ABSTRACT
Betweenness centrality (BC) is a crucial graph problem that measures the significance of a vertex by the number of shortest paths leading through it. We propose Maximal Frontier Betweenness Centrality (MFBC): a succinct BC algorithm based on novel sparse matrix multiplication routines that performs a factor of \( p^{3/3} \) less communication on \( p \) processors than the best known alternatives, for graphs with \( n \) vertices and average degree \( k = n/p^{3/3} \). We formulate, implement, and prove the correctness of MFBC for weighted graphs by leveraging monoids instead of semirings, which enables a surprisingly succinct formulation. MFBC scales well for both extremely sparse and relatively dense graphs. It automatically searches a space of distributed data decompositions and sparse matrix multiplication algorithms for the most advantageous configuration. The MFBC implementation outperforms the well-known ComBlAS library by up to 8x and shows more robust performance. Our design methodology is readily extensible to other graph problems.

Betweenness centrality, sparse matrix multiplication, parallel algorithm, communication cost

1 INTRODUCTION
Graph processing underlies many computational problems in machine learning, computational science, and other disciplines [32]. Yet, many parallel graph algorithms struggle to achieve scalability due to irregular communication patterns, high synchronization costs, and lack of spatial or temporal cache locality. To alleviate this, we pursue the methodology of formulating scalable graph algorithms via sparse linear algebra primitives.

In this paper, we focus on betweenness centrality (BC), an important graph problem that measures the significance of a vertex \( v \) based on the number of shortest paths leading through \( v \). BC is used in analyzing various networks in biology, transportation, and terrorism prevention [4]. The Brandes BC algorithm [10, 36] provides a work-efficient way to obtain centrality scores without needing to store all shortest-paths simultaneously, achieving a quintessential reduction in the memory footprint. To date, most parallelizations of BC have leveraged the breadth first search (BFS) primitive [5, 18, 23, 33, 35, 42, 43], which can be used to implement Brandes algorithm on unweighted graphs [26].

Contrarily to these schemes, we propose to use the Bellman-Ford shortest path algorithm [7, 21] to compute shortest distances and multiplicities. This enables us to achieve maximal parallelism by simultaneously propagating centrality scores from all vertices that have determined their final score, starting with the leaves of the shortest path tree. We refer to this approach as the Maximal Frontier Betweenness Centrality (MFBC) algorithm, because the frontier of vertices whose edges are relaxed includes all vertices that could yield progress. We prove the correctness of the new scheme for computing shortest distances, multiplicities, and centrality scores with a succinct path-based argument applied to factors of partial centrality scores, simplifying the Brandes approach [10].

Each set of frontier relaxations in MFBC is done via multiplication of a pair of sparse matrices. These multiplications are defined to perform the desired relaxation via the use of monoids, monoid actions, and auxiliary functions. This algebraic formalism enables concise definition as well as implementation of MFBC via the Cyclops Tensor Framework (CTF) [41]. CTF is a distributed-memory library that supports tensor contraction and summation; operations that generalize the sparse matrix multiplications MFBC requires. By implementing a robust set of sparse matrix multiplication algorithms that are provably communication-efficient, our framework...
We start by presenting the used graph notation. We represent an

\[
G = (V, E);
\]

where \( V \) and \( E \) are sets of vertices and edges; \( \epsilon \) if \( G \) is weighted, then \( G = (V, E, w) \) where \( w : E \to \mathbb{W} \).

We present a communication cost analysis of the sparse matrix

multiplication, as well as of the MFBC algorithm surpasses

the state-of-the-art. In our evaluation, the new algorithm obtains

up to 8x and measure a reduction in the runtime communication

costs. While CombBLAS is still faster in some cases, our implementation is general to weighted graphs and attains

more consistent performance across different graphs.

### Table 1: Symbols used in the paper; \( v, s, t \in V \) are vertices.

| Symbol | Description |
|--------|-------------|
| \( G \) | a given graph, \( G = (V, E) \); \( V \) and \( E \) are sets of vertices and edges; if \( G \) is weighted, then \( G = (V, E, w) \) where \( w : E \to \mathbb{W} \). |
| \( n, m \) | numbers of vertices and edges in \( G \); \( n = |V| \), \( m = |E| \). |
| \( \rho(v) \) | degree of \( v \); \( \tau \) and \( \rho \) are the average and maximum degree in \( G \). |
| \( d \) | diameter of a given graph \( G \). |
| \( A \) | adjacency matrix of \( G \). |
| \( \lambda(v) \) | betweenness centrality of \( v \). |
| \( \tau(s, t) \) | shortest path distance between \( s, t \). |
| \( \sigma(s, t) \) | number of shortest paths between \( s, t \). |
| \( \delta(s, v) \) | dependency of \( v \) on \( s \); \( \delta(s, v) = \sum_{u \in V} \sigma(s, u, v) / \sigma(s, t) \). |
| \( \pi(s, v) \) | the set of immediate predecessors of \( v \) in shortest paths from \( s \) to \( v \). |

General BC

Semirings

A semiring is defined as a tuple \( S = (\oplus, \otimes) \); \( T \) is a set equipped with two binary operations \( \oplus, \otimes \) such that \( (T, \otimes) \) is a commutative monoid and \( (T, \oplus) \) is a monoid. Semirings are often used to develop graph algorithms based on linear algebra primitives. In this work, we use monoids to enable a succinct formulation.

### 2.3 Algebraic Graph Algorithms

Most graph algorithms can be expressed via matrix-vector or matrix-matrix products. As an introductory example, we consider BFS [16]. BFS starts at a root vertex \( r \) and traverses all nodes connected to \( r \) by one edge, then the set of nodes two edges away from \( r \), etc. BFS can be used to compute shortest paths in an unweighted graph, which we can represent by an adjacency matrix with elements \( A_{ij} \in \{0, 1\} \). In this case, BFS would visit each vertex \( v \) and derive its distance \( r(v, r) \) from the root vertex \( r \).

Algebraically, BFS can be expressed as iterative multiplication of the sparse adjacency matrix \( A \) with a sparse vector \( x_0 \) over the tropical semiring, \( (\oplus, \otimes) \). The tropical semiring is a commutative monoid \( (\mathbb{W}, \min) \) combined with the addition operator (replacing the monoid \( (\mathbb{R}, +) \) and multiplication operator that are usually used for the matrix-vector product). The BFS algorithm would initialize \( x' = 0 \) (the initial distance to \( r \) is 0) and any other element of \( x_0 \) is \( \infty \) (i.e., the initial distance to any other element is \( \infty \)). Each BFS iteration computes \( x_{i+1} = x_i \cdot (\min, +) \cdot A \), then screens \( x_{i+1} \) retaining only elements that were \( \infty \) in all \( x_j \) for \( j < i \). The sparsity of the vector is given by all entries which are not equal to \( \infty \), the additive identity of the tropical semiring.

