Abstract
This study aimed to evaluate different energy sources in multiple supplements on performance, intake, and digestibility of Santa Ines sheep grazing urochloa grass (Urochloa mosambicensis) during the rainy season. The experimental area was divided into seven paddocks of 4 ha each, with an average of dry matter (DM) availability of 3.21 tn/ha. A completely randomized design was carried out, in which there were four treatments, and each treatment was repeated six times. Twenty-four intact lambs (average: 32.0 kg of body weight) were supplemented with a mineral mixture, the control group (MM), mesquite pod meal (MPM), wheat bran (WB), or sorghum grain (SG) as energy sources. The digestibility of DM and crude protein (CP) in MPM and WB is higher than that in MM and SG groups. Neutral detergent fiber (NDF) digestibility was similar between supplemented lambs, and it was higher than the MM. The supplementation promoted higher weight gain than in the control group (0.126 vs. 0.061 g/day, respectively; \( P < 0.001 \)). The supplementation increased the DM, and CP intake. The NDF intake only increased in the WB group. The CP digestibility was higher for the MPM and WB groups than that for MM and SG ones (\( P < 0.001 \)). Sheep supplementation in the rainy season increased the average daily gain (ADG). Any supplement tested in the present study can be used during the rainy season. The choice for the supplement will depend on the availability and costs of the mesquite pod meal, sorghum grain, or wheat bran.

Keywords Energy source · Efficiency · Intake · Supplementation

Introduction
Tropical grass generally may not provide required nutrients for ruminant animals (Voltolini et al. 2009); so, additional supplementation may be necessary (Fieser et al. 2007). During the rainy season, forage can reach its maximum availability and nutritional value, helping lambs to meet their nutritional requirements. However, both attributes (quality and quantity) vary and they depend on the management, soil chemical and physical characteristics, fertilization, and climatic conditions, resulting in an imbalance between supply and demand for nutrients in grazing animals.

Therefore, supplementing other carbohydrate sources in grazing sheep can improve the growth performance of animals, because it directly affects the growth of microbes in the rumen, which has a fundamental effect on the efficiency of feed conversion rate into edible animal products.

Studies have evaluated different sources of supplement for grazing lambs in the dry season (Almeida et al. 2011, 2012) but a few studies have been made during the rainy season (Godfrey and Dodson 2003). Different sources of energy can act differently in the rumen environment and promote different responses in grazing lambs (Nascimento et al. 2010). Sorghum grain, mesquite pod meal, and wheat bran are common feedstuff used in Brazil as a source of energy. One of the reasons to use this feedstuff, as sorghum grain, is the more resistance to periods of drought (Ncube et al. 2014).

Despite the greater availability of forage during the rainy period, it is possible to obtain better results with supplementation (Fajardo et al. 2015; Silva et al. 2019). This might be
due to a better synchronization of energy and protein in the rumen. In this perspective, sources of energy such as mesquite pod meal, sorghum grain, and wheat bran can be used as a source of energy. These energy sources are abundant and have low prices during the rainy season in Brazil and can be used to promote higher gains for grazing lambs as well as to accelerate the final phase and slaughter. Therefore, we hypothesize that supplementation with different energy sources has a significant impact on the performance of lamb grazing even during the rainy season. Thus, the study aimed to evaluate the effect of energy supplementation for sheep grazing during the rainy season on the intake, digestibility, and performance.

### Materials and methods

#### Location

The experiment was conducted at Palmares farm, located in Iaçu, a semi-arid region in Bahia, Brazil (15° 31' 0" S, 40° 14' 1" W). According to Köppen climate classification, the climate of the region is tropical and wet, mesothermic, hot, and rainy during the summer and cold and dry in the winter. The study was conducted during the rainy season, from January to April. During the study, the total rainfall was 158 mm, and the average of minimum and maximum temperature was 19.3 ± 1.98 and 37.1 ± 2.61 °C, respectively.

#### Animals and diets

Twenty-four Santa Inês intact male lambs of 4 months of age and with average initial body weight (BW) of 32.0 ± 1.16 kg were used in this study. A completely randomized design was carried out, with four treatments, six replicates for each treatment, and each animal within the treatment representing a replicate. Ground energy source was used to comprise the multiple supplements: mesquite pod meal (MPM), wheat bran (WB), or sorghum grain (SG) and a control group was kept just in the pasture and receiving only mineral mix (MM) (Ovinofós®, DSM Produtos Nutricionais, São Paulo, Brazil) to supply mineral requirements. The MM was also provided ad libitum to all lambs in treatments receiving ground energy source (MPM, WB, and SG) to avoid a mineral deficiency. Ground corn, soybean meal, and urea were added to the energy sources to make the multiple supplements with 210 g/kg of CP and 782 g/kg of total digestible nutrients (TDN) on a DM basis (Table 1). Therefore, lambs were distributed to receive only the mineral mix (MM), MPM supplement, WB supplement, and SG supplement. The chemical composition of the treatments and pasture is given below (Table 1).

