entropy corrected by a non-holomorphic term [49].

Note that while in the above we assumed that \( p^0 = 0 \) when deriving \( W_1 \), the microscopic result (2.21) is, of course, also valid when \( p^0 \neq 0 \).

4.2. The Quantum Entropy Function on Orbifolds of \( \text{AdS}_2 \times S^2 \)

Next, we turn to \( W_{n_2;m_1,n_1,j} \) given in (4.28). We integrate out the \( \phi^a \) in saddle point approximation, as was done for \( W_1 \). Each \( \phi^a \) integral now yields a factor

\[
\frac{\sqrt{n_2}}{\sqrt{\tau_2}}.
\]

(4.45)

Then, using (4.36) as well as (3.4), we obtain (using the normalization \( \mathcal{N} \) and contour \( \hat{C} \) determined above from \( W_1 \))

\[
W_{n_2;m_1,n_1,j}(q,p) = 2i \frac{(-1)^\ell n_2^{11}}{\sqrt{\text{det}[-\eta_{ab}]} \int \frac{d\tau \wedge d\bar{\tau}}{(\tau - \bar{\tau})^2}} \left[ Y^0 \right]^{12} \tilde{\mu}_{n_2} |^* \times e^{\pi i[|n - \ell_1 + m| \tau^2 + 2i(-\frac{1}{2} \ell m + n + n_1 m)]},
\]

(4.46)

where \( \tilde{\mu}_{n_2} |^* \) denotes the measure \( \tilde{\mu}_{n_2} \) evaluated on the saddle point values \( \phi_0^a \) given in (4.30). We now compare (4.46) with the microscopic result (2.21). The comparison shows that the macroscopic result is more naturally expressed in terms of the 9 integers \( \alpha, \beta, \gamma, \delta, a, b, c, d \) and \( \Sigma \) that are subject to the constraints displayed in (2.5), as

\[
\tilde{\mu}_{n_2} |^* = \frac{\gamma^{12}}{n_2^{25}} \frac{\sqrt{\text{det}[-\eta_{ab}]} \left[ m + a^2 E_2(\rho_0') + c^2 E_2(\sigma_0') \right]}{2|Y^0|^2 (S + S)} \frac{m + a^2 E_2(\rho_0') + c^2 E_2(\sigma_0')}{\eta^{24}(\rho_0') \eta^{12}(\sigma_0')},
\]

(4.47)

although, as discussed in Sect. 3.2, this can be equivalently formulated in terms of the 4 integers \( m_1, n_1, n_2 \) and \( j \). The expression (4.47) reduces to the one for \( \tilde{\mu}_1 |^* \) given in (4.35). To account for the factor \( \frac{\gamma^{12}}{n_2^{25}} \) in (4.47), we write it as

\[
\frac{1}{n_2 \left( n_2 ac \right)^{12}}.
\]

(4.48)
The first factor $\frac{1}{n_2}$ is accounted for by the expression for $Z_{1\text{-}\text{loop}}$ (4.10). The second factor can be accounted for by returning to the candidate measure $\sqrt{\left| \det \text{Im}F_{KL} \right|} e^{4\pi \Omega}$ discussed above and replacing it by

$$\sqrt{\left| \text{Im}F_{KL} \right|_{n_2}} e^{4\pi \Omega}. \quad (4.49)$$

This is similar to what was proposed very recently in [40] in the context of the quantum entropy function for $\frac{1}{8}$ BPS black holes in $\mathcal{N} = 8$ supergravity. However, our $\mathcal{N} = 4$ story is more involved, as the orbifold saddle points are labelled by 4 integers. It is striking that these four numbers are all that is needed to write down the quantum entropy function, including the measure $\mu_{n_2}$. This points to the fact that the orbifolds labelled by $m_1, n_1, n_2$ and $j$ are sufficient to capture the wall-crossing phenomenon from the supergravity path integral, although it is clear we do not have a first principle understanding of the specific combinations of integers that enter (4.47), especially through the quantities $\rho'_0$ and $\sigma'_0$.

