ABSTRACT

Many massive star forming disc galaxies in the redshift range 3 to 0.5 are observed to have a clumpy morphology showing giant clumps of size $\sim$1 kpc and masses of about $10^7 M_\odot$ to $10^{10} M_\odot$. The nature and fate of these giant clumps is still under debate. In this work we use 19 high-resolution simulations of disc galaxies from the NIHAO sample to study the formation and the evolution of clumps in the discs of high redshift galaxies. We use mock HST - CANDELS observations created with the radiative transfer code GRASIL-3D to carry out, for the first time, a quantitative comparison of the observed fraction of clumpy galaxies and its evolution with redshift with simulations. We find a good agreement between the observed clumpy fraction and the one of the NIHAO galaxies. We find that dust attenuation can suppress intrinsically bright clumps and enhance less luminous ones. In our galaxy sample we only find clumps in light (u-band) from young stars but not in stellar mass surface density maps. This means that the NIHAO sample does not show clumpy stellar discs but rather a clumpy light distribution originating from clumpy star formation events. The clumps found in the NIHAO sample match observed age/color gradients as a function of distance from the galaxy center but they show no sign of inward migration. Clumps in our simulations disperse on timescales of a about a hundred Myr and their contribution to bulge growth is negligible.

Key words: galaxies: - formation - galaxies: - high-redshift - galaxies: evolution - galaxies: bulges - galaxies: ISM - methods: numerical

1 INTRODUCTION

The presence of bright clumps in the light distribution of high redshift ($z \approx 0.5–3$) star forming galaxies has attracted a lot of attention both from an observational and a theoretical point of view. Observations have shown that disc galaxies in the early universe have higher gas-fractions (Daddi et al. 2010; Tacconi et al. 2010, 2013; Genzel et al. 2015), star formation rates (Genzel et al. 2006; Förster Schreiber et al. 2006; Genzel et al. 2008) velocity dispersions (Elmegreen & Elmegreen 2005; Förster Schreiber et al. 2006) and a clumpy morphology (Genzel et al. 2008; Förster Schreiber et al. 2011; Guo et al. 2015) compared to their counterparts at $z = 0$.

Observationally these clumps are mostly identified in the rest-frame UV, optical or H$_\alpha$ maps (Elmegreen et al. 2007, 2009; Genzel et al. 2011; Förster Schreiber et al. 2011; Guo et al. 2012; Wuyts et al. 2012; Tadaki et al. 2014; Mu-
Several theoretical studies have focused on an explanation for the formation of these giant star-forming clumps either analytically (Dekel et al. 2009b), in isolated disc galaxy simulations (Bournaud et al. 2007, 2008; Bournaud & Elmegreen 2009; Inoue & Saitoh 2014; Bournaud et al. 2014; Tamburello et al. 2015; Mayer et al. 2016) or in cosmological simulations of galaxy formation (Ceverino et al. 2010, 2012; Genel et al. 2012; Hopkins et al. 2012; Mandelker et al. 2014; Moody et al. 2014; Mandelker et al. 2017). While some clumpy galaxies might be the result of an ongoing merger (Somerville et al. 2001), their overall high fraction cannot be explained by the expected merger rate at these redshifts (Dekel et al. 2009a; Stewart et al. 2009; Hopkins et al. 2010, 2012). Another explanation for the origin of clumps, given the high gas fractions and high gas surface densities in z > 0 galaxies, is disc fragmentation via gravitational (disc) instabilities (Toomre 1964). Indeed, clumps are mainly observed to reside in gravitationally unstable regions (Genzel et al. 2011). The formation scenario invoked for clumps is the same as for local giant molecular clouds: local collapse and fragmentation happens in regions where the self-gravity of gas and stars is stronger than the internal support by pressure and turbulent motions.

As already mentioned, several groups have studied the dynamics and stability of discs with the aid of high resolution numerical simulations (Noguchi 1998, 1999; Dekel et al. 2009b; Agertz et al. 2009; Cacciato et al. 2012; Ceverino et al. 2015; Genel et al. 2012; Inoue & Saitoh 2012; Perez et al. 2013; Tamburello et al. 2015). In most of these studies discs do fragment and break up into large clumps, however there are two different possible scenarios for the fate of the clumps and their subsequent impact on the global evolution of the host galaxy. If clump collapse is very efficient, it could lead to the formation of gravitationally self-bound, long-lived giant star clusters. These clusters will then lose angular momentum within the disc via gravitational torques and dynamical friction and migrate inwards on timescales of about 10^8 yr to build up the central bulge (e.g. Bournaud et al. 2014). This picture seems to be supported by observed color gradients of the clumps within the disc. Clumps closer to the center of a galaxy show redder colors (Förster Schreiber et al. 2011; Guo et al. 2012; Shibuya et al. 2016) although this trend appears to be weak and might be caused by underlying evolved structures like e.g. bulges (van Dokkum et al. 2010; Patel et al. 2013; Morishita et al. 2015; Nelson et al. 2016b).

Conversely if gas cooling is suppressed, as for example in the presence of substantial stellar feedback, the resulting stellar clumps will not be self-bound and will then be quickly

dispersed within the disc before experiencing any drag to the center.

Recent numerical work (Mayer et al. 2016; Oklopčić et al. 2017) has somehow suggested that when robust feedback (needed to reproduce observed galaxy properties at redshift $z = 0$) is invoked, clumps are either short lived transient features or do not form at all. Thus a treatment of feedback, that is able to prevent overcooling seems to be crucial to understand the origin of clumpy galaxies at high redshift. On the other hand these studies were either based on a single simulated galaxy (Oklopčić et al. 2017) or they were lacking cosmological gas inflow (Mayer et al. 2016) and hence more work on the simulation side is needed.

In this work we revise the issue of the formation and evolution of luminous clumps in cosmological simulations of disc galaxies at $z = 1 − 3$ using the NIHAO simulation suite. The NIHAO (Numerical Investigations of Hundred Astrophysical Objects)\(^1\) project is a suite of one hundred high resolution hydrodynamical cosmological simulations. We first compare the “clumpiness” of our galaxies with real galaxies using an observational motivated clump selection procedure based on the UV luminosity of our objects. For this purpose we have post processed all our galaxies with the radiative transfer code GRASIL-3D. (Domínguez-Tenreiro et al. 2014). Subsequently we look at the evolution of these luminous clumps and their relation with the underlying stellar mass distribution to assess their final fate and their overall impact on galaxy evolution.

\(\text{Figure 1.}\) Evolution of the Stellar mass vs. halo mass relation for the selection of hosts. Redshift $z = 0$ (top left), $z = 1$ (top right), $z = 2$ (bottom left), and $z = 4$ (bottom right). For all redshifts shown the simulations agree well with constraints from halo abundance matching (Moster et al. 2013; Behroozi et al. 2013; Kravtsov et al. 2014). Where the relations are extrapolated into mass scales without observational constraints the lines are shown in dashed line style.

\(^1\) Nihao is the chinese word for hello.
the order of one million particles (gas+stars+dm) in each simulated galaxy.

The NIHAO galaxies have been run using cosmological parameters from the Planck Collaboration et al. (2014), namely: \( \Omega_{\text{m}} = 0.3175, \Omega_{\Lambda} = 0.6825, \Omega_{b} = 0.049, H_0 = 67.1 \text{ km s}^{-1} \text{ Mpc}^{-1}, \sigma_8 = 0.8344. \) For the sub-set of simulations used here the mass resolution is either \( m_{\text{dark}} = 1.735 \times 10^6 M_\odot \) or \( m_{\text{dark}} = 2.169 \times 10^7 M_\odot \) for dark matter particles and \( m_{\text{gas}} = 3.166 \times 10^5 M_\odot \) or \( m_{\text{gas}} = 3.958 \times 10^5 M_\odot \) for the gas particles. The corresponding force softenings are \( \epsilon_{\text{dark}} = 931.4 \) pc and \( \epsilon_{\text{dark}} = 465.7 \) pc for the dark matter particles and \( \epsilon_{\text{gas}} = 397.9 \) pc and \( \epsilon_{\text{gas}} = 199.0 \) pc for the gas and star particles, which is the spatial scale more relevant for this study. However, the smoothing length of the gas particles can be much smaller, e.g. as low as \( h_{\text{smooth}} \sim 45 \) pc. See Table 1 for a full list of the our galaxies parameters.