### Experimental design and management

The experimental area was comprised of seven paddocks of 4.00 ha of Urochloa grass (Urochloa mosambicensis), equipped with drink and food troughs, and an availability of 3.21 tn/ha of DM, 482 kg/ha of leaves, 2.26 tn/ha of stems, and 754 kg/ha of dead material (DM basis). To estimate the total forage availability, eight points were randomly chosen per paddock and cuts were made at each point using metal squares (0.50 × 0.50 m). All material within the square was cut at 15.0 cm above the ground, as described by Boswell (1977). These samples were taken to the laboratory, where they were weighed and homogenized, and two subsamples were obtained from each sample. An aliquot was used to determine the total DM content, and another one was divided into leaf, stem, and dead material components. The estimation of the quality of the consumed forage was done with the plucking-hand technique (De Vries 1995).

| Table 1: Proportion of ingredients and the composition of the mineral mix (MM) and multiple supplements and Urochloa grass, expressed on the fresh matter basis |
|---------------------------------|-----------------|--------------|
| Ingredients, g/kg MM1  | Treatments2 | |
| Ground corn grain | | | |
| MPM | WB | SG |
| Soybean meal | | | |
| MPM | WB | SG |
| MPM | WB | SG |
| Urea | | | |
| Composition | Urochloa grass | |
| DM | CP, g/kg DM | NDF, g/kg DM |
| | EE, g/kg DM | ADF, g/kg DM |
| | Lig, g/kg DM | TCHO, g/kg DM |
| | EM, Mcal/kg DM | |

1 MM (control group): calcium 120 g, phosphorus 87.0 g, sodium 147.0 g, sulfur 18.0 g, copper 590 mg, cobalt 40.0 mg, chromium 20.0 mg, iron 1.80 g, iodine 80.0 mg, manganese 1.30 g, selenium 15.0 mg, zinc 3.80 g, molybdenum 300 mg, and fluorine (max) 870 mg, per kg of the product

2 Treatments: mineral mix (MM), mesquite pod meal (MPM), wheat bran (WB), sorghum grain (SG)

3 Composition: dry matter (DM), crude protein (CP), neutral detergent fiber (NDF), acid detergent fiber (ADF), ether extract (EE), lignin (Lig), total carbohydrates (TCHO), metabolizable energy (EM)
According to each treatment, lambs were put together in a group in one paddock of 4.00 ha. Aiming to reduce the influence of a variation of forage DM availability, the animals were moved to another paddock every 5 days to remove the effect of the pasture in the treatments. Lambs were allowed to access the paddocks from 7:00 am to 5:00 pm, and then, they were taken to the pens to be supplemented in feeders. Collective pens had 1.00 m²/lamb, with 6 animals each. They had access to the supplementation provided in the trough at a ratio of 10.0 g/kg body weight, based on the mean body weight of the group, with no leftovers.

The experimental period lasted 95 days: 15 days of adaptation, 70 days for performance evaluation, and 10 days for intake and digestibility evaluations.

Performance measurement

The animals were weighed at the beginning and at the end of the experiment. Lambs were weighed on the 15th of every month to adjust the quantity of the supplement provided, and also to make up the average daily gain during this evaluation period (the fifteenth day of each month). The average daily gain (ADG) was estimated by the following equation:

\[
ADG \text{ (g/day)} = \frac{FBW - IBW}{N}
\]

where \(ADG\) is the average daily gain; \(FBW\) is the final body weight considering the total gain, during 15 days; \(IBW\) is the initial body weight; and \(N\) is the number of days of weighing (every 15 days) in the experiment. The feed conversion (FC) was determined as a function of intake and animal performance according to the following equation: \(FC = DMI / ADG\). The feed efficiency (FE) was measured as a function of total weight gain and \(DMI\) as follows: \(FE = \text{total weight gain} / DMI\).