Adding a total derivative, and neglecting the exponentially suppressed contributions that are encoded in $R$ (cf. (2.32)), we can write (4.46) as

$$W_{n_2; m_1, n_1, j}(q, p) = e^{i\pi \varphi} \frac{(-1)^\ell}{\gamma} \frac{4\pi (2iac)^{13}}{\epsilon} \int \frac{d\tau \wedge d\bar{\tau}}{\tau_2^2} \left( \frac{26 + 2\pi m |\tau|^2 - \ell \tau_1 + n}{\tau_2} \right) \times e^{\frac{n_2}{|\varphi|}} [4\text{Im} F(0)(\phi + ip - q \cdot \phi)]^{\varphi} - 12 \log (\eta^2(\rho'_0)\eta^2(\sigma'_0)\tau_2), \quad (4.50)$$

where $\varphi$ is given in (2.29). The expression (4.50) is well suited to provide an alternative gravitational description based on 2D Euclidean wormholes. We expand on this in the next section.

5. **Wormhole Interpretation**

We return to the Euclidean line element (3.1) and bring the two-dimensional part

$$ds^2 = v_*(r^2 - 1)d\theta^2 + \frac{dr^2}{r^2 - 1}, \quad \theta \equiv \theta + \frac{2\pi}{n_2}, \quad r > 1, \quad (5.1)$$

to the form (5.6). This can be done as follows [50]. First, by performing the rescaling $r \to n_2 \, r$ and $\theta \to \theta/n_2$ [12], the line element (5.1) becomes

$$ds^2 = v_* (r^2 - s^2)d\theta^2 + \frac{dr^2}{r^2 - s^2}, \quad \theta \equiv \theta + 2\pi, \quad s = \frac{1}{n_2}. \quad (5.2)$$

Next, defining

$$\rho = \frac{1}{2s} \log \frac{r + s}{r - s}, \quad \rho > 0, \quad (5.3)$$

we obtain

$$ds^2 = v_* \frac{s^2}{\sinh^2(s\rho)} (d\theta^2 + d\rho^2), \quad \theta \equiv \theta + 2\pi, \quad \rho > 0. \quad (5.4)$$
Next, using the map \[50\]
\[\tan \left( \frac{s}{2} \left( \sigma + iT \right) \right) = \tanh \left( \frac{s}{2} \left( \rho + i\theta \right) \right) \] (5.5)
with \(-\pi < s\sigma < 0\) and \(-\infty < T < \infty\), we obtain the line element
\[ds^2 = v_s \frac{s^2}{\sin^2(s\sigma)} \left( dT^2 + d\sigma^2 \right), \quad -\pi < s\sigma < 0, \quad -\infty < T < \infty, \quad s = \frac{1}{n_2}. \] (5.6)

When \(s = 1\), this line element describes a strip of width \(\pi\) that represents global AdS2.

Both line elements (5.1) and (5.6), together with a constant dilaton \(\Phi_0 = \frac{1}{8\pi G_N^{(2)}}\), are solutions of 2D Euclidean JT gravity. The appearance of this theory can be understood from a dimensional reduction of the 4D theory as follows. As explained in [33], the near-horizon geometry (3.1) (and its two-dimensional counterpart (5.1)) relevant for the quantum entropy function is obtained by considering the near-horizon near-extremal limit of a non-extremal 4D black hole. In the near-horizon region and close to extremality, we can consider the reduction of the 4D gravity theory on a two-sphere whose size is given by a linear perturbation \(\Phi\) around the extremal value \(v_*\). This perturbation plays the role of the dilaton in the effective 2D theory, and the action after dimensional reduction is, to first order in \(\Phi\), given by [51]
\[S_{JT} = -\frac{1}{8\pi G_N^{(2)}} \left[ \frac{1}{2} \int_M d^2x \sqrt{g} R + \int_{\partial M} dt \sqrt{h} K \right] - \frac{1}{2} \int_M d^2x \sqrt{g} \Phi \left( R + \frac{2}{v_*} \right) \]
\[\quad - \int_{\partial M} dt \sqrt{h} \Phi \left( K - \frac{1}{\sqrt{v_*}} \right), \] (5.7)
where \(K\) is the extrinsic curvature of the manifold \(M\) and \(h\) is the induced metric on the boundary \(\partial M\). Evaluating this action on the orbifolded disc geometry (5.1) gives
\[-I_{JT} = -\frac{1}{4n_2 G_N^{(2)}} \], (5.8)
while the on-shell action of the orbifolded strip with line element (5.6) vanishes. This shows that the Bekenstein–Hawking entropy of the 4D black hole is recovered by the orbifolded disc geometry as
\[-I_{JT} = \frac{2\pi}{n_2} \Phi_0 = \frac{\pi v_*}{n_2 G_N^{(4)}}, \] (5.9)
where we used the KK relation \(1/G_N^{(2)} = \text{vol}(S^2)/G_N^{(4)} = 4\pi v_/G_N^{(4)}\) to relate the 2D and 4D Newton constants. The contribution to the path integral from the geometry (5.6) is suppressed since it has vanishing Euler characteristic. Observe that the entropy (5.9) equals the leading term in the exponent of the quantum entropy function (4.50) evaluated at the extremum,
\[\frac{\pi}{n_2} [4\text{Im} F^{(0)}(\phi + ip) - q \cdot \phi]_* = \frac{\pi v_*}{n_2 G_N^{(4)}}. \] (5.10)
The Bekenstein–Hawking entropy above receives higher-derivative corrections. Focusing on the case \( n_2 = 1 \) for the moment, we propose to identify the additional contributions to the exponent in (4.42) as arising from additional fields living on the orbifolded strip (5.6), namely 24 chiral and 24 anti-chiral massless periodic scalar fields. To motivate this, we periodically identify the strip coordinate
\[
T + 2\pi \tau_2 \cong T ,
\] (5.11)
and study the effect of adding the matter fields on the geometry (5.6). Observe that we impose a fixed periodicity given in (2.48) and specified by the 4D attractor equations. This is necessary to compare results in the 2D picture to the extremum of the 4D quantum entropy function.