NIHAO galaxies have been proven to match remarkably well many of the properties of observed galaxies, as for example results from abundance matching (Wang et al. 2015), metals distribution in the Circum Galactic Medium (Gutcke et al. 2017), the local velocity function (Macciò et al. 2016) and the properties of stellar and gaseous disc (Obreja et al. 2017), the local velocity function (Macciò et al. 2016). Overall NIHAO simulated galaxies are among the most realistic simulations run in a cosmological context. This means that the NIHAO sample is a perfect test bed to study the occurrence and properties of clumps in high redshift galaxies.

2.1 Hydrodynamics

The NIHAO simulations were run with a modified version of the smoothed particle hydrodynamics (SPH) solver GASOLINE (Wadsley et al. 2004) with substantial updates made to the hydrodynamics as described in (Keller et al. 2014). We will refer to this version of GASOLINE as ESF-GASOLINE2.

This modified version of hydrodynamics removes spurious numerical surface tension and improves multi-phase mixing by calculating \( P/\rho^2 \) as a geometrical average over the particles in the smoothing kernel as proposed by Ritchie & Thomas (2001). The Saitoh & Makino (2009) timestep limiter was implemented so that cool particles behave correctly when a hot blastwave hits them and ESF-GASOLINE2 uses the Wendland C2 smoothing kernel (Dehnen & Aly 2012) to avoid pairing instabilities. The treatment of artificial viscosity has been modified to use the signal velocity as described in Price (2008) and the number of neighbor particles used in the calculation of the smoothed hydrodynamic properties was increased from 32 to 50.

Cooling via hydrogen, helium, and various metal-lines is included as described in Shen et al. (2010) and was calculated using cloudy (version 07.02; Ferland et al. 1998). These calculations include photo ionization and heating from the Haardt & Madau (2005) UV background and Compton cooling in a temperature range from 10 to 10^9 K. Finally we adopted a metal diffusion algorithm between particles as described in Wadsley et al. (2008).

2.2 Star Formation and Feedback

In the fiducial NIHAO runs gas is eligible to form stars according to the Kennicutt-Schmidt Law when it satisfies a temperature and density threshold. The simulations employ the star formation recipe as described in Stinson et al. (2006) which is summarized below. Stars form from cool (T < 15,000K), dense gas (\( n_{\text{th}} > 10^3 \) cm^{-3}). The threshold number density \( n_{\text{th}} \) is set to the maximum density at which gravitational instabilities can be resolved in the simulation: \( n_{\text{th}} = 50 \rho_{\text{gas}}/\epsilon_{\text{gas}} = 10^3 \text{ cm}^{-3} \), where \( \rho_{\text{gas}} \) denotes the gas particle mass and \( \epsilon_{\text{gas}} \), the gravitational softening of the gas. The value of 50 denotes the number of neighboring particles. The gas fulfilling these requirements will then be converted into stars according to the following equation:

\[
\frac{\Delta M_{\text{star}}}{\Delta t} = c_{\text{star}} \frac{M_{\text{gas}}}{t_{\text{dyn}}}
\]

where \( \Delta M_{\text{star}} \) is the mass of the star particle formed, \( M_{\text{gas}} \) the gas particle’s mass, \( \Delta t \) is the timestep between star formation events (here: \( 8 \times 10^7 \text{ yr} \)) and \( t_{\text{dyn}} \) is the gas particles dynamical time, \( c_{\text{star}} \) is the star formation efficiency, i.e. the fraction of gas that will be converted into stars during the time \( t_{\text{dyn}} \) and is taken to be \( c_{\text{star}} = 0.1 \).

Stellar feedback is implemented in two modes as described in Stinson et al. (2013). The first mode accounts for the energy input from stellar winds and photo ionization from luminous young stars. This pre-SN feedback, that was dubbed Early Stellar Feedback (ESF) in Stinson et al. (2013), happens before any supernovae explode and consists of 10% of the total stellar flux, \( 2 \times 10^{38} \) erg of thermal energy per \( M_\odot \) of the entire stellar population. The efficiency parameter for the coupling of the energy input is set to \( \epsilon_{\text{ESF}} = 13\% \). And for the pre-SN feedback, unlike the SN feedback, the radiative cooling is left on.

The second mode accounts for the energy input via supernovae and starts 4 Myr after the formation of the star particle, and it is implemented using the blastwave formalism described in Stinson et al. (2006). In this approach supernova input energy (i.e. thermal feedback) into the interstellar gas surrounding the region were they formed, but since the gas receiving the energy is dense, it would quickly be radiated away due to its efficient cooling. For this reason, cooling is delayed for particles inside the blast region for \( \sim 30 \) Myr. See Stinson et al. (2013) for an extended feedback parameter search.

3 THE GALAXY SAMPLE

In order to match the stellar range of the observed galaxies at high redshift we have selected from the NIHAO sample all the galaxies with stellar masses larger than \( M_{\text{star}} > 10^9 M_\odot \) at redshift \( z = 1.5 \), obtaining a final sample of 19 galaxies. From these galaxies we use all the snapshots in the redshift range \( 3 > z > 0.25 \) where the stellar mass of the galaxy is larger than the above threshold mass. This selection criteria leaves us with 203 snapshots in the redshift range \( 3 > z > 1 \), 155 in the redshift range \( 1 > z > 0.5 \) and 130 in the redshift range \( 0.5 > z > 0.25 \).

For this work the virial mass, \( M_{200} \), of each halo is defined as the mass of all particles within a sphere containing \( \Delta = 200 \) times the cosmic critical matter density, \( \rho_{\text{crit}} \). The virial radius, \( R_{200} \), is defined accordingly as the radius of this sphere. The haloes in the zoom-in simulations were identified using the MPI+OpenMP hybrid halo finder.
AHF2 (Knollmann & Knebe 2009; Gill et al. 2004). The stellar $M_{\star}$, and the gas, $M_{\text{gas}}$ masses are measured within a sphere of radius, $r_{\text{gal}} \equiv 0.2R_{200}$. The star formation rate, SFR, is measured as the mass of stars formed inside $r_{\text{gal}}$ over the preceding Gyr and the gas fraction $f_{\text{gas}}$ is defined as the fraction of cold gas ($T < 3 \times 10^4$ K) over the total baryonic mass within $r_{\text{gal}}$. The main parameters of the 19 NIHAO galaxies are listed in Table 1.

As already mentioned before the strength of the (stellar) feedback has a strong impact in promoting or suppressing the formation of stellar clumps. The efficiency of the feedback can be tested by looking at how realistic the properties of simulated galaxies are w.r.t. observed ones.

### 3.1 Stellar mass-halo mass relation

Fig. 1 shows the evolution of the stellar mass vs. halo mass relation since redshift $z = 4$ (a look back time of $\sim$12 Gyr); NIHAO simulations (blue circles) show a very good agreement with the abundance matching relations from Behroozi et al. (2013) and Moster et al. (2013). At redshift 2 and 1 some of the higher mass galaxies show about a factor of 2 to many stars but this is consistent with e.g. the FIRE simulation Hopkins et al. (2014). Some of this discrepancy w.r.t abundance matching results might be due to systematic uncertainties in the form of the stellar Initial Mass Function (IMF, e.g. Conroy & van Dokkum (2012); Dutton et al. (2013a,b)). Thus for massive galaxies ($M_{\star} \gtrsim 10^{11}M_{\odot}$) the stellar masses may be underestimated by a factor of 2 when assuming a Milky Way IMF.