Fecal output measurement

Fecal output data was determined by using chromium oxide (\(\text{Cr}_2\text{O}_3\)) at 2 g/animal and day (Hill and Anderson 1958) as an external marker, in the morning and in the afternoon. The external marker was packed in bags and introduced in the esophagus of the lambs by using a PVC (polyvinyl chloride) apparatus. Fecal samples were collected during 5 days from the 6th to the 10th day after starting the supply of the marker, every 3 h directly from the animal’s rectum, making up eight samples during the 24 h of the day. Then, compound samples were made per day and frozen at −20 °C. Fecal recovery was measured by the ratio of the amount of marker excreted and the ingested amount. The fecal DM was estimated by the marker through the equation as follows:

\[
fecal \text{ DM} \left( \frac{mg}{g} \right) = \frac{IM}{FM} \times 10
\]

where \(IM\) is the ingestion of the marker (mg/g; DM basis) and \(FM\) is the fecal marker (mg/day; DM basis).

Chemical analysis

For the determination of the indigestible acid detergent fiber (iADF), 0.5 g of the feces was taken; supplements and hand-plucked samples were packed in non-woven fabric (NWF-100 g/m²) (Polypropylene Nonwoven Fabric, MH Industry, Ningbo, China) of 4×5 cm and they were inserted in the rumen in the proportion of 20.0 mg of DM/cm² of the surface. The samples were triplicated and inserted in lingerie bags for each treatment, and were incubated for 264 h (Casali et al. 2008). After removing the bags from the rumen, they were washed in running water and immediately transferred to a forced ventilation oven (60 °C) for 72 h. The NDF and ADF contents were determined according to Van Soest et al. (1991). Evaluations of DM, CP (N×6.25), and ether extract (EE) contents were estimated by the methods 930.15, 984.13, and 920.39 of the AOAC (2005), whereas ash content was calculated as 100 – organic matter. The lignin content was analyzed by the sulfonic acid solubilization method following the procedures described by Gomes et al. (2011).

Calculations and statistical analysis

The voluntary forage intake was estimated as described by Arthington and Spears (2007). The DM intake (DMI) was determined by the ratio between the fecal excretion and the internal indicator indigestibility, as described earlier, using the equation proposed by Detmann et al. (2001):

\[
DMI = \frac{[(FE \times MCF) - CIS / CIFOR] + DMIS}{DMI}
\]

where \(DMI\) is the dry matter intake (kg/day); \(FE\) is the fecal excretion (kg/day); \(MCF\) is the marker concentration in the animal feces (kg/kg); \(CIS\) is the concentration of iADF in the supplement (kg/day); \(CIFOR\) is the concentration of iADF in forage (kg/kg); and \(DMIS\) is the intake of supplement DM (kg/day). Supplement intake was measured by the quantity supplied divided by the number of animals of the treatment. The average intake of the supplement was 0.057, 0.415, 0.411, and 0.415 g/kg for MM, MPM, WB,
and SG, respectively. Due to fixed supplementation, no statistical analysis was performed for supplement intake.

\[ SR = \frac{\text{Forage intake when unsupplemented} - \text{Forage intake when supplemented}}{\text{Supplement intake}} \]

A \( SR < 1 \) kg/kg means that total DMI on the supplemented group is higher than total DMI on the unsupplemented group. A \( SR = 1 \) kg/kg means that total DMI on the supplemented group is the same as total DMI on the unsupplemented group (Bargo et al. 2003).

To calculate the \( SR \), the average of forage intake of the unsupplemented animals was used. Total carbohydrates (TCHO) were calculated according to Sniffen et al. (1992) using the equation \( \text{TCHO} = 100 - (\%CP + \%EE + \%ash) \). Metabolizable energy was estimated according to NRC (2001).

The data was analyzed using the Statistical Analysis System (SAS 2001) (SAS Institute, Version 8.2, NC, USA), after verification of the normality by the PROC UNIVARIATE statement. The data was analyzed using the PROC GLM procedure, according to the completely randomized design model:

\[ Y_{ij} = \mu + SUP_i + \epsilon_{ij} \]

where \( Y_{ij} \) is the dependent variable, \( \mu \) is the overall mean, \( SUP_i \) is the fixed effect of supplements, and \( \epsilon_{ij} \) is the random error.

The model considers the supplements as fixed effect and animals were the experimental units. The statistical analysis of the substitution rate (SR) was performed using only the supplemented animals, because there was no effect of substitution in the animals unsupplemented. The comparisons between means were performed by Tukey’s range test. In all models, the statistical significance between means was declared to be \( P < 0.050 \).