As discussed in [18], the matter fields backreact on the geometry. The equation \( R + \frac{2}{v_*} = 0 \) remains unchanged, but the dilaton equation of motion now acquires a source term due to the scalar fields,
\[
\nabla_\mu \nabla_\nu \Phi - g_{\mu\nu} \Box \Phi + \frac{1}{v_*} g_{\mu\nu} \Phi = - \langle T_{\mu\nu} \rangle ,
\] (5.12)
where the matter stress-tensor \( T_{\mu\nu} \) receives a classical and a quantum contribution [18], \( \langle T_{\mu\nu} \rangle = T^{\text{class}}_{\mu\nu} + T^{\text{quantum}}_{\mu\nu} \). The classical contribution can be obtained by solving the massless wave equation for the scalars. We will restrict ourselves to backreacted configurations which are time-independent, in which case the mode expansion of each bosonic scalar collapses to a constant and ensures that \( T^{\text{class}}_{\mu\nu} = 0 \). Note that this corresponds to the absence of imaginary source terms deforming the JT action [18]. The quantum contribution to \( \langle T_{\mu\nu} \rangle \) can be computed by first going to the cylinder geometry \( ds_{\text{cyl}}^2 = dT^2 + d\sigma^2 \) and then mapping the result to the strip geometry. In doing so, one generically picks up a contribution from the conformal anomaly. In our setting, the two sets of the 24 periodic scalars precisely constitute the degrees of freedom of critical closed bosonic string theory, which ensures the absence of the left and right conformal anomalies. Then, the contribution to the stress-tensor is a one-loop effect made possible by the periodic identification (5.11), and we assume that there are no contributions from higher-loop effects. In total, the backreaction of the scalars renders the dilaton non-constant as [18]
\[
\Phi(\sigma) = -24 \mathcal{E}(\tau_2) \left( 1 - \frac{\sigma + \frac{\pi}{2}}{\tan \sigma} \right) ,
\] (5.13)
where we have chosen the integration constant so that \( \Phi \) is periodic. Here,
\[
\mathcal{E}(x) = \sum_{n \geq 1} \frac{1}{4\pi \sinh^2(\pi nx)} - \frac{1}{24\pi} ,
\] (5.14)
is a charge-dependent constant since \( \tau_2 = \sqrt{\Delta} \) according to (2.48). The resulting non-constant dilaton background yields a finite on-shell value for the action and can be interpreted as a 2D Euclidean wormhole solution, as discussed in [18]. In the semi-classical limit of large \( \tau_{2*} \), this on-shell action is exponentially suppressed relative to (5.9). This semi-classical limit also ensures that \( \Phi \ll \Phi_0 \) (so long as one stays away from the endpoints of the \( \sigma \) interval),

The Gravitational Path Integral 3337
Vol. 24 (2023)
which is the regime where the dimensionally reduced 4D gravity theory is well approximated by JT gravity.