### 2.4 Brandes’ Algorithm

BC derives the importance of a vertex \( v \) using the number of shortest paths that pass through \( v \). Let \( \hat{\sigma}(s, t) \) be the number of shortest paths between vertices \( s, t \), and let \( \sigma(s, t, v) \) be the number of such paths that pass via \( v \), \( \sigma(s, t, v) = \sigma(s, t, v) + \sigma(s, t) = 0 \). The centrality score of \( v \) is defined as \( \lambda(v) = \sum_{s, t} \sigma(s, t, v) / \sigma(s, t) \). Define the dependency of a source vertex \( s \) on \( v \) as \( \delta(s, v) = \sum_{t} \sigma(s, t, v) / \sigma(s, t) \). Then, let \( \lambda(v) = \sum_{s} \delta(s, v) \) where \( \delta(s, v) \) satisfies the recurrence: \( \delta(s, v) = \sum_{w} \delta(s, w) \cdot \sigma(s, v, w) / \sigma(s, t) \). Brandes’ scheme [10] uses this recurrence to compute \( \lambda(v) \) in two passes. First, multiple concurrent BFS traversals compute \( \sigma(s, v) \) and \( \delta(s, v) \), \( v \in V \), obtaining a predecessor tree over \( G \). Second, the tree is traversed backwards (from the highest to the lowest distance) to compute \( \delta(s, v) \) and \( \lambda(v) \) based on the equations above.

Brandes’ algorithm has been a subject of many previous efficiency studies [5, 15, 23, 24, 28, 29, 33, 36–38, 42, 43, 46, 47]. Some efforts considered distributed memory parallelization [8, 19, 20]. The only distributed memory BC implementation done using matrix primitives we are aware of exists in CombBLAS [11]. To the best of our knowledge, we provide the first communication cost analysis of a BC algorithm, and the first implementation leveraging 3D sparse matrix multiplication. A mix of graph replication and blocking have been previously used for BC computation [8], but for any \( k \geq j \) with \( s(i) \in S \) for each \( i = j : k \). We denote the elementwise application of a monoid operator to a pair of matrices as \( A \oplus B \) for any \( A, B \in \mathbb{R}^{m \times n} \).

Monoids

A monoid \( (S, \oplus) \) is a set \( S \) closed under an associative binary operation \( \oplus \) with an identity element. A commutative monoid \( (S, \oplus) \) is a monoid where \( \oplus \) is commutative, and

\[
\bigoplus_{i=j}^{k} s(i) = s(j) \oplus s(j+1) \oplus \cdots \oplus s(k)
\]
We now describe our algebraic maximal frontier BC algorithm with lower weight; if the weights of \( x \) and \( y \) are equal, then their multiplicities are summed.

4.1 MFBF: Computing Shortest Paths

The core idea behind MFBF is to use and extend Bellman-Ford so that constitutes the multpath frontier: it contains the multpaths of the nodes whose multiplicity changed in the previous iteration. Here, each element-wise operation acts on a multpath (an element from \( T \)) and an edge weight (an element from \( A \)); we refer to this operation as the Bellman-Ford Action.

Formalism: Our MFBF algorithm (Algorithm 1) iteratively updates a matrix \( T \) of multpaths via forward traversals from each source vertex. This is done in the inner loop (lines 3-7) where the \( T \) tensor with partial multiplicity scores is updated in each iteration using Bellman-Ford Action \( \bullet_{(\ominus,f)} \) where the function \( f \) is defined as

\[
 f : \mathbb{M} \times \mathbb{W} \rightarrow \mathbb{M}, \quad f(a,w) = (a, w + w, a, m).
\]

\( f \) is interpreted as an action of the monoid \((\mathbb{W},+)\) on the set \( \mathbb{M} \). This concept generalizes to \( n \times k \) matrices, where we have a monoid action \( \bullet_{(\ominus,f)} \) with monoid \((\mathbb{W}^n,\oplus)\) on the set \( \mathbb{M}^n \times k \).

4.1.3 Algorithm and Correctness.

Intuition: We obtain shortest path distances and multiplicities via MFBF (Algorithm 1): a Bellman-Ford variant that relaxes all edges adjacent to vertices whose path information changed in the previous iteration. 

The edge relaxation is done via matrix multiplication of the adjacency matrix and a multpath matrix, which appends edges to the existing frontier of vertices via function \( f \), then uses the multpath operator \( \oplus \) to select the minimum distance new set of paths, along with the number of such new paths. This partial multiplicity score is subsequently accumulated to \( T \) if it corresponds to a minimum distance path from the starting vertex. Note that the multiplicity is set to 1 (line 1) even if the corresponding weight equals \( \infty \). Thus, such edges are considered in the main loop (line 3). When a path to \( v \) with a finite distance is found, it replaces such a multiplicity.

Algorithm 1 [\( T = \text{MFBF}(A, \vec{\delta}) \)]

\[
\text{Input:} \quad A: n \times n \text{ adjacency matrix, } \vec{\delta} \text{ list of starting } n_s \text{ vertices}
\]

\[
\text{Output:} \quad T: \text{multpath matrix of distances and multiplicities from vertices } \vec{\delta}
\]

1. \( T(s,v) := (A(\vec{\delta}(s),v),1) \) \( \triangleright \) Initialize multpaths.
2. \( T = T \) \( \triangleright \) Initialize multpath frontier
3. \( \text{while } T(s,v) \neq (\infty,0) \text{ for some } s, v \) do
   4. \( T := T \bullet_{(\ominus,f)} A \) \( \triangleright \) Explore nodes adjacent to frontier
   5. \( T := T \oplus T \) \( \triangleright \) Accumulate multiplicities
5. Determine new frontier based on updates to the vertex path information \( \triangleright \)
6. if \( T(s,v), m > 0 \lor T(s,v), w > T(s,v), w \) then \( T(s,v) := (\infty,0) \)
7. end while

Formalism: We can prove that Algorithm 1 will output the correct shortest distances and multiplicities.

Lemma 4.1. For any adjacency matrix A and vertex set \( \vec{\delta}, T = \text{MFBF}(A, \vec{\delta}) \) satisfies \( T(s,v) = (\tau(s,v), \sigma(s,v)) \).
Formalism: The elements of $\zeta$ have computed the algorithm and leads to a simpler proof of correctness. Once we have computed $\zeta$, we can construct $\delta$ simply via multiplication by elements of $\sigma$, which we have already computed via MFBF.

Proof. Let the maximum number of edges in any shortest path from node $s$ be $d$. For $j \in 1 : d, v \in V \setminus \{s\}$, let each $h_j(s,v) \in M$ be a multpath corresponding to the weight and multiplicity of all shortest paths from vertex $s$ to vertex $v$ containing up to $j$ edges (if there are no such paths, $h_j(s,v) = (\infty, 0)$). Further, let each $h_j(s,v) \in M$ be a multpath corresponding to the weight and multiplicity of all shortest paths from vertex $s$ to vertex $v$ containing exactly $j$ edges (if there are no such paths, $h_j(s,v) = (\infty, 0)$). Note that $h_0(s,v)$ contains the weight and multiplicity of all shortest paths from vertex $s$ to vertex $v$, since no shortest path can contain more than $d$ edges, therefore $h_d(s,v) = (\tau(s,v), \bar{\sigma}(s,v))$. Further, by the definition of $\odot$, we have $h_j(s,v) = \bigoplus_{q=1}^j h_j(s,v)$. Let $T_j(s,v)$ be the state of $T(s,v)$ after the completion of $j - 1$ iterations of the loop from line 3. We show by induction on $j$ that $T_j(s,v) = h_j(s,v)$ and $T_{j+1}(s,v) = \hat{h}_j(s,v)$, and subsequently that after $d - 1$ loop iterations, $T_d(s,v) = h_d(s,v)$. For $j = 1$, no iterations have completed and we have $T_1(s,v) = (A(s,v), 1)$, as desired. For the inductive step, we show that given $T_j(s,v) = h_j(s,v)$, one iteration of the loop on line 3 yields $T_{j+1}(s,v) = h_{j+1}(s,v)$. We note that by definition of $\odot$, only paths with a minimal weight $T_j(s,u).w$ contribute to $T_{j+1}(s,v)$, and (again by definition of $\odot$),

$$T_{j+1}(s,v).m = \sum_{u \in P} w.m,$$

where $P = \{T_j(s,u) : T_j(s,u).w + A(s,v) = T_{j+1}(s,v).w\}$, i.e., $T_{j+1}(s,v).m$ is the sum of the multiplicities of all the minimal weight paths from vertex $s$ to $v$ consisting of $j + 1$ edges. Our expression for $P$ is valid, since each must consist of a minimal weight path of $k$ edges from vertex $s$ to some vertex $u$, which is given by $T_j(s,u)$ and another edge $(a,v)$ with weight $A(u,v)$.