### Results

#### Intake

The DMI (kg/day) was higher for MPM and WB treatments, but MM and SG had similar DMI (\( P = 0.001 \)). However, there was no difference among the treatments in DMI expressed as %BW and DM of forage (DMf) (kg/day) (\( P > 0.050 \)), although the DMf expressed in %BW was higher in MM, if compared with the other treatments (\( P < 0.001 \)). The CP intake was lower in MM treatment compared to the supplementation (\( P < 0.001 \)), but it was similar among the supplements. However, when the ingestion of NDF was expressed in % of BW, there was an increase in NDF intake for the MM treatment, if compared with the other treatments (\( P = 0.021 \)). No effect of supplement was reported for substitution rate (\( P = 0.053 \)) (Table 2).

#### Apparent digestibility and performance

The DM digestibility was higher in the WB group without difference among the other treatments (\( P = 0.003 \)). The CP digestibility was higher for the MPM and WB groups.

### Table 2

| Item \(^1\) | Treatments \(^2\) | SEM \(^3\) | \( P \)-value |

\(^1\)Treatment: \( MM \), mineral mix; \( MPM \), mesquite pod meal; \( WB \), wheat bran; \( SG \), sorghum grain. \(^2\)Item: DMI, dry matter intake expressed in kg/day and % of body weight; DMf, dry matter from forage (kg/day); DMc, dry matter intake from concentrate (kg/day); DMf (%BW), DM of forage expressed in % of body weight; CP (g/day), crude protein intake; NDF (kg/day), neutral detergent fiber intake; NDF (%BW), neutral detergent fiber intake expressed in % of body weight; SR, substitution rate. \(^3\)SEM, standard error mean. Statistical difference was declared when \( P < 0.050 \).

\( a, b, c \) Means within a row with different superscripts differ.
(P < 0.001). The MM group presented the lowest value with intermediate digestibility for the SG treatment (P < 0.001). The NDF digestibility was similar among the supplemented animals and higher if compared to the control group (MM) (P = 0.002). The supplementation of grazing lambs increased the final body weight and ADG, if compared to the MM group (P < 0.001). The lambs that received MPM and WB gained 6.43 kg more than the ones in the control group and 6.63 kg more for the lambs receiving SG treatment, compared to the control group (P < 0.001); however, there was no difference among energy source, as well as for feed conversion (P < 0.0001). The lambs supplemented with SG presented higher feed efficiency than the MPM and WB treatments (P < 0.0001), with lower feed efficiency for the control treatment (MM) (Table 3).

**Discussion**

Supplementation is necessary when forage does not meet the nutritional requirements of animal grazing (Fieser et al. 2007). However, some aspects of this technology may occur in this situation as an additive, substitutive, or combined effect. In the present study, an additive effect was observed with increase of the total DMI when the lambs were supplemented, without a decline in the forage DMI as described in Table 2. The reduction on forage DMI is a common occurrence when a supplement is provided for animals grazing (Stockdale 2000). Similarly to the present study, Franco et al. (2017) observed an increase of the total DMI of supplementation for grazing lambs improves the total DMI when 16.0 g/kg of BW of supplementation was provided for European x Zebu young bulls. In the present study, the level of supplementation was 10.0 g/kg of BW. A low level of supplementation for grazing lambs improves the total DMI due to a possible improvement in the ruminal environment. When a more fermentable substrate is provided, the bacteria that degrade fiber grow faster, making it possible a rapid degradability of the digesta.

To statistically describe the degree of the SR, we performed the analysis just for supplemented groups. The average of SR was −0.925, with the lower SR for SG treatment being −0.642, without differences among the treatments. A SR < 1 implies that the total DMI of supplemented animals is higher if compared to the unsupplemented animals (Bargo et al. 2003), as shown in the present study. The lower negative value of SR in the SG treatment indicates a higher energy balance in this group, if compared to MPM and WB groups. Tedeschi et al. (2019) reported that SR is high when the energy balance is positive and the supplementation is based on starchy concentrations.

The energy of the supplement provides a negative feedback and consequently negatively impacts the voluntary feed intake (Tedeschi et al. 2019); thus, the use of a source of energy could promote a decrease in total DMI. However, in the present study, the total DMI was increased with supplementation, showing an associative effect between forage and the energy source used as a supplement.