The path integral of the scalar fields on the geometry (5.6) with the identification (5.11) produces the one-loop partition functions

\[ \frac{1}{\eta^{24}(i\tau_2^*)} \frac{1}{\bar{\eta}^{24}(i\bar{\tau}_2^*)}, \]

which can be complexified as \( \tau_2^* \to -i\tau^* \) and \( \bar{\tau}_2^* \to i\bar{\tau}^* \), respectively, to produce a contribution of

\[ \eta^{-24}(\tau^*_s) \bar{\eta}^{-24}(-\bar{\tau}^*_s), \]

which corresponds precisely to the \( \omega \) and \( \bar{\omega} \) contributions at the extremum of the 4D quantum entropy function, where \( \omega \) is defined in (4.20). Our picture therefore suggests that the 2D Euclidean wormholes provide an alternative way to obtain the contribution to the 4D quantum entropy function coming from loop corrections to the supergravity prepotential. Going further, the partition functions (5.15) also include a zero-mode contribution of \( 1/\sqrt{\tau_2^*} \) for each pair of left- and right-movers, which correctly reproduces the non-holomorphic correction \( \log(\tau_2^*)^{-12} \) given in (4.21).

Putting the various contributions together, we find that the 2D wormhole picture at \( s = 1 \) accounts for the corrections to the Bekenstein–Hawking entropy,

\[ \frac{1}{4G_{(2)}^N} + \log \eta^{-24}(\tau^*_s) + \log \bar{\eta}^{-24}(-\bar{\tau}^*_s) + \log(\tau_2^*)^{-12}, \]

which nicely match the exponent in the integrand of the 4D quantum entropy function (4.42) at the extremum. Observe that such a comparison is explicit in the covariant formulation (4.42) of the localized supergravity path integral rather than in the formulation (4.41), which provides a physical motivation for the addition of the total derivative term that expresses the quantum entropy function in terms of the deformed special geometry given in (4.43).

To discuss the \( n_2 \neq 1 \) interpretation, we should understand how the Bekenstein–Hawking entropy and the saddle point value \( \tau^*_s \) are modified when orbifolding. The former was discussed for general \( s = 1/n_2 \) above and the orbifold simply suppresses the contribution by \( n_2 \). For the latter, we switch to a 4D point of view where we propose that the two sets of chiral and anti-chiral matter fields are each anchored at different antipodal points of the 2-sphere as a consequence of supersymmetry [52, 53]. The argument of the Dedekind functions in (4.50) consist of \( \tau \) and \( \bar{\tau} \) dressed by the Greek, Latin and \( \Sigma \) integers characterizing the orbifold. The change in the arguments as one moves between antipodal points is given by the operation

\[ \tau \to \bar{\tau}, \quad \begin{pmatrix} a & b \\ c & d \end{pmatrix} \to \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \quad \Sigma \to -\Sigma. \]

At this stage, we do not have a good understanding of the precise dressing of \( \tau \) and \( \bar{\tau} \) leading to the \( \rho'_0 \) and \( \sigma'_0 \) arguments demanded by the microscopic counting in (2.18). Nevertheless, our wormhole picture leads to valuable
insights into two puzzles. The first is the question of how the Euclidean wormholes of \([19,54]\) contribute to the \(N = 4\) counting formula. The second has to do with instanton contributions to \(N = 4\) BPS black hole microstates encoded in the Dedekind functions. What we have seen is that the usual interpretation in terms of marginal decays of two-centred states \([2,22]\) can be equivalently thought of as contributions from 2D wormholes in the \(\text{AdS}_2\) factor of the near-horizon geometry of the single-centred \(\frac{1}{4}\) BPS black hole. We stress, however, that the wormholes we have discussed should not be thought of as additional saddle points to the quantum entropy function path integral. Rather, they provide an alternative space-time interpretation of the deformed special geometry \((4.43)\) entering the degeneracy formula in the covariant picture. We will come back to this point in the discussion.

We now have two equivalent macroscopic descriptions of \(N = 4\) BPS black hole microstates, one in terms of the quantum entropy function in 4D \(N = 4\) supergravity and the other in terms of 2D Euclidean wormholes. Each of these admits a holographic dual, and we will now comment on the equivalence between them.