Comparison to the VELA galaxies (Ceverino et al. 2015; Inoue et al. 2016; Moody et al. 2014) (colored triangles in Fig. 1) shows these galaxies tend to substantially overproduce stellar masses at redshift 2. Inclusion of radiation pressure as an additional source of feedback in these galaxies (VELARP) brings them in better agreement with the abundance matching relation. This in comparison to the results from the FIRE simulation and from NIHAO indicates that inclusion of some sort of feedback prior to supernova (Ceverino: radiation pressure; Hopkins: radiation pressure, stellar winds, and photoionization; NIHAO: strong photoionization included as thermal energy) is needed to reproduce the stellar mass-halo mass relation at high redshifts.

It is worth noticing that the VELA galaxies were not run down to redshift 0 so there is no information whether these simulations do or do not provide realistic present day galaxies. For reference we also include the isolated simulations by Perret et al. (2014) taken from the MIRAGE sample.

### 3.2 Gas fractions

Together with the total stellar mass, another important quantity in determining the stability of a disc in a galaxy is the fraction of cold gas.

In Fig. 2 we show the gas fraction defined as $f_{\text{gas}} = M_{\text{gas}}/(M_{\star} + M_{\text{gas}})$ as a function of stellar mass compared to observations at redshift 0 from Dutton et al. (2011) (left panel) and observations from the PHIBBS survey (Tacconi et al. 2013) for galaxies at redshift 1-1.5 (right panel). The selected NIHAO galaxies follow nicely the trend observed by Dutton et al. (2011).

The discrepancy at these lower masses might be due to different measurement methods in the simulations and the observations. In the simulations we use all the gas with a temperature smaller than 3 $\times$ 10$^4$ K in a sphere of radius $r_{\text{gal}} = 0.2R_{200}$ while the observations measure atomic and molecular gas with a correction factor for helium (Dutton et al. 2011).

As was shown in Stinson et al. (2015) a simple temperature cut overestimates the amount of neutral gas, especially at lower masses. The galaxies are also broadly in agreement with the observations from the PHIBBS survey data (Tacconi et al. 2013) shown as black dots. The incompleteness corrected relation from the PHIBBS survey is shown as the grey shaded area.
agreement with the incompleteness corrected measurements from the PHIBBS survey (gray band) for galaxies in the redshift range 1 < z < 1.5. For reference we also show the gas fractions of the VELA galaxies (Ceverino et al. 2015; Inoue et al. 2016; Moody et al. 2014), the FIRE galaxy from Oklopić et al. (2017) and the MIRAGE sample (Perret et al. 2014). The VELA sample and the FIRE galaxy are well in agreement with the NIHAO sample as well as the observed gas fractions. The two higher mass MIRAGE galaxies show very high gas fractions of 60% in slight tension with the completeness corrected PHIBBS observations. Although galaxies with such high gas fractions are observed they are likely not typical.

4 RADIATIVE TRANSFER

In order to compare the fraction of galaxies with clumps in the simulations and in the CANDELS galaxy sample we post-process our simulations with the radiative transfer code GRASIL-3D (Domínguez-Tenreiro et al. 2014). The post-processing step insures we account for the effects of dust attenuation and cosmological redshift, thus allowing for a meaningful comparison between simulations and observations.

GRASIL-3D is a three-dimensional radiative transfer code designed to be used with the outputs of hydrodynamical simulations. The code solves the radiative transfer equation for dusty media on a regular grid. The treatment of dust is based on the formalism of the GRASIL model (Silva et al. 1998; Granato et al. 2000), which has been successfully used with semi-analytical models of galaxy formation. The key feature of this dust model is that it does a detailed non-equilibrium calculation for polycyclic aromatic hydrocarbons molecules and dust grains smaller than 150 Å, thus allowing for a proper description of the cirrus emission in mid-infrared (Guhathakurta & Draine 1989).

An important point to remember is that any RT post-processing of simulated galaxies introduces a few more sub-grid parameters on top of those already included in the hydrodynamical codes. In the case of GRASIL-3D, these parameters are particularly related to the properties of the molecular clouds (MCs). Since short-lived massive stars are spatially associated with MCs, it is well established that much of the dust reprocessing of stellar light occurs inside MCs. In the case of most cosmological simulations these small scales are not resolved, and as such, dust reprocessing has to be modeled. In GRASIL-3D, the interstellar medium is split into MCs and diffuse cirrus, by assuming the densities of unit hydrodynamical gas masses to follow a lognormal probability distribution function with a mean equal to the local gas density. The dispersion of the distribution is a free parameter. In this manner, the fraction of the gas mass above a certain density threshold gives the MC contribution, while the rest is considered cirrus. Thus, the first two parameters GRASIL-3D needs are the MC density threshold and the dispersion of the density distribution function.

In GRASIL-3D the dust reprocessing of stellar populations is age-dependent, similar to the implementation in GRASIL which was the first model to take age into account. Practically, stars younger than a certain age, t0, radiate all their energy inside MCs, while stars older than 2t0 have already dispersed their MC cocoons. In the intermediate age regime, the fraction of energy dumped inside the MC is a decreasing function of stellar age. The last parameter the code needs is the spatial extent of molecular clouds. Once these sub-grid parameters are set, GRASIL-3D solves the RT equation by treating separately the light reprocessing in the dense and diffuse interstellar medium.

Finally, the stellar particles luminosities are computed according to the simple stellar population models of Bruzual & Charlot (2003) (which is the only option available in the current version of GRASIL-3D) assuming a Chabrier IMF (Chabrier 2003).

The code has already been used to study the star formation main sequence of simulated galaxies (Obreja et al. 2014), the properties of high redshift clusters and protoclusters in sub-mm and IR (Granato et al. 2015), and the correlations between IR fluxes of z=0 simulated galaxies and their baryonic content (Goz et al. 2016). These studies have shown that GRASIL-3D reproduces observables (e.g. broad band fluxes, spectral energy distributions) when used with realistic galaxy simulations.

In order to run GRASIL-3D on the simulated NIHAO galaxies, we need to specify the four parameters discussed above. We chose the fiducial values for disc galaxies of Domínguez-Tenreiro et al. (2014): 14 pc for the molecular cloud radius, 5 Myr for the molecular cloud destruction timescale, $3.3 \times 10^{4} M_{\odot} \text{kpc}^{-3}$ for the molecular clouds threshold density, and a dispersion of the log-normal gas density probability distribution function of 3. We do not perform any GRASIL-3D parameter study in this work, given both the high computational cost implied and the fact that the above mentioned values have been shown to reproduce normal star forming galaxies (e.g. Silva et al. 1998; Goz et al. 2016). Finally, we chose pixel sizes corresponding to the resolution of the Hubble Space Telescope (HST) at the given redshift of the snapshots (0.06”).

After running GRASIL-3D on all the snapshots of our galaxy sample in the redshift range ∼0.25-3, we apply the same HST filter selection with the same magnitude cuts and surface brightness limits as chosen in Guo et al. (2015). For snapshots in the redshift range 3 > z > 2 we select the F775W filter, for 2 > z > 1 we select the F606W filter and for z < 1 we select the F435W filter to detect clumps. The outcome of the radiative transfer calculations results in mock observations of our simulations closely matching the ones of CANDELS galaxies used by Guo et al. (2015). A selection of images for the galaxy g7.55e11 at redshift z ∼ 1.3 in all three filters used are shown in Fig. 3 in comparison to an RGB map of the stellar luminosity (left panel). For the RGB map we calculate the stellar luminosity of a star particle given its age and metallicity in three different bands (see next section for a more detailed description). The radiative transfer images show the luminosity maps of the same galaxy in the three filters used for the analysis (from left to right: F435W, F606W, F775W). As described above, for the given snapshot time of z ∼ 1.3 we would use for the clump analysis the F606W image, while for higher redshifts we would use the F435W filter and for lower redshifts the F775W one.