In the present study, CP intake increased with supplementation. The average intake of the supplemented lambs was 162 g/day, and the lambs fed only with the MM consumed 88.1 g/day of CP per day, 74.1 g lower than the supplemented lambs. When goats were supplemented on the pasture, CP intake increased (Silva et al. 2016). Due to the high protein content of these feedstuffs, more CP intake of supplemented lambs was expected. The ingestion of more CP (g/day) implies more nitrogen and amino acids that can be used by the microbial population in the rumen as fibrolytic and non-fibrolytic bacteria, and this is directly linked with ADG (Bishaw and Melaku 2008). Ramos et al. (2019) observed that the increase of protein in the diet of summer grazing lambs increased the body weight gain.

**Table 3** Nutrient apparent digestibility and performance of lambs supplemented during the rainy season

| Item² | Treatment¹ | SEM³ | P-value |
|-------|------------|------|---------|
|       | MM         | MPM  | WB      | SG      |       |

a, b, c Means within a row with different superscripts differ
The DM, CP, and NDF apparent digestibility was affected by supplementation, more due to the higher digestibility of the concentrate than to the forage itself (Almeida et al. 2012), shown by the lower digestibility of NDF for the control group in this study. In the present study, better digestibility of DM in supplemented groups was obtained in WB. These results can be justified by the characteristics of the energy sources. The structure of the WB is more easily attacked by the microbial population in the rumen, increasing the digestibility by rapid fermentation. This characteristic seems to be the reason to increase the digestibility of the DM for this treatment. Habib et al. (2001) showed that WB has a maximum rate of degradation and effective degradability.

In the present study, the lambs supplemented with SG and MPM had a lower DM and CP digestibility. However, the data does not provide a clear explanation for these results. One plausible explanation is that these treatments had a lower retention time in the rumen due to its chemical and physical properties. Feeds with high fermentable carbohydrates pass faster through the total tract and decrease the degradation rate (Yahaghi et al. 2013). The lack of effect for energy source in NDF digestibility can be attributed to the frequency of the allowance to the supplementation, promoting low changes in the rumen environment (Dieho et al. 2017).

At grazing conditions, lambs that received supplementation had higher performance than those that were not supplemented. The pasture alone does not have the capacity to supply the total animal’s nutritional requirement in all situations. Even in conditions of greater availability of the forage, a higher weight gain is not achieved or the weight gain is smaller than the expected. The present study demonstrates that supplementation during the rainy season may be a strategy to increase weight regardless of the source of energy during the rainy season.

In the present study, the FBW and ADG of supplemented lambs were higher than those for the control group. These results reinforce the importance of supplementation, as reported by Baroni et al. (2010) and Silva et al. (2014, 2016) in grazing systems. Greater weight gain in supplemented lambs is mainly due to the increased energy and protein intake and the ratio of metabolizable protein/energy (Singh et al. 2013). In our study, the results demonstrate that the supplementation increased the ADG twofold if compared to the control group, explained by the increase of the energy availability provided by the diets. So, even under conditions of pasture availability, the use of supplementation can be necessary to obtain higher weight gains. Interesting, the live weight gain per hectare was improved (+ 7.04 kg) when sheep was supplemented in the rainy season, but not during the dry season (Silva et al. 2019). The result of this study supports the point that the response to supplementation depends on the forage quality and availability. Additionally, the results sustained our hypothesis that it is necessary to supplement even during the rainy season.

Despite that, no difference among energy source was detected, showing that any of the energy sources can be used during the rainy season. In this situation, the availability and costs of the feeds can be the factors that determine the use of one or another source of energy. Similarly, Nascimento et al. (2010) performed a study with different sources of energy supplementation and they did not observe a difference between treatments. The ADG increased 9.57% in supplemented animals when different protein supplements were used (Carvalho et al. 2015), with gains of 80.0 g/day, much lower than those observed in the present study. Similarly, Almeida et al. (2012) observed a higher ADG of lambs supplemented with 7.23 g/day with MM alone, a value that is lower than in the present study (61.7 g/day).

The control group needed an intake 4.50 kg/day of DM more than in the other treatments to gain 1.00 kg of body weight. This result implies that MM alone does not provide enough energy for the lambs, shown by the low digestibility of the forage. So, the results of the present study support the hypothesis that provides supplementation for grazing lambs even during rainy season is a good strategy for higher weight gains. Given the obtained results, it can be concluded that the supplementation for grazing lambs increased intake of DM, CP, and NDF. Any supplement tested in the present study can be used during the rainy season. The choice of the supplement will depend on the availability and costs of the supplement.

Acknowledgements The authors would like to thank the Palmares, located at Macarani, BA, Brazil, farm to provide the area and the animals and the Universidade Estadual do Sudoeste da Bahia, located at Itapetinga, BA, Brazil, to provide the laboratory to perform the chemical analysis.