6. Relating DFF- and Liouville-Type Actions in One Dimension

For our holographic investigations, we first consider a special class of time-dependent perturbations of the attractor geometry given in [16]. These perturbations involve fluctuations of the size of the \(S^2\) factor while keeping all other scalars at their attractor values. They have been analysed in [14–16] who found that their effect can be holographically encoded in a Lorentzian 1D DFF-type model [13], whose action is of the form

\[
\int dt \left[ \frac{(\nu')^2}{\nu} + \frac{a}{\nu} \right].
\]

(6.1)

Here, \(\nu(t)\) is the time-dependent perturbation of the size of the \(S^2\), \(a \in \mathbb{R}\) is defined in terms of the non-extremality parameter as well as the radius of the \(\text{AdS}_2\) factor in the attractor background, and the action is written in Poincaré time. Converting to global time coordinates and redefining \(dt \rightarrow \alpha(t) \, dt\), the action of the holographic model reads [55]

\[
S_{\text{DFF}} = \int dt \left[ \frac{(\nu')^2}{\alpha \nu} + \alpha \left( \frac{a}{\nu} + b \nu \right) \right],
\]

(6.2)

where \(b \in \mathbb{R}\) is induced by the change to global time coordinate. Setting \(\alpha(t) = 1\), taking \(a < 0\), \(b < 0\), and substituting \(\nu(t) = x^2(t)\) shows that (6.2) can be brought to the form of a DFF action [13],

\[
S_{\text{DFF}} = \int dt \left[ 4(x')^2 - \left( \frac{|a|}{x^2} + |b|x^2 \right) \right].
\]

(6.3)
When $a, b > 0$, the parameter $b$ in (6.2) can be absorbed by scaling $\nu \to \sqrt{\frac{a}{b}} \nu$ and $\alpha \to \frac{\alpha}{\sqrt{b}}$, which gives

$$S_{\text{DFF}} = \sqrt{a} \int dt \left[ \frac{(\nu')^2}{\alpha \nu} + \alpha \left( \frac{1}{\nu} + \nu \right) \right].$$  \hfill (6.4)

On the other hand, Liouville-type models have recently been shown to arise in the study of holographic duals of JT gravity [56,57] and in the study of certain perturbations of the 2D dilaton in the AdS$_2$ geometry (5.6) underlying the Euclidean wormhole description [19,54]. We now show that the Lorentzian DFF model (6.4) can be rewritten as the Liouville model shown to underlie the description of 2D Euclidean wormholes [19,54].

When considering the time perturbation of the size of the $S^2$, one must set $a > 0$ in (6.2), cf. Equation (3.94) in [16]. Therefore, in the following, we will take $a > 0$ and $b > 0$ and simply set $a = b = 1$ in view of the scaling freedom mentioned above (6.4). We then relate the DFF-type action (6.4) to the following Liouville-type action:

$$S_{\text{Liouv}} = \int dt \left[ \frac{1}{2} (l')^2 + 2e^{-l} \right],$$ \hfill (6.5)

where $l(t)$ encodes the perturbation of the 2D dilaton [19,54].

To relate $\nu(t)$ to $l(t)$, we compare the terms in the actions (6.4) and (6.5) and infer the relations

$$\alpha \left( \frac{1}{\nu} + \nu \right) = 2e^{-l},$$ \hfill (6.6)

$$\frac{(\nu')^2}{\alpha \nu} = \frac{1}{2} (l')^2.$$

The first equation determines $\alpha(t)$ in terms of $\nu(t)$ and $l(t)$. On the other hand, by combining these two equations we obtain

$$(\nu')^2 \left( \frac{1}{\nu^2} + 1 \right) = 4 \left[ (e^{-\frac{l}{2}})^{\prime} \right]^2,$$ \hfill (6.7)

whose solution expresses $\nu(t)$ in terms of $l(t)$ through

$$- \log \left( \frac{1 + \sqrt{1 + \nu^2}}{\nu} \right) + \sqrt{1 + \nu^2} = \pm 2 e^{-\frac{l}{2}},$$ \hfill (6.8)

and $\alpha(t)$ is determined by the first equation in (6.6). Observe that the correspondence between the DFF- and Liouville-type models involves a non-trivial reparametrization of time.

The equivalence between Liouville- and DFF-type actions complements the equivalence between the 4D quantum entropy function and the 2D Euclidean wormhole picture we have proposed in the previous section. We see this as a suggestive holographic counterpart of the alternative macroscopic accounting of the $N = 4$ BPS black hole microstates based on Euclidean wormholes.
7. Conclusions

We have shown that the exact microscopic degeneracy formula extracted from the inverse of the Igusa cusp form lends itself to two rewritings (2.4) and (2.6), each endowed with its own distinct macroscopic interpretation.