T. Buck et al.
5 CLUMP DETECTION

In this study we perform an observationally motivated clump selection, while other theoretical works on this subject focused on identifying clumps as regions of high surface density of gas or stars (Genel et al. 2012; Ceverino et al. 2015; Tamburello et al. 2015; Mayer et al. 2016; Inoue et al. 2016; Oklopković et al. 2017)

Observed clumps are mostly detected as UV bright or Hα bright clumps and we thus decided to select clumps in the luminosity maps of our galaxies with and without radiative transfer post-processing. We will refer to clumps detected in non dust-attenuated images as intrinsic clumps, while we will call clumps in the RT-processed images observed clumps. This allows us to do a proper comparison with both observations and previous theoretical studies.

5.1 Intrinsic clump selection

For every galaxy and every snapshot in the redshift range \( z = 0.25 - 3 \) we create UV-light images by calculating the UV luminosity of every star particle given its age, metallicity and its IMF under the assumption that these particles represent simple stellar populations (SSPs). We use the PYNBODY-package\(^2\) to perform these calculations. This package includes a grid of SSP luminosities for different stellar ages and metalicities in several bandpasses. The grids are calculated using Padova Simple stellar populations from Girardi\(^3\) (Marigo et al. 2008; Girardi et al. 2010).

Our clump finding procedure is similar to the one used by Oklopković et al. (2017) and we will briefly describe it here. For all snapshots we first rotate the galaxies face-on, using the total angular momentum of the stars within a sphere of 10 kpc around the center of the halo. We then select all star particles in a cylinder of radius 10 kpc and height of 6 kpc centered on the galaxy and then construct the luminosity maps by binning the particle positions onto a 2d-grid of bin size 100 pc.

We sum up all luminosities of the star particles in one cell to get its total luminosity. After that we smooth the luminosity map by convolving it with a Gaussian filter of 0.02 hpc standard deviation (FWHM \( \sim \) 2 kpc) to account for the particle’s softening. We checked that taking the softening into account before binning the data onto the grid does not make a significant difference in terms of clump detection.

Using the procedure described above we can also create maps of different quantities, e.g. the surface density maps of gas can be calculated by summing up all the mass in one bin and then dividing the result by the surface area of the bin. Figure 4 shows the u-band luminosity map (upper left), the SFR surface density map (lower left) with the SFR calculated as the stellar mass formed over the last 500 Myr, surface density of cold gas (upper right) and a RGB stellar composite image of the stars (lower right), where RGB stands for the colors used to render the stars (old stars are rendered with a Red color, intermediate aged stars with Green and young stars Blue). As expected, intrinsic clumps found in the u-band luminosity agree very well with clumps in the SFR surface density. Once we created a map of a given quantity we further calculate the mean value of all non-empty bins and the according standard deviation. We then use the Python package astrodendro\(^4\) to find over-densities in the maps. The astrodendro package calculates hierarchical trees of structures so called dendrograms in the maps. There are three parameters needed by the package to calculate the tree. i) A threshold value to define the clump which we set to three standard deviations above the mean value (we checked that our results are robust if we alter this value, see fig. A1 in the Appendix), ii) The minimum difference between two close structures to count them as separate clumps; we set this to 10% following Oklopković et al. (2017). iii) The minimum number of pixels within a clump which is set to be 30 pixels resulting in an effective radius of \( \sim \) 300 pc which is consistent with the gravitational softening of the gas and star particles of our simulations.

We make a significant difference in terms of clump detection. An example of the outcome of this clump finding algorithm is shown in Figure 4 where u-band selected clumps are over-plotted on all four face-on images with white contours.

AstroDendro package already comes with tools to measure the size (surface area) of each clump in the plane of the disc (x-y-plane). Given the surface area, \( A \), of each

\(^3\) http://stev.oapd.inaf.it/cgi-bin/cmd

\(^4\) http://www.dendrograms.org/
clump we can calculate an effective radius of the clump, \( R^2 = A/\pi \). We follow the assumption by Oklopčić et al. (2017) and take the extent of each clump perpendicular to the plane of the disc as equal to \( 2R \) centered on the densest part of the clump. All stellar and gas particles falling into this volume of space are counted as belonging to the clump and clump properties such as luminosity, mass, etc. can be calculated from these particles. We checked that the enclosed mass does not depend strongly on the exact choice of the clump’s vertical extent, as long as it is on the order of the disc scale height. Most of the snapshots show one large clump in the center of the galaxy which can be matched to the bulge component. Thus, we excluded from the search area the innermost 1 kpc around the center of the galaxy.

5.2 Clump selection in radiative transfer images

While the above clump selection is useful to study physical properties of clumps, a comparison to observed galaxies is difficult due to missing dust attenuation and cosmological redshift. Therefore we look for clumps directly in the dust attenuated radiative transfer (RT) maps computed as explained in section 4.

On the RT images we adjust our clump finder to better match the observational clump selection as described in Guo et al. (2015) (section 3). We first calculate the background mean after applying a 3\( \sigma \) clipping and then we select clumps as local maxima which are at least 3\( \sigma \) above the mean. Again we checked how results change if this threshold is changed to 2 or 4\( \sigma \) (see fig. A2 in the Appendix). Because we adjusted the pixel size of the RT images to match the resolution of

Figure 4. Face-on maps of intrinsic u-band luminosity (upper left), SFR surface density (lower left), cold gas surface density (upper right), and RGB stellar composite (lower right). The white contours show the clumps selected in the intrinsic u-band luminosity map.
In order to compare our simulations with the observations used by Guo et al. (2015), we constructed HST mock images with GRASIL-3D (Domínguez-Tenreiro et al. 2014) for all snapshots in the redshift range $0.3 < z < 3$ of our 19 NIHAO galaxies. We then apply the same filters (F435W, F606W and F775W) and surface brightness cuts used by Guo et al. (2015) to our mock images and look for clumps as described in section 5.2.

In Fig. 6 we compare the fraction of simulated galaxies with at least one off-center clump with that of observations. The left panel shows the comparison between the complete simulation sample (blue) and different observations. Overall the clumpy fraction in NIHAO galaxies follows quite well the clumpy fraction derived by Shibuya et al. (2016) (purple dotted line) and agrees within the error bars with the results of Guo et al. (2015) (black short-long dashed line). The right panel shows the results when galaxies are separated into three stellar mass bins $\log(M_*/M_\odot) < 9.8$, blue; $9.8 < \log(M_*/M_\odot) < 10.6$, green; $\log(M_*/M_\odot) > 10.6$, red.

There is a peak in the clumpy fraction of about 60-70% at $z = 1.5 - 2$ in both simulations and observations. At higher and lower redshifts the clumpy fraction goes down to 50% at $z \sim 3$ and to 40% at $z \sim 0.5$, dropping even further in the simulations to 20% at $z \sim 0.25$, thus matching observations by Murata et al. (2014).

When inspecting the different mass bins separately we still find a good agreement between simulations and observations. Specifically we see that at low redshifts the two less massive bins (blue and green bands and points) agree well with observed clumpy fractions for the same mass ranges. However, the highest mass galaxies (red band) in NIHAO show a clumpy fraction slightly too high but still in agreement with the observations within their error bars. At intermediate redshifts the high and low mass bins agree again well with the observations but the intermediate mass bin (green band) shows a too high clumpy fraction although in agreement with measurements from Wuyts et al. (2012). Finally due to the selection function of the NIHAO galaxies, we do not have any data for the highest mass bin, however, the other two mass bins agree well with the observed clumpy fraction.

Another observable to which we can compare our RT calculations is the fractional contribution of the clump’s UV flux to the total galaxy UV flux. Following Guo et al. (2015) we call this quantity $C_{UV}$. In Figures 7 and 8 we show $C_{UV}$ as a function of the clump size and of the galaxy mass, respectively.