4.2 MFBr: Computing Centrality Scores

Once we have obtained the distances and multiplicities of shortest paths from a set of starting vertices via MFBr, we can begin computing the partial centrality scores. We perform this by traversing the shortest-path tree from the leaves to the root. This time, the maximal frontier is composed of all vertices whose leaves have just reported their centrality scores.

4.2.1 Centpath Monoid.

Intuition: To propagate partial centrality scores, we use centpaths, which store a distance, a contribution to the centrality score, and a counter. Similarly to the multpath monoid, we define a centpath monoid $(C, \odot)$ with an operator that acts on any two centpaths $x$ and $y$, and returns the one with lower weight; if the weights of $x$ and $y$ are equal, then the partial centrality factors and counter values of the two centpaths are summed.

Formalism: Instead of working with partial centrality scores $\delta(s,v)$ (defined in Section 2.4) we work with partial centrality factors (as in [37]):

$$\zeta(s,v) = \delta(s,v)/\bar{\sigma}(s,v) = \sum_{w \in \pi(s,v)} \left( \frac{1}{\bar{\sigma}(s,w)} + \zeta(s,w) \right).$$

Computing $\zeta$ rather than $\delta$ simplifies the algebraic steps done by the algorithm and leads to a simpler proof of correctness. Once we have computed $\zeta$, we can construct $\delta$ simply via multiplication by $\bar{\sigma}$, which we have already computed via MFBF.

Edgar Solomonik, Maciej Besta, Flavio Vella, and Torsten Hoefler

Algorithm 2 $[Z] = MFBr(A, T)$

Input: $A$: $n \times n$ adjacency matrix, $T$: matrix of distances and multiplicities

Output: $Z$: centpath matrix of partial centrality factors

// Existential qualifiers $\forall \in 1 : n$ (denoting starting vertices) are implicit and $\forall v \in 1 : n$ (denoting intermediate vertices).

$\forall$ Initialize centpaths by finding counting predecessors $\forall$

1: $Z(s,v) := (T(s,v), w, 0, 1)$
2: $Z = Z \odot (Z \cdot A^T)^I$
3: Initialize centpath frontiers $\forall$
4: if $Z(s,v).c = 0$ then $Z(s,v) := (T(s,v), w, 1/T(s,v).m, -1)$
5: else $Z(s,v) := (\infty, 0, 0)$
6: $Z = Z \cdot A^T$
7: Back-propagate frontiers of centralities $\forall$
8: Turn off counters for nodes that already appeared in a frontier $\forall$
9: $Z(s,v).c = 0$ then $Z(s,v) := (T(s,v), w, Z(s,v).p + 1/T(s,v).m, -1)$
10: $Z(s,v) := (\infty, 0, 0)$
11: end while
12: end if

A centpath $x = (x.w, x.p, x.c) \in C = \mathbb{R} \times \mathbb{R}$ is a path with a weight $x.w \in \mathbb{R}$, partial centrality score $x.p \in \mathbb{R}$, and a counter $x.c \in \mathbb{Z}$. Our algorithm will converge to a centpath $x$ for each pair of starting and destination nodes $s, v$, where the partial dependency factor $x.p = \zeta(s,v)$. The counter $x.c$ is used to keep track of the number of predecessors who have not propagated a partial dependency factor up to the node $v$ in a previous iteration. The counter is decremented until reaching zero, at which point the final centrality scores of all predecessors have been integrated into $x.p$ and it is then propagated from $v$ up to the root $s$.

The centpath monoid operator $\odot$ is defined as

$$\forall x, y \in C, \ x \odot y = \begin{cases} x & : x.w > y.w \\ y & : x.w < y.w \\ (x.w, x.p + y.p, x.c + y.c) & : x.w = y.w. \end{cases}$$

4.2.2 Brandes Action.

Intuition: Our MFBr algorithm (Algorithm 2) iteratively updates a matrix $Z$ of centpaths via forward propagation of partial centrality factors from the leaves of the shortest path tree.

Formalism: In the inner loop (lines 5-12), $Z$ is computed with $\cdot (\odot, g)$, where function $g$ is defined as

$$g : \mathbb{C} \times \mathbb{R} \to \mathbb{C}, \ g(a, w) = (a.w - w, a.p, a.c).$$

$g$ may be interpreted as an action of the monoid $(\mathbb{R}, +)$ on set $\mathbb{C}$.

4.2.3 Algorithm and Correctness.

Intuition: For weighted graphs, a single vertex may appear many times in the frontier as its shortest path information and multiplicity is corrected, unlike in traversals in BFS or Dijkstra’s algorithms, where the total number of nonzeros in the matrix multiplication operand $T$ sums to $(n-1)n_g$ over all iterations. For the Brandes step, we can avoid propagating uninitialized information as we already know the structure of the shortest path trees.

MFBr (Algorithm 2) propagates centrality factors optimally via the counter kept by each centpath, putting vertices in the frontier only when all of their predecessors have already appeared in previous frontiers. The counter is initialized to the number of predecessors, is decremented until reaching 0, added to a frontier and set to $-1$ to avoid re-adding the vertex to another frontier. This approach is strictly better than propagating partial centrality scores, which
We accomplish this by disjointly partitioning \( k \)-paths as in Bellman-Ford (Dijkstra’s algorithm requires \( n - 1 \) matrix multiplications).

**Formalism:** We can demonstrate correctness of the algorithm by showing that the counter mechanism serves to correctly define each frontier in the shortest path tree.

Lemma 4.2. For any adjacency matrix \( A \) and a multigraph \( T \) containing shortest path distances and multiplicities, \( Z = \text{MFBr}(A, T) \) satisfies \( \bar{Z}(s, v), p = \bar{\lambda}(s, v) \).

Proof. We prove that the partial BC scores are computed correctly after \( d - 1 \) iterations of the loop in line 5 if all shortest paths from \( s \) in \( G \) consist of at most \( d \) edges. Before we denote the shortest distance from node \( s \) to \( v \) as \( r(s, v) \) and the multiplicity as \( \bar{\lambda}(s, v) \). We define \( \bar{Z}_j(s, v) \in Z \) as the sum of all minimal distance paths of at most \( j \) edges from \( s \) ending at \( u \) that are on the minimal distance path between \( s \) and \( u \),

\[
k_j(s, v) = \sum_{u, v \in \bar{P}_j(s, v)} \frac{1}{\bar{\lambda}(s, u)}, \quad \text{where} \quad P_j(s, v) = \{(u, w)\mid j = 1, w \in (1 : n)^j, r(s, u) + A(u, w_1) + A(w_1, w_2) + \ldots + A(w_{j-1}, v) = r(s, v)\}
\]

