The self-consistent rate theory for surface growth in the submonolayer regime is generalized from mono- to multi-component systems, which are formed by codeposition of different types of atoms or molecules. As a new feature, the theory requires the introduction of pair density distributions to enable a symmetric treatment of reactions among different species. The approach is explicitly developed for binary systems and tested against kinetic Monte Carlo simulations. Using a reduced set of rate equations, only a few differential equations need to be solved to obtain good quantitative predictions for island and adatom densities, as well as densities of unstable clusters.

I. INTRODUCTION

Growth of solid structures on surfaces, induced by atomic or molecular deposition, has become a widely applied method for generating materials of nanoscale dimensions. The resulting clusters or thin films are often metastable and their structure depends on kinetics rather than thermodynamics. Understanding and control of such growth processes are prerequisites for designing nanomaterials of practical use. Multi-component systems are particularly promising in this respect because of their larger structural variability compared to single-component systems. In the submonolayer growth regime one-monolayer islands can act as seeds for 3D structures that emerge in later stages of growth.

Island nucleation and submonolayer growth of binary systems, driven by co-deposition of two species $A$ and $B$, has recently been investigated by using rate equations and kinetic Monte-Carlo (KMC) simulations. Generalized relations were established that describe the scaling of stable island densities with the partial fluxes $F_{\alpha}$, adatom diffusion coefficients $D_{\alpha}$ and mutual binding energies $E_{\alpha\beta}$. Simulations also showed that island density data, when combined for different compositions, enable to extract microscopic parameters for mixed systems. Of particular value is the possibility to determine the binding energy $E_{AB}$ between unlike atoms in the presence of a surface.

In the rate equations for submonolayer growth, capture numbers $\sigma_{\alpha}$ appear as parameters, which determine the attachment rate of diffusing adatoms to islands of size $s$. Already in the single-component case it is known that for a quantitative description of island densities as a function of coverage $\Theta$, it is essential to deal with effective capture numbers $\sigma_{\alpha}(\Theta, \Gamma)$. Their dependence on the coverage $\Theta$ and the “$D/F$-ratio”, $\Gamma = D/F$, reflects the fact that the efficiency of an island of size $s$ to capture adatoms is affected by the shielding by other islands in its neighborhood. Within a mean-field description of these shielding effects, a central $s$-sized island is thought to be embedded in an effective medium, characterized by an absorption length $\xi$ for the adatoms. This length describes the capture efficiencies of all islands in an averaged manner. As the rate of capture by the central island is determined by the $\xi$-dependent adatom density profile in its vicinity, one arrives at a self-consistency condition for $\sigma_{s}$. Originally, this self-consistent theory was formulated for diffusion-limited irreversible growth. Later it has been extended to include detachment kinetics and to examine capture numbers in the presence of cluster diffusion and adsorbate interactions.

Our goal here is to generalize the self-consistent theory of diffusion-limited growth to multi-component systems. In order to obtain capture numbers which are symmetric under the exchange of species, it is needed to introduce pair distribution functions. The treatment will be focuses on binary systems, where trimers and larger islands are stable irrespective of composition, whereas the stability of dimers $AA$, $AB$, and $BB$ is allowed to be composition dependent. Generalizations are discussed in Sec. VI.

II. RATE EQUATIONS FOR BINARY SYSTEMS

Following earlier work, we start out from rate equations for island densities in a system of two species $A$ and $B$. For simplicity, we will speak about $A$ and $B$ “atoms”, but these could be also molecules, if their geometrical arrangement with respect to the substrate topology does...
not play an essential role for the time evolution of island densities. The $A$ and $B$ species are assumed to be deposited as adatoms (no cluster deposition) and to be mobile on the surface. They undergo nucleation and desorption reactions among themselves, and they attach to and detach from already formed islands of larger size. These larger islands are considered to be immobile. The coverage $\Theta$ is supposed to be small enough so that coalescence of islands can be neglected. Direct impingement of arriving atoms onto already existing islands and desorption processes are neglected, or they may be taken into account by inducing properly re-scaled fluxes. Furthermore, we limit our discussion to cases where the largest unstable islands are composed of not more than two atoms. Then the time evolution of adatom densities $n_{\alpha}$, $\alpha = A, B$, is given by

$$\frac{dn_{\alpha}}{dt} = F_{\alpha} - 2D_\alpha \sigma_{\alpha}^{\alpha} n_{\alpha}^2 - (D_A + D_B) \sigma_1^{AB} n_A n_B - D_\alpha n_{\alpha} \sum_{s \geq 2} \sigma_s^{\alpha} n_s + K_2^{AB} n_A n_B + 2K_2^{\alpha\alpha} n_{\alpha\alpha}. \tag{1}$$