Clump sizes found in the RT calculations of the NIHAO sample are in agreement with observed clump sizes from Förster Schreiber et al. (2011) and with intrinsic clump sizes if the pixel scale is matched to the HST pixel scale (see Appendix B).

Figure 8 shows the comparison between the observed $C_{UV}$ as a function of stellar mass and the NIHAO one in three different redshift bins $0.5 < z < 1$, $1 < z < 2$ and $2 < z < 3$. As in Guo et al. (2015) the clump contribution to the total UV flux of the galaxy is calculated for all galaxies.
Figure 6. Evolution of the fraction of galaxies with at least one observed off-center clump. The left panel shows the evolution of the clumpy fraction for the whole NIHAO sample (blue line) compared to observations from Guo et al. (2015) (black dash-dotted line) and Shibuya et al. (2016) (purple dotted line). The shaded band shows the 1σ scatter. The right panel shows the evolution of the clumpy fraction splitted into different mass bins. Colored bands show the result for our simulations, colored open symbols show the according values from Guo et al. (2015) and colored filled symbols show the results from Shibuya et al. (2016). Grey open symbols show results from other observational studies: diamonds for Wuyts et al. (2012), squares are from Tadaki et al. (2014), pentagons are from Overzier et al. (2009), inverse triangles from Puech (2010), stars from Elmegreen et al. (2007) and dots from Murata et al. (2014).

Figure 7. Clump contribution to the rest-frame dust attenuated UV light of galaxies as a function of clump size for the NIHAO sample (orange dots) and observations from Förster Schreiber et al. (2011) (black dots). The gray dashed line indicates the lower limit on clump sizes set by our clump finding procedure.

not only the clumpy ones. In the two lower redshift bins simulations (orange points) agree well with observations (black squares) within their error bars, while the contribution of UV light from clumps of intermediate mass galaxies in the highest redshift bin is too high in NIHAO. A partial explanation of this excess could be related to the difference in the sample size in this redshift bin: ~70 simulation snapshots vs several thousand galaxies in CANDELS. Furthermore we did not add noise to our images which might lead to recovering more clumps than the observers would do. Despite this discrepancy NIHAO recovers quite well the observed UV light fraction of clumps.

Mock observations of simulated clumpy galaxies have already been studied before using different methods (see e.g. Genel et al. (2012); Moody et al. (2014); Tamburello et al. (2016)) and similar results to ours were found. Genel et al. (2012) converted the SFR of one of their zoom-in cosmological galaxy (s224) to Hα flux, convolving it with a Gaussian of FWHM=0.17 and putting it at redshift z = 2.2 to mimick SINFONI observations. They found that their short lived clumps are consistent with the SINFONI observations of galaxies at redshift z = 2.2. Moody et al. (2014) run the radiative transfer code SUNRISE (Jonsson 2006; Jonsson et al. 2010; Jonsson & Primack 2010) on their sample of 8 cosmological zoom-in simulated clumpy galaxies producing mock HST observations in four different filters. Unlike this work these authors additionally add noise to their images. They find qualitatively very similar results to the ones found here; a clump selection in longer wavelength maps results in lower clump counts compared to shorter wavelength maps. Furthermore these authors find that if clumps are selected in mock observations, stellar mass maps or gas surface density maps the outcome shows vastly different clumps (see e.g. their figure 5). There is only a minority of clumps showing up simultaneously in two or more maps. This is also confirmed by Tamburello et al. (2016) who used the radiative transfer code TRAPHIC (Pawlik & Schaye 2008, 2011) to create Hα maps of ionizing radiation of their non-cosmological simulations of galaxies. These authors add different levels of noise to their mock images and convolve the images with
Gaussians with different values of FWHM to mimic different spatial resolutions. They find that the recovered properties of clumps strongly depend on the noise level and the spatial resolution. Clump sizes and masses can change by more than a factor of 2 depending on the sensitivity and the spatial resolution.

However, in this study we focus on the evolution of the clumpy fraction. This is the first time that such an observational motivated comparison of the clumpy fraction in the light distribution between observations and simulations has been carried out. Our results show that the NIHAO galaxies have a realistic light distribution suggesting that they are a good testbeds for a better understanding of the origin and fate of these luminous clumps. Therefore, in the next sections we analyze the physical properties of the intrinsic clumps.

6.2 Properties of the intrinsic clumps in NIHAO

In order to better understand the physical properties of the clumps, we analyze in detail the intrinsic clumps.

Selecting U-band luminous clumps results in a variety of clumps with different properties for every galaxy and over a vast redshift range \(0 < z < 3\). In total we find 682 U-band clumps in 488 snapshots in the selected redshift range (203 snapshots within \(3 > z > 1\), 155 within \(1 > z > 0.5\) and 130 within \(0.5 > z > 0.25\)).

In Fig. 9 we show some of the properties of NIHAO UV intrinsic clumps. The mass (gas+stars) distributions is shown in the top left panel of the figure. Independently of redshift the mass of clumps in U-band maps always peaks at \(\sim 10^8 M_\odot\) with a maximum clump mass around \(\sim 10^9 M_\odot\) and a minimum around \(\sim 10^7 M_\odot\). This minimum value is mainly due to the resolution of our simulation which fixes the minimum pixel size of our maps (see section 5.1). These results do not change if we select only the 6 most massive galaxies which most closely resemble the observed galaxies as can be seen by comparing the thick dashed lines with the thin dotted lines in fig. 9.

The upper right panel shows the distribution of the clump gas fraction defined as 

\[ f_g = M_{\text{gas}}/(M_{\text{gas}} + M_{\text{star}}). \]

Our clump finding algorithm has no specific lower mass limit. The lower limit on the clump mass is set by the size limit (300 pc) and the surface density of the selected clump. The lowest clump masses we find in the redshift bins are as follows: \(0.25 < z < 0.5: 2.7 \times 10^4 M_\odot, 0.5 < z < 1: 7 \times 10^3 M_\odot, 1 < z < 3: 1.3 \times 10^5 M_\odot\). The clump gas fraction shows a slight trend to higher gas fractions at higher redshifts \((1 < z < 3)\) and a more flat distribution at lower redshifts \((0.5 < z)\). For intermediate redshifts we see a slight bimodality with clumps showing either very low gas fractions or very high ones close to \(f_g = 1\). This is in contrast with Oklopcic et al. (2017) who find a peaked distribution of clump gas fraction with the maximum around gas fractions of \(f_g = 0.3\). This discrepancy comes from the difference in the selection method. We select u-band bright clumps while Oklopcic et al. (2017) select clumps in gas surface density.

Despite the fact that we find giant clumps of masses greater than \(10^7 M_\odot\) the contribution of these clumps to the total baryonic mass of the galaxy disc is less than 1% as shown in the lower left panel of figure 9. The sizes of the clumps found in the NIHAO galaxies range from \(\sim 300\) pc to \(\sim 900\) pc with a median value of \(450\) pc for every redshift bin (see the Appendix for a comparison between observed and intrinsic clump sizes, as well as for the clump size dependence on pixel scale). The lower bound is given again by our resolution (we fixed the minimum effective radius to be 300 pc). Finally most of the clumps we found are round(ish) in shape and sometimes slightly elongated (see, e.g. Fig. 4).

The next question to address is what determines if a galaxy has one or more luminous clumps. In Fig. 10 we show the correlation between stellar mass, SFR, cold gas fraction \((f_g)\) and the mean surface density within the half mass radius \((\Sigma_{\text{hm}})\) and color code each galaxy according to the “morphology” of the light distribution (clumpy=orange, non-clumpy=green).

In the lower triangle of the plot every galaxy is shown at every snapshot in the redshift range \(0 < z < 3\) as a point while in the upper right triangle we show a kernel density estimation of the point distribution. On the diagonal we show the marginal histograms of the property in the according column for clumpy/non-clumpy galaxies.