Since \( P_j(s, v) \) is the set of all shortest paths between \( s \) and \( v \) that are parts of shortest paths between \( s \) and \( u \), for each \( u \) there are \( \bar{\lambda}(s, u)/\bar{\lambda}(u, v) \) such paths, and therefore,

\[
k_j(s, v) = \sum_{u, v \in \bar{P}_j(s, v)} \frac{1}{\bar{\lambda}(s, u)} = \sum_{u=1}^{n} \frac{\bar{\lambda}(s, u)}{\bar{\lambda}(s, u)\bar{\lambda}(u, v)}.
\]

We now show that \( \bar{Z}_j(s, v) \) can be expressed in terms of \( \bar{Z}_{j-1}(s, u) \) for all \( u \in P_j(s, v) \) (the 1-edge shortest-path neighborhood of \( v \) from \( s \)). We accomplish this by disjointly partitioning \( P_j(s, v) \) into \( P_1(s, v) \) and \( \bigcup_{u \in P_j(s, v)} P_{j-1}(s, u) \), which yields,

\[
k_j(s, v) = \sum_{u, v \in \bar{P}_1(s, v)} \frac{1}{\bar{\lambda}(s, u)} + \sum_{u, v \in \bar{P}_{j-1}(s, u)} \frac{1}{\bar{\lambda}(s, w)} + k_{j-1}(s, u)
\]

Let \( Z_j(s, v) \) be the state of \( Z(s, v) \) and \( Z_j(s, v) \) be the state of \( Z(s, v) \) after the completion of \( j - 1 \) iterations of the loop on line 5. We argue by induction on \( j \) that for all \( j \in \{1, \ldots, d\} \), \( Z_j(s, v), p = k_j(s, v) = \bar{Z}_j(s, v) \) and

\[
Z_j(s, v) = (r(s, v), 1/\bar{\lambda}(s, v) + \bar{\lambda}(s, v), -1)
\]

if and only if the largest number of edges in any shortest path from any node \( u \to v \) such that \( r(s, v) = r(s, u) + r(u, v) \), is \( j - 1 \). In the base case, \( j = 1 \) and thus \( Z(s, v), p = k_1(s, v) = \bar{Z}_1(s, v) = \bar{\lambda}(s, v) = 0 \) for all vertices \( v \) with no predecessors (leaves in the shortest path tree); these vertices are set appropriately in \( Z_1 \).

For the inductive step, the update on line 5 contributes the appropriate factor of \( 1/\bar{\lambda}(s, u) \) from each predecessor vertex \( u \). Next, each such predecessor vertex \( u \) must have been a member of a single frontier by iteration \( j \), since the larger number of edges in any shortest path from \( u \) to any node \( v \) must be no greater than \( j - 1 \). Therefore, the counter \( Z_j(s, v), c = 0 \), which means \( Z_j(s, v) \) is set appropriately (for subsequent iterations \( k > j \), \( Z_k(s, v) \) is set appropriately since we set \( Z(s, v), c = -1 \) at iteration \( j + 1 \)).

### 4.3 Combined BC Algorithm

To obtain a complete algorithm for BC, we combine MFBF and MFBr into MFBC (Algorithm 3). MFBC is parametrized with a batch size \( n_b \) and proceeds by computing MFBF and MFBr to obtain partial centrality factors for \( n_p \) starting vertices at a time. These factors are then appropriately scaled by multiplicities \( \bar{\lambda}(u, v) \) and accumulated into a vector of total centrality scores.

Theorem 4.3. For any adjacency matrix \( A \) and \( n_p \in \{1, n\} \), \( \lambda = \text{MFBC}(A, n_p) \) satisfies \( \bar{Z}(s, v), p = \bar{\lambda}(s, v) \).

Proof. We assume \( n \) mod \( n_p = 0 \), if it does not then \( n \) mod \( n_p \) disconnected vertices can be added to \( G \) without changing \( \lambda \). For each vertex batch, MFBF computes the correct shortest distances and multiplicities \( T \) by Lemma 4.1. For each \( T \), MFBr computes the correct partial centrality scores \( Z \) by Lemma 4.2. Thus, at iteration \( i \), \( T(s, v), m = \bar{\delta}(i - 1) n_p + s, v \) and \( Z(s, v), p = \bar{\delta}(i - 1) n_p + s, v \). Next, over all iterations, line 5 expands to

\[
\bar{\lambda}(s, v) = \sum_{s \in V} Z(s, v), p \cdot T(s, v), m = \sum_{s \in V} \bar{\delta}(s, v) \cdot \bar{\lambda}(s, v).
\]

### 5 COMMUNICATION COMPLEXITY

MFBC leverages all the available parallelism in the problem to accelerate overall progress. We now formally study its scalability by bounding its communication complexity. We first present a cost model (Section 5.1). In Section 5.2 we derive the communication costs for sparse matrix multiplication, by far the most expensive operation in MFBC. We assume sparse matrices with arbitrary dimensions and nonzero count. In several cases, to concretize the model and derive tighter bounds, we use matrix multiplication (tensor contraction) routines in CTF. However, this does not limit our analysis as CTF employs a larger space of sparse matrix multiplication variants than any previous work. Our results provide a communication bound that is substantially lower than previous results for sparse matrix multiplication when the number of nonzeros is imbalanced between matrices. As this scheme is a critical primitive not only in graph algorithms, but in numerical algorithms such as multigrid, this theoretical result is of stand-alone importance.

Finally, in Section 5.3, we express the cost of MFBC in terms of the communication cost of the sparse matrix multiplications it executes. Our analysis shows that the latency (synchronization) cost of MFBC may in several cases be higher than the best-known all-pairs shortest-path algorithms by a factor proportional to the number of batches \( n/n_p \), which in turn depends on the available memory.
Simultaneously, MFBC can operate with $O(m/p)$ memory per processor, while all-pairs shortest-paths algorithm require $\Omega(n^2/p)$ memory per processor. Finally, the communication bandwidth cost of MFBC is identical or better than all the used comparison targets.

5.1 Cost Model

We use a parallel execution model where we count the number of messages and amount of data communicated by any processor. We do not keep track of the number of CPU operations because, for sparse matrix multiplication, all the considered algorithms have an optimal computation cost, and for BC our algorithm is work-optimal in the unweighted case. The computation cost in the weighted case depends on the number of times each vertex appears in a path.

We assume that multiplying any two blocks of equal dimension is proportional to the block size. Thus, we assume that the number of nonzeros is asymptotically load-balanced. Thus, when multiplying blocks $(A, B)$ on a grid of $p$ processors and move the data in steps to multiply matrices. 3D algorithms can be based on point-to-point or collective communication. The former are up to $O(\log p)$ faster in latency, but the latter generalize easier to rectangular processor grids. The algorithms are naturally extended to handle sparse matrices by treating the matrix blocks as sparse matrices.

5.2 Parallel Sparse Matrix Multiplication

We first analyze the product of sparse matrices $A^{m \times k}$ and $B^{k \times n}$ that produce matrix $C^{m \times n}$. We use algorithms based on 1-, 2-, and 3-dimensional matrix decomposition. They all have a computation cost of $O(\text{flops}(A, B)/p)$, which we omit.

All the considered algorithms and implementations use matrix blocks that correspond to the cross product of a subset of columns and a subset of rows of the matrices. The blocks are chosen oblivious of the matrix structure. For sparse matrices with a sufficiently large number of nonzeros, randomizing the row and column order implies that the number of nonzeros of each such block is proportional to the block size. Thus, we assume that the number of nonzeros in any block of dimensions $b_1 \times b_2$ of a sparse matrix $A^{m \times k}$ has $O(\min(\text{nnz}(A)b_1b_2/(mk))$ nonzeros so long as $mk/(b_1b_2) \leq p$. When $\text{nnz}(A) \gg p$, the assumption holds true with high probability based on a balls-into-bins argument [41].