The formula (2.4) expresses the single-centred degeneracy as a Rademacher series controlled by a finite number of polar degeneracies corresponding to negative discriminant states. The macroscopic interpretation of (2.4) is in terms of the quantum entropy function, whose semi-classical limit describes the Wald entropy of a single-centred black hole in the presence of $R^2$ interactions. These interactions are conveniently encoded in the $N = 2$ Wilsonian holomorphic prepotential $F = F^{(0)} + 2i\omega$, cf. (4.2). Furthermore, the polar degeneracies are interpreted macroscopically as two-centred $\frac{1}{4}$ BPS bound states together with a continued fraction structure [25] associated with their decays at walls of marginal stability in the axio-dilaton moduli space. The polar degeneracies come from the degeneracies of the individual $\frac{1}{2}$ BPS centres and are generated by the Dedekind functions arising from the instanton correction $\omega$. The full quantum entropy function correctly reproduces the microscopic degeneracies (2.4) upon summing over the individual orbifolded background contributions $W_{n_2m_1,n_1,j}$ provided we set the measure on the localizing manifold according to (4.47). This agreement relies on the 1-to-1 map obtained in Sect. 3.2 between the four integers $(n_2,m_1,n_1,j)$ characterizing the orbifolds and the eight integers characterizing the set $P$ together with $\Sigma$. It is remarkable that, just as in the case of $\frac{1}{8}$ BPS black holes in $N = 8$ supergravity [40], such orbifolds are the only gravitational backgrounds needed to recover the microscopic single-centred degeneracies extracted from $1/\Phi_{10}$. This fact points to a vanishing contribution of other types of backgrounds to the quantum entropy function, similar to the situation studied in [58,59] for supersymmetric indices.

The formula (2.6) is more naturally interpreted macroscopically in terms of a 2D theory of gravity. The action of the theory is that of JT gravity (5.7) coupled to the field content of critical closed bosonic string theory on Euclidean AdS$_2$ (or an orbifold thereof) with specific boundary conditions. The partition function of the 2D theory receives a classical contribution from the 2D disc geometry, which is precisely the semi-classical entropy obtained in the quantum entropy function formalism at the two-derivative level and encoded in the prepotential $F^{(0)}$. The bosonic string scalars enter the one-loop level, and their effect on the partition function is to generate holomorphic contributions proportional to Dedekind functions as well as non-holomorphic contributions. In the quantum entropy function, these are precisely the instanton correction $\omega$ and the non-holomorphic correction $\Omega$. This also prompts us to interpret the instanton and non-holomorphic contributions as being due to 2D Euclidean wormholes. Let us remark that in the case with maximal supersymmetry analysed in [40], such corrections are forbidden by the high amount of supersymmetry. We therefore do not expect a corresponding 2D interpretation to be relevant in the $N = 8$ supergravity setting.
This interpretation is also consistent with the associated 1D holographic dual models. The model capturing perturbations of the size of the $S^2$ factor in the four-dimensional black hole near-horizon geometry is a Lorentzian DFF-type model with action $6.4$. This action can be reformulated via an appropriate time reparametrization as a Liouville-type model with action $6.5$, which is holographically dual to perturbations of the 2D dilaton on the global Euclidean AdS$_2$ strip. These perturbations source 2D Euclidean wormholes.

While the microscopic degeneracies of single-centred $\frac{1}{4}$ BPS black holes are now well understood, our analysis highlights a couple of interesting open problems. From the quantum entropy function perspective, the main issue that remains is to obtain a first principle derivation of the localization measure given in $4.47$. While we have explained how this measure can be obtained from a saddle point approximation of the $N = 2$ symplectic invariant measure proposed in [46], the latter is only defined up to the inclusion of symplectically invariant factors. Symplectic invariance alone therefore cannot suffice in fixing the measure and guarantee an agreement between the quantum entropy function and the microscopic degeneracies. It would be most interesting to understand how $4.47$ arises naturally in the $N = 4$ setting. To this end, the formulation $4.50$ of the quantum entropy function may prove useful. From the 2D wormhole perspective, it is crucial to go beyond the identification of the various contributions to the quantum entropy function in a semi-classical approximation, and to clarify the role of wormhole configurations at the quantum level. We hope to report on these questions in the future.

Acknowledgements