Clumpy and non-clumpy galaxies mostly separate in two distinct populations in these parameter spaces. We find that clumpy galaxies show high cold gas fractions, are less centrally concentrated (lower value of \(\Sigma_{\text{hm}}\)) and show low and average SFRs and stellar masses. In contrast non-clumpy galaxies are more centrally concentrated, have low gas fractions and are among the highest mass galaxies with high SFR. Qualitative similar correlations are found by Tadaki et al. (2014) (e.g. their Fig. 1) for galaxies from the SXDF-UDS-CANDELS field and by Shibuya et al. (2016) (e.g. their Fig. 7, 8, 9) for HST photo-z and Lyman break galaxies.

There is one notable difference between simulations and observations. From observations one would expect the highest mass, highest star forming galaxies to be clumpy. Here we find that the lower mass, lower star forming galaxies are preferentially clumpy. This can be explained by the fact that our simulations are more centrally concentrated than observed galaxies, and as a consequence the gas in the simulated discs is less prone to gravitational instabilities (Martig et al. 2009). Furthermore, we use non dust-attenuated properties for this plot. As we showed in Fig. 5, the degree of clumpiness in non-dust attenuated images can be different from that of dust-attenuated ones. Some of the most massive galaxies in particular, are not clumpy in the non-dust attenuated maps, but clumpy in the mock radiative transfer images. However, other galaxies show the opposite behavior; they are clumpy in the non-dust attenuated maps and not clumpy in the mock images. Therefore in figure 11 we give the clumpy fraction as a function of stellar mass, SFR, cold gas fraction and mean surface density within the half mass radius for both intrinsic and observed clumps, as well as the observational data from Tadaki et al. (2014). For our intrinsic clumps we find a negative-correlation between clumpy fraction and stellar mass, SFR and mean central surface density and a correlation of clumpy fraction with the cold gas fraction of the galaxies. While intrinsic clumps show a strong evolution with all four galaxy parameters (anticorrelation with the galaxy’s stellar mass, SFR and central surface density and correlation with the cold gas fraction) we do not find such an evolution for our observed clumps. This is due to the beforehand mentioned dust attenuation. Our
Figure 8. Average intrinsic clump contribution to the rest-frame dust attenuated UV light of galaxies as a function of stellar mass in three different mass bins. The observations from Guo et al. (2015) are shown as black squares and the results from NIHAO are shown with orange dots.

Figure 9. Clump properties for three different redshift bins ($z < 0.5$, $0.5 < z < 1$, $1 < z < 3$) for u-band selected clumps. The top left panel shows the total clump mass, the top right shows the clump gas fraction, the bottom left panel shows the clump mass as a fraction of galaxy mass and the bottom right panel shows the clumps effective radii with the solid vertical orange line indicating the lower limit of clump sizes set by our selection criteria. Thick dashed lines show the results for the whole galaxy sample while thin dotted lines show results for only the 6 most massive galaxies. The colored solid lines in the top left panel show the median mass of clumps in the whole sample and the dotted lines show the median mass of clumps for the most massive galaxies.
Figure 10. Properties of host galaxies and their correlation with clumpy morphology for all galaxies and all redshifts in our sample. We show correlations of stellar mass (left column), SFR (second column), cold gas fraction (third column) and the mean surface density within the half mass radius (right column) with each of the other quantities and distinguish clumpy from non-clumpy galaxies. Red colored points and lines show galaxies with a clumpy morphology (at least one off center clump) and green squares/lines show non clumpy galaxies. The lower left triangle shows all snapshots for all galaxies with single dots while the upper right triangle shows a kernel-density estimation of the point distribution. The diagonal shows the marginal histogram of the property of the given column.

6.3 Clumps in light or clumps in mass?

A lot of discussion is going on whether the observed clumps in high-redshift galaxies represent self-bound clumps of stars orbiting within the disc or if they are simply a concentration of luminous young stars with practically non dynamical influence on the disc.

To start to answer this question in the upper panel of observed clumps, however, show very good agreement with the observational data, which also shows no strong correlation between the clumpy fraction and galaxy parameters. This result further supports the need for a careful modeling of dust obscuration when comparing galaxy morphologies between simulations and observations.
Figure 11. The fraction of clumpy galaxies as a function of host galaxy parameters for intrinsic and observed clumps in comparison to observations from Tadaki et al. (2014). From left to right we show the clumpy fraction as a function of stellar mass $M_*$, SFR, cold gas fraction and the mean surface density within the half mass radius.

Figure 12. Mean number of clumps per galaxy for clumps selected in different wavelength bands. The upper panel shows the mean number of clumps for clump selected in the u-band (blue dots), the v-band (green lower triangles), the i-band (red squares) and the h-band (black upper triangles). The lower panel shows a comparison of the mean number of clumps selected in the u-band (blue dots) with clumps selected in the gas surface density maps (purple diamonds) and the stellar surface density maps (orange stars). The points are slightly offset to avoid overlap.

Figure 12 we looked at the clumpiness of stars in different wavelength bands (u, v, i, h). It is clear from the plot that moving to longer wavelength the disc clumpiness tend to disappear, and practically no clumps are detected in the h band.

This seems to suggest that observed and simulated clumps in the non-dust attenuated u-band are not actually bound structures of stars. This result is even more clear in the lower panel of figure 12 where we look at the presence (or lack thereof) of clumps in maps constructed for different quantities: u-band luminosity, gas and stellar masses. As already noted in figure 4 clumps in the u-band match clumps in the gas surface density, but when we look at the stellar mass maps they are extremely smooth and no clumps are detected by our algorithm in practically any of our galaxies.

This is confirmed by a visual inspection of one of the NIHAO galaxies (same already shown in fig 4) in figure 13, where there is clearly a lack of any substructure in the stellar mass map. This is maybe the most important result of our study. Despite having galaxies as clumpy as the observed ones in light maps, we found no evidence of any self-bound stellar structure in the mass maps of the same galaxies. We are facing here luminous clumps and not dynamical ones. The good match between clumps in the u-band and the gas surface density maps suggests that observed clumps are simply a manifestation of localized (clumpy) star formation regions, as also observed in redshift zero galaxies.

This is also confirmed by the life-time of the these luminous clumps: most of the clumps disappear between two consecutive simulation snapshots in NIHAO, setting an upper limit to their dissolution time of about 200 Myr, less than one dynamical time of the galaxy. Figure 14 shows the fraction of clump stars still close together in consecutive snapshots ($\sim 200$ Myr). We track the star particles of every clump identified in a given snapshot via their particle IDs. In this manner, we evaluate how many stellar particles are still within a region of 1$R_{eff}$ or 2$R_{eff}$ around the clumps center of mass in the next snapshots. We show the median fraction of clump stars still within a region of 1$R_{eff}$ with a blue line and the according 16th and 84th percentile as a blue shaded region. The yellow line and yellow shaded region give the the median fraction of clump stars still within a region of 2$R_{eff}$. With the exception of a few of the most massive clumps, we find that all clumps lose more than 90% of their mass between two consecutive snapshots.

These results are at odds with previous works (Dekel et al. 2009b; Bournaud & Elmegreen 2009; Bournaud et al. 2014; Ceverino et al. 2010, 2015; Mandelker et al. 2014), which suggested that clumps are gravitationally bound structures that migrate towards the center under the influence of dynamical friction. In support of this picture there is the observation of a color gradient of clumps as a function of distance from the galaxy center ( Förster Schreiber et al. 2011; Shibuya et al. 2016), with clumps closer to the cen-
Figure 13. Face-on maps of u-band luminosity (upper left), SFR surface density (lower left), cold gas surface density (upper right) and stellar mass surface density maps (lower right). The stellar mass surface density map is extremely smooth. White contours show again the clumps selected in the u-band luminosity map.

Figure 14. Fraction of clump stars still close together after 200Myr. For every identified clump we show the fraction of clump stars still close together in the following snapshot. The blue line shows the median fraction of clump stars still within a region of $1R_{\text{eff}}$ around the clump’s center of mass while the yellow line shows the median fraction of clumps stars still within $2R_{\text{eff}}$.