We also assume that multiplying any two blocks of equal dimensions yields about the same number of nonzero products and output nonzeros. This assumption does not impact our communication-cost analysis, but allows us to assert that the computational work is asymptotically load-balanced. Thus, when multiplying blocks of size $b_1 \times b_2$ of matrix $A$ and $b_3 \times b_4$ of matrix $B$, the number of nonzeros in the output block contribution to matrix $C$ is

$$O\left(\min\left(\frac{\text{nnz}(C)}{mn}, \frac{\text{flops}(A, B)}{mnk}, \frac{\text{flops}(B, C)}{mnk}\right)\right).$$

For a sparse matrix corresponding to uniform random graphs, the respective numbers are

$$\text{flops}(A, B) = \frac{\text{nnz}(A) \cdot \text{nnz}(B)}{mk} \cdot nk = \frac{\text{nnz}(A) \cdot \text{nnz}(B)}{k}$$

and

$$\text{nnz}(C) \approx \min(mn, \text{flops}(A, B)).$$

We can invoke the same balls-into-bins argument [41] to argue that the work load-balance assumption holds, by arguing about the induced layout of the flops$(A, B)$ operations as a third-order cyclically distributed tensor.

5.2.1 1D Algorithms. 1D decompositions are the simplest way to parallelize a matrix multiplication. There are three variants, each of which replicates one of the matrices and blocks the others into $p$ pieces. Variant A replicates $A$ via broadcast and assigns each processor a set of columns of $B$ and $C$. Variant B broadcasts $B$ and assigns each processor a set of rows of $A$ and $C$. Variant C assigns each processor a set of columns of $A$ and rows of $B$, computes their product, and uses a reduce to obtain $C$. The communication cost of version $X$ of a 1D algorithm for $X \in \{A, B, C\}$ is

$$W_X(X, p) = O\left(a \cdot \log p + \beta \cdot \text{nnz}(X)\right).$$

The algorithm is optimal for square matrices, but other variants achieve lower communication cost when the number of nonzeros in the two operand matrices are different.

Our implementation uses three variants of 2D algorithms using broadcasts and (sparse) reductions. The variant AB broadcasts blocks of $A$ and $B$ along processor grid rows and columns, while the variants AC and BC reduce $C$ and broadcast $A$ and $B$, respectively. CTF uses lcm($p_r$, $p_c$) (lcm is the least common multiple) broadcasts and adjustments, and reduces $p_r$ and $p_c$, so that lcm$(p_r, p_c) \approx \max(p_r, p_c)$ steps of collective communication are performed. When each matrix block is sparse with the specified load balance assumptions, the costs achieved by these 2D algorithms are given in general by

$$W_{YZ}(X) \in \{A, B, C\} \text{ as } W_{YZ}(Y, Z, p_r, p_c) =$$

$$O\left(\alpha \cdot \log(p) + \beta \cdot \left(\frac{\text{nnz}(Y)}{p_r} + \frac{\text{nnz}(Z)}{p_c}\right)\right).$$

5.2.2 2D Algorithms. 2D algorithms [1, 13, 45] block all matrices on a grid of $p_r \times p_c$ processors and move the data in steps to multiply matrices. 2D algorithms can be based on point-to-point or collective communication. The former are up to $O(\log p)$ faster in latency, but the latter generalize easier to rectangular processor grids. The algorithms are naturally extended to handle sparse matrices by treating the matrix blocks as sparse matrices.

We derive 3D algorithms (and implement in CTF) by nesting the three 1D algorithm variants with the three 2D algorithm variants.
The cost of the resulting nine 3D variants on a $p_1 \times p_2 \times p_3$ processor grid with the 1D algorithm applied over the first dimension is

$$W_{XYZ}(X, Y, Z, p_1, p_2, p_3) = W_k(X[p_1, p_3])$$

$$= \begin{cases} W_{YZ}(Y, Z[p_1], p_2) : X = Y, \\ W_{XZ}[X[p_1, Z], p_2, p_3] : X = Z, \\ W_{XYZ}[X[p_1, Y, Z], p_2, p_3] : X \neq Y, Z, \end{cases}$$

for $(X, Y, Z) \in \{A, B, C\} \times \{AB, AC, BC\}$, with notation $X[p_2, p_3]$ denoting that the 1D algorithm operates on blocks of $X$ given from a $p_2 \times p_3$ distribution, while $Y[p_1]$ and $Z[p_1]$ refer to 1D distributions. This cost simplifies to

$$W_{XYZ}(X, Y, Z, p_1, p_2, p_3) = O\left( \alpha \cdot \max(p_1, p_2, p_3) \log(\min(p_1, p_2, p_3)) + \beta \cdot \frac{\text{nnz}(X)}{p_2p_3} \right).$$

As we additionally consider pure 1D and 2D algorithms, then pick the 1D, 2D, or 3D variant of least cost. Provided unlimited memory, the execution time of our sparse matrix multiplication scheme is no greater than

$$W_{\text{MM}}(A, B, C, p) = O\left( \min_{p_1, p_2, p_3} \left[ \alpha \cdot \max(p_1, p_2, p_3) \log p + \beta \cdot \left( \frac{\text{nnz}(A)}{p_1p_2} \delta(p_3) + \frac{\text{nnz}(B)}{p_2p_3} \delta(p_1) + \frac{\text{nnz}(C)}{p_1p_3} \delta(p_2) \right) \right] \right),$$

where $\delta(x) = 1$ when $x \geq 1$ and $\delta(1) = 0$.

### 5.3 Parallel Betweenness Centrality

We finally use the matrix multiplication analysis to ascertain a communication cost bound for MFBC, which performs the bulk of the computation via generalized matrix multiplication. We focus on unweighted graphs; the associated proofs heavily use the fact that each vertex appears in a unique frontier. We then (Section 5.3.1) discuss weighted graphs; in this case we cannot anymore use the same technique to ascertain bounds on the size of each frontier.

**Theorem 5.1.** For any unweighted $n$-node $m$-edge graph $G$ with adjacency matrix $A$ and diameter $d$, on a machine with $p$ processors with $M = \Omega(cm/p)$ words of memory each, for any $c \in [1, p]$, MFBC (Algorithm 3) can execute with communication cost

$$W_{\text{MFBC}}(n, m, p, c) = O\left( \alpha \cdot \frac{d^2n}{m} \sqrt{\frac{m}{p}} \log p + \beta \cdot \left( \frac{n^2}{\sqrt{cp^2}} + \frac{n \sqrt{m}}{p^{2/3}} \right) \right).$$

**Proof.** MFBC is dominated in computation and communication cost by multiplications of sparse matrices, triggered by the operator $\cdot(\otimes_f)$ within MFBB and $\cdot(\otimes_g)$ within MFBr. There are up to $2d + 1$ such matrix multiplications in total. Without loss of generality, we consider only the $d$ within MFBB, letting $F_i$ be the frontier $(T_i \otimes_f A)$ which include $F_{i+1}$ but can be much denser. We can then bound the cost of MFBC as

$$W_{\text{MFBC}} = O\left( \min_{n_1, n_2} \sum_{i=1}^d W_{\text{MM}}(A, F_i, G_i, p) \right)$$

$$= O\left( \min_{n_1, n_2} \sum_{i=1}^d \min_{p_1, p_2, p_3} \left[ \alpha \cdot \max(p_1, p_2, p_3) \log p + \beta \cdot \left( \frac{m}{p_1p_2} \delta(p_3) + \frac{\text{nnz}(F_i)}{p_2p_3} \delta(p_1) + \frac{\text{nnz}(G_i)}{p_1p_3} \delta(p_2) \right) \right] \right).$$

The MFBC algorithm requires $O(nn_1/p)$ memory to store $T$, therefore, we have $nn_1/p = O(M)$, and select $n_1 = cm/n$.

$$W_{\text{MFBC}} = O\left( \frac{n^2}{cm} \sum_{i=1}^d \min_{p_1, p_2, p_3} \left[ \alpha \cdot \max(p_1, p_2, p_3) \log p + \beta \cdot \left( \frac{m}{p_1p_2} \delta(p_3) + \frac{\text{nnz}(F_i)}{p_2p_3} \delta(p_1) + \frac{\text{nnz}(G_i)}{p_1p_3} \delta(p_2) \right) \right] \right).$$

We use a 3D algorithm with $p_1 = p_2 = \sqrt{c/3}$, $p_3 = c$, which replicates $A$ via a 1D algorithm, then employs the BC variant of a 2D algorithm, using $O(cm/p)$ memory. A’s replication can be amortized over up to $d$ sparse matrix multiplications and over the $n^2/cm$ batches, since $A$ is always the same adjacency matrix. Thus,

$$W_{\text{MFBC}} = O\left( \beta \cdot \frac{cm}{p} + \frac{n^2}{cm} \left( \sum_{i=1}^d \left[ \alpha \cdot \sqrt{p/c} \log p + \beta \cdot \left( \frac{\text{nnz}(F_i)}{\sqrt{pc}} + \frac{\text{nnz}(G_i)}{\sqrt{pc}} \right) \right] \right) \right),$$

and furthermore, over all $nn_1$ batches the total cost is

$$W_{\text{MFBC}} = O\left( \frac{d^2n}{m} \sqrt{\frac{m}{p}} \log p + \frac{cm}{p} + \frac{d}{m} \left( \frac{n^2}{\sqrt{pc}} \right) \right).$$

Now, since the graph is unweighted, we know that each vertex appears in a unique frontier, so $\sum_{i=1}^d \text{nnz}(F_i) \leq nn_1 = cm$. Therefore, each node can be reached from 3 frontiers (the one it is a part of, the previous one, and the subsequent one), therefore $\sum_{i=1}^d \text{nnz}(G_i) \leq 3cm$. Then, the total bandwidth cost over all $d$ iterations and $cm/n$ batches is $O(\beta \cdot (n^2/\sqrt{cp} + cm/p))$. This cost is minimized for $c = p^{1/3}(n^2/m)$, so with $M = \Omega(n^2/p^{2/3})$ memory, the cost $O(\beta \cdot n \sqrt{m/p^{2/3}})$ can be achieved.

### 5.3.1 Discussion on Weighted Graphs

Our communication cost analysis can be extended to weighted graphs, provided bounds on $\sum_i \text{nnz}(F_i)$ and $\sum_i \text{nnz}(G_i)$ for each batch. The quantity $\sum_i \text{nnz}(F_i)$ can be bounded given an amplification factor bounding the number of Bellman-Ford iterations in which the shortest path distance between any given pair of source and destination vertices is changed. However, we do not see a clear way to bound $\sum_i \text{nnz}(G_i)$ for weighted graphs. We evaluate MFBC for weighted graphs in the subsequent section, observing a slowdown proportional to the factor of increase in the number of iterations with respect to the unweighted case (in the unweighted case it is the diameter $d$).

### 5.3.2 Comparison to Other Analyses

We are not aware of other communication cost studies of BC, but we can compare our approach to those computing the full distance matrix via all-pairs shortest-paths (APSP) algorithms, requiring at least $n^2/p$ memory,
We work with adjacency matrices with weights in a set \( \mathbb{W} \). MFBC matches this bandwidth cost, while using only \( O(cm/p) \) memory. Further, given sufficient memory \( M = \Omega(n^2/p^{2/3}) \), our algorithm is up to \( \min(n/\sqrt{m},p^{2/3}) \) times faster. When also considering an algorithm that replicates the graph as an alternative, the best speed-up achievable by MFBC is for \( M = \Theta(n^2/p^{2/3}) \) memory with \( n/\sqrt{m} = p^{1/3} \), and when \( \beta \gg \alpha \), in which case \( W_{\text{MFBC}}(n,n^2/p^{2/3},p,p^{2/3}) = O(\beta \cdot n^2/p) \) is \( p^{1/3} \) times faster than Floyd-Warshall, path doubling, or Dijkstra with a replicated graph.

### 5.3.3 Discussion on Latency

The Floyd-Warshall ASPP algorithm has latency cost \( O(\alpha \cdot \log p) \) \([44]\) using \( O(n^2/p^{2/3}) \) memory. Given this amount of memory, MFBC can achieve a latency of

\[
O\left(\alpha \cdot d \log p \left(\frac{n^2}{\sqrt{mp}} + \frac{n}{\sqrt{m}}\right)\right)
\]

It might be possible to improve this latency cost by using different sparse matrix multiplication algorithms.

#### 5.3.4 Discussion on Scalability

The capability of our algorithm to employ large replication factors \( c \) gives it very strong scalability properties. If each processor has \( M = O(m/p_0) \) memory, it is possible to achieve perfect strong scalability in bandwidth cost using up to \( p_0^{3/2}n^3/m^{3/2} \) processors, or even up to \( p_0^{3/2}n^2/mn \),

\[
W_{\text{MFBC}}(n,m,c_0,\epsilon) = \frac{1}{c} W_{\text{BF}}(n,m,c_0,1)
\]

is satisfied, so strong scalability is achieved in all costs from \( p_0 \) to \( p_0^{3/2}n^2/m \) processors. This range in strong scalability is better than that achieved by the best known square dense matrix multiplication algorithms, \( p_0 \) to \( p_0^{3/2} \) \([40]\).

## 6 IMPLEMENTATION

We implement two parallel versions of MFBC using CTF. The first, CTF-MFBC, uses CTF to dynamically select data layouts without guidance from the developer. The second, CA-MFBC, predetermines the 3D processor grid layout that we used to minimize theoretical communication cost in the proof of Theorem 5.1. We first summarize the functionality of CTF and explain how it provides the sparse matrix operations necessary for MFBC. We then give more details on how CTF handles data distribution and communication.

### 6.1 From Algebra to Code

CTF permits definition of all well-known algebraic structures and implements tensor contractions with user-defined addition and multiplication operators \([41]\). Matrices can encode graphs and subgraphs (frontiers); tensors of order higher than two can represent hypergraphs. As graphs are sufficient for the purposes of this paper, we refer only to CTF matrix operations. An \( n \times n \) CTF matrix is distributed across a World (an MPI communicator), and has attributes for symmetry, sparsity, and the algebraic structure of its elements. We work with adjacency matrices with weights in a set \( \mathbb{W} \). The Matrix\( \langle \mathbb{W} \rangle \) is defined by

\[
\text{Matrix}\langle \mathbb{W} \rangle \equiv A(n,n,\text{SP},D,Y);
\]

where \( D \) is a World and \( Y \) defines the Monoid\( \langle \mathbb{W} \rangle \) of weights with minimum as the operator.
involves only a transposition, but for sparse matrices, CTF additionally converts data stored as index–value pairs (coordinate format) to a compressed-sparse-row (CSR) matrix format.