Figure 15 shows the average age of simulated clumps as a function of their distance from the center. The stellar age of a clump is the (mass weighted) average age of all stars within the clump, which of course is a mix of stars actually formed in the clump and the underlying stellar population. As reference, we show in the same figure the mean stellar age of the global stellar disc population as a function of distance from the galactic center. The gradient is quite weak with a slight increase of stellar ages in the outskirts of the disc, consistent with expectations from stellar migration (El-Badry et al. 2016).

We find that most clumps are in the central parts of the galaxy within 5 kpc from the center, (but keep in mind that we excluded the innermost 1 kpc from our analysis). In NIHAO we find a wide range of clump stellar ages from ~200 Myr up to about 2 Gyr in the lowest redshift snapshots in agreement with observed ages of stellar populations in high redshift clumps (Elmegreen & Elmegreen 2005; Elmegreen et al. 2009; Förster Schreiber et al. 2011; Genzel et al. 2011; Guo et al. 2012; Wayts et al. 2012). Stellar ages of clumps are generally slightly younger than the underlying mean age of the disc stars, consistent with the picture of clumps being sites of intense star formation.

Interestingly we recover the observed trend of clumps in the outskirts being younger than clumps in the central parts of the galaxies. Contrary of what was suggested by some authors, who ascribe this gradient to a migration of clumps, we find that this effect is strongly due to a selection bias. Clumps in the central parts of the galaxy include more underlying disc stars which increases the mean stellar age while in the outskirts the density of the stellar disc decreases and clumps are less polluted by disc stars and thus appear younger.

Although we recover the observed trend of clump ages as a function of radius, this is not a signature of clumps spiraling inwards and moving to the center as we will show in the next section.

6.4 The evolution and final fate of light clumps

If light clumps were self bound structures of stars it would be natural to expect them to spiral in under the influence of dynamical friction. Previous studies have indeed argued that high redshift clumps can be responsible for the building of bulges at high redshift (Ceverino et al. 2010; Bournaud et al. 2014).

As discussed in the previous section our simulations suggest a quite different scenario, and hence it is interesting to ask what is the evolution of our luminous (but not bound) clumps.

For every clump in every galaxy we track its evolution by calculating the mean galacto-centric distance of all its stars at later times ($r(z)$), and we normalize this number by the distance at the time the clump was firstly detected ($r(z_{\text{form}})$). For stars moving inwards we expect the ratio $r(z)/r(z_{\text{form}})$ to be below one and the opposite for particles moving outwards.

Figure 16 shows the evolution of the ratio $r(z)/r(z_{\text{form}})$ as a function of redshift for all our NIHAO galaxies. In the plot we also show the same quantity for a “control sample” of disc stars; for each clump with a given amount of stars, we select an identical number of disc stars at the same galacto-centric distance as the clump of interest at the time of its first detection. The shaded region shows the 16th and 84th percentile. The orange dots in Fig. 16 show that there is no preferential inwards migration for clump stars. If anything there is a slight trend for clump stars to migrate outwards.
When compared to the control sample of disc stars, clump stars do not show any particular difference, they behave in a very similar manner. Similar results for the lack of inward migration of clumps are found by Oklopcić et al. (2017) who looked at the angular momentum change between the final and initial snapshot in which a clump is visible. These authors do find a roughly equal likelihood for clumps to lose and to gain angular momentum. Thus, these results indicate that clump migration is not governed by dynamical friction but rather by gravitational torquing or tidal forces.

Since we plot the average distance, it could still be possible that a substantial migration of stars inward is compensated by a same amount of stars moving outwards. Therefore, we look in Fig. 17 at the mass contribution from clump stars to the galaxy bulge at $z = 0$. We first decompose each galaxy at redshift zero into a disc and spheroidal component using the same procedure described in Obreja et al. (2016). All stars marked as belonging to the spheroid and having a galacto-centric distance smaller than 1 kpc are regarded as bulge stars.

We then calculate the fraction of disc and bulge mass due to stars that have been found in clumps at some earlier point in time. In Figure 17 we plot the ratio of mass from clumps in the bulge $M_{\text{clump, bulge}}$ to mass from clumps in the disc $M_{\text{clump, disc}}$ as a function of bulge to disc ratio $M_{\text{bulge}}/M_{\text{disc}}$ of the galaxy. Similar to the previous plot we show clump stars as orange dots and our control sample as green squares. The dashed grey line shows the 1:1 relation. Overall clump stars seems to be equally distributed between the bulge and the disc at $z = 0$. Furthermore when compared to the control sample clump stars seems to have the same final fate as any other stars in the disc.

We can then conclude that, consistently with not being gravitational bound, light clumps in high redshift galaxies do not preferentially move inwards as time goes by and, do not preferentially contribute to the bulge growth.

7 SUMMARY

We use 19 galaxies from the high mass end ($M_*>10^{9} M_{\odot}$ at $z \sim 1.5$) of the NIHAO sample to analyze them in detail for their clumpy morphology and quantify the clumpy fraction of this simulation suite in the redshift range $0 < z < 3$. The NIHAO sample is a suite of high-resolution cosmological hydrodynamical simulations of galaxies in the mass range $10^{9} M_{\odot} < M_{200} < 4 \times 10^{12} M_{\odot}$ which reproduces realistic galaxy properties over this huge range of galaxy masses. Unlike most other theoretical studies which looked for giant clumps in galaxies we do not select clumps in gas or stellar mass maps but we select clumps in luminosity maps. We apply two different selection methods: intrinsic clumps are selected in the non dust attenuated rest frame $u$-band images closely matching the observational selection method, while for observed clumps we run the radiative transfer code GRASIL-3D (Domínguez-Tenreiro et al. 2014)) on the 488 snapshots of our sample to create realistic mock HST observations of the galaxies. In this way we can directly compare the clumpy fraction of the NIHAO suite to the observed clumpy fraction from Guo et al. (2015) and Shibuya et al. (2016).

Our main findings can be summarized as follows:

- Comparing the observed clumpy fraction, the number of galaxies/snapshots with at least one off-center clump, of our RT images to the observed clumpy fraction of Guo et al. (2015), Shibuya et al. (2016) we find very good agreement between our simulations and the observations (see figure 6). The NIHAO sample can well reproduce the observed number of clumpy galaxies and their evolution with redshift and perfectly matches the correlation of the clumpy fraction of galaxies with stellar mass (compare figure 11). Sizes of clumps found in the NIHAO sample agree well with observed clump sizes (Fig. 7). Furthermore, we recover the observed UV-light contribution of clumps to the total UV-light of the galaxy with ~ 30% of the light coming from clumps.
- Selecting intrinsic clumps in the rest frame $u$-band images results in clump masses of few times $10^{9} M_{\odot}$ to $10^{10} M_{\odot}$.
sizes of about 300 pc to 900 pc and gas fractions spanning a wide range from 0.1 to 0.9. These findings agree well with observed sizes and masses of giant clumps. However, although clumps are prominent in u-band luminosity maps they contribute only a small fraction of less than 1% to the disc mass (compare figure 9).

- For this work intrinsic clumps are selected in stellar light and can only be found in young stars showing up in the the u-band. Selecting clumps in longer wavelength bands like the v-, h- or i-band the number of clumps found drops to zero (see figure 12) and we can not find clumps in stellar mass at all. This recovers the findings of Wuyts et al. (2012) that clumps are only present in short wavelength images but not in the inferred stellar mass maps (compare also figure 13). Thus, we find clumpy star formation but no clumpy stellar discs in the NIHAO galaxies.