CTF uses BLAS [30] routines for blockwise operations whenever possible (for the datatypes and algebraic operations provided by BLAS). We additionally use the Intel MKL library to multiply sparse matrices, with three variants: one sparse operand, two sparse operands, and two sparse operands with a sparse output. Substitutes for these routines are provided in case MKL is not available. Further, for special algebraic structures or mixed-type contractions, general unoptimized blockwise multiplication and summation routines are used. Users can also provide manually-optimized routines for blockwise operations, which we do not leverage for MFBC.

CTF predicts the cost of communication routines, redistributions, and blockwise operations based on linear cost models. Besides latency \( \alpha \) and bandwidth \( \beta \), CTF also considers the memory bandwidth cost and computation cost of redistribution and blockwise operations. The dimensions of the submatrices on which all kernels are executed for a given mapping can be derived at low cost a priori. To determine sparsity of blocks, we scale by either the nonzero fraction of the operand matrix or the estimated nonzero fraction of the output matrix. Automatic model tuning allows the cost expressions of different kernels to be comparable on any given architecture. CTF employs a model tuner that executes a wide set of benchmarks on a range of processors, designed to make use of all kernels for various input sizes. Tuning is done once per architecture or whenever a kernel is added or significantly modified.

## 7 Evaluation

We present performance results for the CTF (unmodified v1.4.2) implementation of MFBC (CTF-MFBC) and for CombBLAS. Our benchmarks use the CombBLAS betweenness centrality code and benchmark included in the CombBLAS v1.5.0 distribution. on the Blue Waters Cray XE6 supercomputer. We provide a mix of performance benchmark tests, working with different types of graphs:

1. real-world social-network and citation graphs [31].
2. synthetic weighted and unweighted R-MAT graphs [14].
3. Erdős-Rényi random graphs [22].

Real-world graphs and R-MAT graphs serve to provide effective strong scaling experiments. We consider different types of weak scaling experiments using uniform graphs. For edge-weak scaling, we keep the number of edges per processor and the nonzero fraction constant. For vertex-weak scaling, we keep the number of vertices per processor and the average degree constant.

CTF-MFBC achieves consistent scalability patterns for all types of graphs. It outperforms CombBLAS on various tests, but not uniformly so. Large speed-ups are achieved for real, R-MAT, and uniform random graphs with the average vertex degree above 100.

### 7.1 Experimental Setup

To debug and tune our code, we used the NERSC Edison supercomputer, a Cray XC30 as well as the CSCS Piz Dora machine, a Cray XC40. Each Edison compute node has two 12-core HT-enabled Intel Ivy Bridge sockets with 64 Gb DDR3-1866 RAM. Each node of Piz Dora has two 18-core Intel Broadwell CPUS (Intel® Xeon® E5-2695 v4). The network is the same on both of these machines, a

Cray’s Aries implementation of the Dragonfly topology [27]. We then collected our final set of benchmarks on Blue Waters, a Cray XE6 supercomputer. Each Blue Waters XE node has two 16-core AMD 6276 Interlagos sockets; there are 22,500 nodes in total. The network is a Cray Gemini torus. The performance-portability of CTF made it easy to transition the code between these machines. Our choice of machines was based on resource availability.

For both CTF and CombBLAS, we benchmarked a range of batch-sizes for each graph and processor count. We show the highest performance rate over all batch sizes, which was usually achieved by the largest batch-size that still fit in memory. Such batches run for on the order of minutes, so we executed each batch only once, rather than testing many iterations. Due to the large overall time-granularity of the benchmarks, we observed that system noise did not affect the runtime in the first 2 significant digits.

We use the metric of edge traversals per second (TEPS) to quantify performance. The number of edge traversals scales with the size of the graph. For betweenness centrality on a connected unweighted graph, each edge is traversed to consider shortest paths from every starting node. We use all one MPI process per node and benchmark on core counts that are powers of four, as CombBLAS requires square processor grids. CTF can leverage threading and execute efficiently on most core-counts, but we maintain powers of four for all experiments for consistency and simplicity.

**Considered graphs** We used two classes of synthetic graphs: R-MAT (power-law) and random-uniform. We varied the density for both types of synthetic graphs. Generally these graphs have a low diameter, which roughly reflects social-network graphs, a key application domain of betweenness centrality. We also use real-world SNAP [31] graphs (Table 2) of various sparsities and diameters. Our CTF-MFBC code preprocessed all graphs to remove completely disconnected vertices.

| ID | Name                  | directed? | n   | m   | d   |
|----|-----------------------|-----------|-----|-----|-----|
| frd| Friendster            | undirected| 65.6M| 1.8B| 32  |
| ork| Orkut social network  | undirected| 3.1M | 117M| 9   |
| ljm| LiveJournal membership| directed  | 4.8M | 70M | 16  |
| cit| Patent citation graph | directed  | 3.8M | 16.5M| 22  |

Table 2: The analyzed real-world graphs (sorted by \( n \)). All graphs are unweighted and have diameter \( d \) with 90-percentile effective diameter \( d \) [31].

### 7.2 Strong Scaling

We begin our performance study by testing the ability of MFBC to lower time to solution by using extra nodes (strong scaling). Our strong scaling experiments evaluate MFBC with respect to CombBLAS on both real-world and synthetic graphs.

**Real-world graphs** Our selection of graphs (Table 2) considers three social-network graphs and a patent citation graph. Two of the graphs are directed and two are undirected. The diameter of the Orkut and LiveJournal graphs is relatively small, but Orkut is significantly denser. The patent citation graph has the largest diameter, posing the biggest challenge to betweenness centrality computation. The Friendster graph has roughly 15X more vertices and edges than any of the other graphs, and a fairly large diameter.

CTF-MFBC performs best for the Orkut graph, as the sparse matrix multiplications are more computation-intensive for denser graphs with low diameter (the latter implying denser frontiers). The somewhat larger diameter of LiveJournal and the significantly
larger diameter of the patent citation graph take a toll on the absolute performance. However, the strong scalability is reasonable for all three of these graphs, as speed-ups of around 30X are achieved for each, when using 64X more nodes. The smallest number of nodes on which CTF-MFBC successfully executes the Friendster graph is 32, with good scalability to 128 nodes. The graph is the largest social network available in the SNAP dataset.

On the other hand, we observed relatively volatile performance for these graphs for CombBLAS, shown in Figure 1(b). In absolute terms the performance of CombBLAS on LiveJournal and the patent citation graph compare well to CTF-MFBC. On the other hand, we were unable to successfully execute the Friendster graph with CombBLAS. Further, CTF-MFBC is up to 7.6X faster for the Orkut graph. We don’t have a good understanding of the radical change in performance of the CombBLAS benchmark (in different directions for different graphs) when transitioning from 8 to 32 nodes. On 32 nodes, CombBLAS reports a 10X improvement performance for LiveJournal by using a batch size of 8192 rather than 512, while for Orkut the corresponding improvement is only 3X.

**R-MAT graphs** We work with two R-MAT graphs, for both of which \(\log_2(n) = S = 22\), while the average degree is controlled by \(k \approx E \in [8, 128]\). Disconnected vertices are removed in CTF-MFBC and skipped for consideration as starting vertices in CombBLAS. R-MAT graphs have a low diameter, so a small number of matrix products is done in the unweighted case.

Figure 1(c) compares CTF-MFBC with CombBLAS for strong scaling on these R-MAT graphs. We omit points where we were not able to get CombBLAS to successfully execute betweenness centrality on the graph. Overall, the performance is roughly the same for the case with small average degree \(E=8\). However, CTF-MFBC performs significantly better when \(E=128\).