- Comparing the properties of intrinsic clumpy and non-clumpy galaxies in figure 10 we find a bimodality between these two. Clumpy galaxies show high cold gas fractions, are less centrally concentrated and show low and average SFRs and stellar masses. In contrast non-clumpy galaxies are more centrally concentrated, have low gas fractions and are among the highest mass galaxies with high SFR. These correlations for intrinsic clumps are strongly altered if we use observed clumps to divide our galaxy sample into clumpy and non-clumpy galaxies as was shown in figure 11. Especially the clumpy fraction as a function of stellar mass for our observed clumps is in very good agreement with the observed relation. Thus, we conclude that a careful modeling of dust obscuration has to be taken into account for a direct comparison of galaxy morphologies between simulations and observations.

- The mean mass weighted stellar ages of clumps in the simulations show the same trend as observed color gradients of clumps (e.g. Shibuya et al. (2016)). Clumps in the outskirts of the galaxies are younger and clumps in the center are almost as old as the underlying mean mass weighted stellar age of the disc stars (see figure 15). This trend can be
attributed to the fact, that the stellar density of disc stars is lower in the outskirts and higher in the center, thus when selecting clumps in images the contribution/pollution of disc stars to the clump is higher in the center than in the outskirts. That is why the mean mass weighted stellar ages of clumps and stellar disc are more similar in the galaxy center than in the outskirts.

- We find that clumps in the NIHAO sample do not spiral inwards and do not contribute much mass to the bulge. Clumps get quickly disrupted and disperse. They lose about 90% of their mass in less than 200 Myr (see fig. 14). We trace the stars of the clumps through time down to redshift zero and follow their mean radius and do not find any net inward migration of clump stars. Indeed, we find that clump stars and disc stars behave the same way, both do not show signs of a net inward migration as we have shown in figure 16 and 17. Furthermore, we quantify how much mass these stars contribute to the bulge and to the disc of the galaxies. Clump stars and randomly selected disc stars contribute the same mass to the bulge. Thus we do not see any indications that clumps in NIHAO would contribute to preferentially build up the bulge.

ACKNOWLEDGMENTS

We thank the referee for valuable comments that improve the readability of the paper. The authors like to thank Hans-Walter Rix for fruitful discussions and very helpful comments on this work. This research made use of the PYNBODY package Pontzen et al. (2013) to analyze the simulations and used astrodendro, a Python package to compute dendrograms of Astronomical data (http://www.dendrograms.org/) to find clumps. The authors acknowledge support from the Sonderforschungsbereich SFB 881 The Milky Way System (subproject A2) of the German Research Foundation (DFG). Simulations have been performed on the THEO clusters of the Max-Planck-Institut fuer Astronomie at the Rechenzentrum in Garching and the HYDRA and DRACO cluster at the Rechenzentrum in Garching. Further computations used the High Performance Computing resources at New York University Abu Dhabi. We greatly appreciate the contributions of all these computing allocations.

APPENDIX:

A: Sensitivity to detection threshold

In this section we analyse how the properties of intrinsic clumps change if we change the sensitivity of our clump finding algorithm. Our fiducial clump selection picks up clumps in the u-band images which stick out at least 3σ above the mean u-band luminosity of the 10 kpc x 10 kpc images. In order to quantify the robustness of our results we rerun our clump finding algorithm on all our snapshots with a reduced threshold of 3σ and with an increased threshold of 4σ. In figure A1 we compare the clump properties found with all three thresholds. The upper panel shows the clump masses found, the middle panel shows clump gas fractions and the lower panel shows clump sizes. We do not see any differences in the properties of the clumps identified using different thresholds. Clump masses of all three selection thresholds peak around 10^8 M⊙.

In this section we analyse how the properties of intrinsic clumps change if we change the sensitivity of our clump finding algorithm. Our fiducial clump selection picks up clumps in the u-band images which stick out at least 3σ above the mean u-band luminosity of the 10 kpc x 10 kpc images. In order to quantify the robustness of our results we rerun our clump finding algorithm on all our snapshots with a reduced threshold of 3σ and with an increased threshold of 4σ. In figure A1 we compare the clump properties found with all three thresholds. The upper panel shows the clump masses found, the middle panel shows clump gas fractions and the lower panel shows clump sizes. We do not see any differences in the properties of the clumps identified using different thresholds. Clump masses of all three selection thresholds peak around 10^8 M⊙. However, we see as would have been expected that a clump selection with a threshold of 2σ picks up much more clumps compared to the 3 and 4σ selections. The same is true for the clump selection in the radiative transfer images. Figure A2 shows the evolution of the clump fraction for a selection threshold of 2σ above the mean flux in the given band (upper panel) and for a selection threshold of 3σ (lower panel) as opposed to our fiducial selection threshold of 3σ. For a selection threshold of 2σ above the mean flux we find a clumpy fraction which is well in agreement with observations and the one obtained with a threshold of 3σ. By visual inspection of the clumps found we verify that a selection threshold of 2σ picks up a significant amount of spurious, low surface brightness clumps in galaxies which

Figure A1. Clump properties for three different clump selection thresholds ($2\sigma$, $3\sigma$, $4\sigma$) for u-band selected clumps. The top left panel shows the total clump mass, the middle panel shows the clump gas fraction and the bottom left panel shows the clumps effective radii with the solid vertical orange line indicating the lower limit of clump sizes set by our selection criteria. The colored solid lines in the top left panel show the median mass of clumps and the dotted lines show the mean mass of clumps.

Figure A2. Evolution of the fraction of galaxies with at least one observed off-center clump for a selection threshold of $2\sigma$ (upper panel) and $4\sigma$ (lower panel). Both panel show the evolution of the clumpy fraction for the whole NIHAO sample (blue line) compared to observations from Guo et al. (2015) (black dash-dotted line) and Shibuya et al. (2016) (purple dotted line). The shaded band shows the $1\sigma$ scatter.

by eye would not have been classified as clumpy. This is the reason for the increased clumpy fraction for this threshold value. The agreement between the threshold value of 3 and $4\sigma$ makes us conclude that our fiducial selection threshold of $3\sigma$ works properly.

B: Dependence of clump size on pixel scale
Recent work by Behrendt et al. (2016) and by Tamburello et al. (2016) found that clump sizes depend on the chosen spatial resolution and giant clumps would break up into smaller clumps if the spatial resolution is increased. In this section we test what happens to the clump sizes found in this study if the spatial resolution is changed. For our intrinsic clump selection we have chosen a pixel scale which is comparable to the physical resolution of our simulation. Therefore, we are already using the highest spatial resolution our simulations allow for. However, we change the pixel scale of our intrinsic clump selection to match the one of our RT runs (HST spatial resolution). Accordingly, we changed the minimum pixel per clump of our clump finder from 30 to 5
Finally, clump sizes of intrinsic clumps found in the images with HST pixel scale agree well with clump sizes found in the RT run of the same pixel scale.

C: Images

Figure A3. Comparison of clump sizes for intrinsic clumps and clumps in the RT runs for different pixel scales. The black line shows our fiducial intrinsic clump selection, the orange line shows clump sizes for intrinsic clump selection with the HST pixel scale, the blue line shows clump sizes from our fiducial clump selection in the RT run and the green line shows clump sizes for RT runs with doubled resolution (half the pixel scale of HST). The colored vertical lines show the according median clump sizes and the vertical gray dashed line shows our resolution limit on clump sizes.
Figure A4. Impression of the cold gas surface density. From left to right: increasing stellar mass at redshift 0, from bottom to top increasing time. Lower bounds of gas surface densities are set to $10 M_{\odot} \text{pc}^{-2}$ and maximum values are set to $300 M_{\odot} \text{pc}^{-2}$. 
Figure A5. Impression of RGB composite images. From left to right: increasing stellar mass at redshift 0, from bottom to top increasing time.
Figure A6. Impression of the outcome of the RT runs. From left to right: increasing stellar mass at redshift 0, from bottom to top increasing time. For snapshots in the redshift range $3 > z > 2$ we select the F775W filter, for $2 > z > 1$ we select the F606W filter and for $z < 1$ we select the F435W filter to detect clumps. This filter selection roughly corresponds to the rest frame UV at these redshifts (Guo et al. 2015).