Figure 1(c) also compares CTF-MFBC performance for R-MAT graphs with edge weights randomly selected as integers in the range \([1, 100]\) versus unweighted R-MAT. In these tests, the number of sparse matrix multiplications doubles and the frontier stays relatively dense for several steps of Algorithm 1, thus the overall performance of MFBC decreases by more than a factor of two with the inclusion of weights.

### 7.3 Weak Scaling

We now test CTF-MFBC’s parallel scalability, while keeping \(m/p\) constant (weak scaling). We use uniform random graphs, in which all nodes have the same expected vertex degree, and every edge exists with a uniform probability. We consider “edge weak scaling” where \(n^2/p\) is kept constant and “vertex weak scaling” where \(n/p\) is kept constant. CTF-MFBC achieves good edge weak scaling, but deteriorates in efficiency for vertex weak scaling, a discrepancy justified by our theoretical analysis.

Figure 2(a) provides “edge weak scaling” results, in which the sparsity percentage of the adjacency matrix, \(f = 100 \cdot m/n^2\), stays constant. The data confirms the observation that MFBC performs best for denser graphs. CTF-MFBC scales well, which is expected, since the communication cost term \(O(\beta \cdot n^2 / \sqrt{p})\) grows in proportion with \(\sqrt{p}\), while the amount of computation per node \(O(mn/p)\) also grows in proportion with \(\sqrt{p}\).

Figure 2(b) provides “vertex weak scaling” results, in which the vertex degree \(k\) stays constant. We were unable to get CombBLAS to execute successfully on 64 nodes for the graphs with
$n = 740K$ vertices. CTF-MFBC performs again better than CombBLAS when the average degree of the graph is large, but both implementations deteriorate in performance rate with increasing node count. This deterioration is predicted by our communication cost analysis, since in this weak scaling mode the term $O(\beta \cdot n^2 / \sqrt{p})$ grows in proportion with $p^{3/2}$, while the amount of work per node $O(mn/p)$ grows in proportion with $p$. Therefore, unlike edge weak scaling, vertex weak scaling is not sustainable, the number of words communicated per unit of work grows with $\sqrt{p}$.

### 7.4 Communication Cost

We experimentally measured the communication complexity incurred by CTF-MFBC and CombBLAS. Communication in both codes is dominated by collective communication routines. We profiled the time spent in communication (excluding time to synchronize) as well as used the parameters passed to MPI routines to build an analytical model. To get the critical path costs, we follow the communication pattern: for each collective over a set of processors, we maximize the critical path costs incurred by those processors so far. Broadcast and reduce of a message of size $n$ over $p$ processors have the cost $2n \cdot \beta + 2 \log_2(p) \cdot \alpha$ (twice that of scatter and allgather). At the end of execution, we consider the maximum over all processors for each cost, thus obtaining the greatest amount of data communicated along any dependent sequence of collectives, as well as the greatest amount of messages communicated along any (possibly different) dependent sequence of collectives.

| graph          | code    | W (GB) | S (#msgs) | comm (sec) | total (sec) |
|---------------|---------|--------|-----------|------------|-------------|
| Orkut         | CombBLAS | 19.71  | 546.9K    | 48.81      | 233.7       |
| Orkut         | CTF-MFBC | 7.010  | 184.6K    | 46.95      | 111.6       |
| LiveJournal   | CombBLAS | 10.21  | 190.6K    | 54.03      | 238.5       |
| LiveJournal   | CTF-MFBC | 8.794  | 94.69K    | 54.00      | 100.2       |

Table 3: Critical path times and costs collected on 40% cores of Blue Waters, all for a single batch of 512 starting vertices. Total time includes overhead of additional profiling barriers.

Table 3 shows that CTF-MFBC uses fewer messages and performs less collective communication than CombBLAS in some cases. In various other cases, CombBLAS performed less communication. For the patent citations graph, CombBLAS performs significantly faster than CTF. The blocked layout and choice of starting vertices likely permits CombBLAS to exploit locality for this directed graph. Further, the back-propagation stage for CTF-MFBC (which is dynamically computed, rather than stored from BFS) takes considerably longer (performing more work in the directed case).

Overall, we can conclude that either the CombBLAS or CTF-MFBC implementation may incur more communication, depending on the type of graph. CTF-MFBC seems to require less for denser graphs (e.g. Orkut and uniform random). Persistence of layout and more accurate performance models would further reduce communication costs.

### 8 CONCLUSION

Our new maximal frontier algorithm for betweenness centrality achieves good parallel scaling due to its low theoretical communication complexity and a robust implementation of its primitive operations. The algebraic formalism we use for propagating information through graphs enables intuitive expression of frontiers and edge relaxations, making it extensible to other graph problems such as maximum flow. We expect that the approach of selecting frontiers to maximize overall progress also leads to good parallel algorithms for other graph computations.

By implementing MFBC on top of Cyclops Tensor Framework (CTF), we have introduced the first application case-study of CTF for a non-numerical problem. MFBC with CTF shows substantial improvements in performance over CombBLAS for some graphs, while additionally being general to weighted graphs. Automatic parallelism for sparse tensor contractions with arbitrary algebraic structures is useful in many other application contexts. The communication-efficiency achieved by sparse matrix multiplication routines in CombBLAS and CTF has a promising potential for changing the way massively-parallel graph computations are done.

### 9 ACKNOWLEDGEMENTS

This research is part of the Blue Waters sustained-petascale computing project, which is supported by the National Science Foundation (awards OCI-0725070 and ACI-1238993) and the state of Illinois. Blue Waters is a joint effort of the University of Illinois at Urbana-Champaign and its National Center for Supercomputing Applications. We thank Hussein Harake, Colin McMurtrie, and the whole CSCS team granting access to the Piz Dora machine and for their excellent technical support. Maciej Besta was supported by Google European Doctoral Fellowship and Edgar Solomonik was supported by an ETH Zurich Postdoctoral Fellowship.

10 REPRODUCIBILITY APPENDIX

We describe our benchmarking methodology in Section 7. Here, we provide some more technical details to allow reproduction of our results on the Blue Waters machine or a similar architecture. We make our anonymized code for betweenness centrality available in the repository https://github.com/solomonik/graph_centrality. The repository also includes a modified CombBLAS benchmark that generates uniform random graphs.

Compilation

We built CTF using the Intel compiler module v5.2.82 with an additional gcc v5.3.0 module loaded. We built CombBLAS using purely the gcc v5.2.82 module. These modules were the latest available at the start of April 2017.

We built CTF with flags `-fast` and `-no-ipo` as well as with profiling output on. We built CombBLAS with the default optimization flags `-O2`. No changes were made to the contents of either software internally to the aforementioned versions (CTF v1.4.1, CombBLAS v1.5.0).

Execution

We provide our submission job generation scripts below. In some cases, we rerun parts of scripts if they did not complete in the expected time.

Real-World graphs

```bash
#!/bin/bash

snp=$1
nodes=$((2*$snp*$snp))
p=$((32*$nodes))
cat > real.script$nodes.sh <<EOF
#!/bin/bash
#PBS -l nodes=$nodes:ppn=32:xe
#PBS -l walltime=03:00:00
#PBS -N ctf_btwn_central
#PBS -e $PBS_JOBID.err
#PBS -o $PBS_JOBID.out
#PBS -W umask=0027
cd $PBS_O_WORKDIR
for bsize in 128 512 2048 8192
done
EOF

cd $PBS_O_WORKDIR

for bsize in 128 512 2048 8192
do
    aprun -n $p ./betwcent ../graphs/patents 1 $bsize -f ../graphs/livejournal/livejournal.txt