Positive contributions to (1) arise from the partial fluxes $F_{\alpha} = x_\alpha F$, with $x_\alpha$ the fraction of $\alpha$-atoms and $F = F_A + F_B$ the total flux, and from the decay of the different kinds of dimers with densities $n_{\alpha\beta}$. Negative contributions refer to the formation of dimers and attachment of adatoms to $s$-sized islands. Note that the diffusion coefficient for the relative motion of $A$ and $B$ is $D_A + D_B$. In the sum over $s$, the term $s = 2$ involves $n_2 = n_{AA} + n_{AB} + n_{BB}$. The rate equations for dimer densities are

$$\frac{dn_{\alpha\alpha}}{dt} = D_\alpha \sigma_1^{\alpha\alpha} n_{\alpha}^2 - (\sum_\beta D_\beta \sigma_2^{\beta\beta} n_{\alpha\beta}) n_{\alpha\alpha} - K_2^{\alpha\alpha} n_{\alpha\alpha}, \tag{2}$$

$$\frac{dn_{AB}}{dt} = (D_A + D_B) \sigma_1^{AB} n_A n_B - (\sum_\beta D_\beta \sigma_2^{\beta\beta} n_{AB}) - K_2^{AB} n_A n_B. \tag{3}$$

The upper indices in the capture numbers $\sigma_1^{\alpha\beta}$, $\sigma_s^{\alpha\beta}$ and decay rates $K_s^{\alpha\alpha}$ serve to distinguish the types of adatoms that are involved in a reaction. The $\sigma_1^{\alpha\beta}$ and $K_2^{\alpha\beta}$ respectively, refer to formation and dissociation of an $\alpha\beta$-dimer. The $\sigma_s^{\alpha\beta}$, $s \geq 2$, refer to the capture of an $\alpha$ adatom by an island composed of $s$ atoms. The geometry of such island is represented by a circular shape (formation of compact islands) with radius $R_s = s^{1/2} R_1$, where $R_1$ is the adatom radius. Since we allow composition-dependent (“mixed”) dimer stabilities, some of the decay rates can be zero. For the purpose of calculating $n_{\alpha}$, $n_{\alpha\beta}$ and the total density of stable islands, $N$, it appears sufficient to ignore any further composition dependences of parameters beyond those given in Eqs. (2) and (3).

The densities of islands with $s > 2$ evolve according to

$$\frac{dn_s}{dt} = \sum_\alpha D_\alpha n_{\alpha} (\sigma_{s-1}^{\alpha} n_{s-1} - \sigma_{s}^{\alpha} n_s). \tag{4}$$

### III. Irreversible Growth

In the self-consistent rate theory, analytical expressions for the capture numbers and decay rates are derived by introducing an effective medium that describes adatom capture in an averaged manner by an absorption length $\xi$. For binary systems, the effective medium is characterized by two different absorption lengths $\xi_\alpha$ for the two adatom species. To define $\xi_\alpha$, the evolution equations (1) for monomer densities with zero decay terms ($i = 1$) are rewritten as

$$\frac{dn_{\alpha}}{dt} = F_{\alpha} - \frac{1}{\tau_\alpha} n_{\alpha}, \tag{5}$$

where $\tau_\alpha^{-1} = D_\alpha/\xi_\alpha^2$ is the reaction rate of $\alpha$ adatoms in the effective medium, and

$$\xi_\alpha^{-2} = \sum_\beta (1 - \delta_{\alpha\beta}) \sigma_1^{\alpha\beta} \left(1 + \frac{D_\beta}{D_\alpha}\right) n_\beta + 2\sigma_2^{\alpha\alpha} n_{\alpha} + \sum_{s \geq 2} \sigma_s^{\alpha} n_s. \tag{6}$$

Deposition, diffusion and absorption of adatoms within the effective medium are described by local densities $\tilde{n}_\alpha (r)$ with $n_\alpha = \int V d^2r \tilde{n}_\alpha (r)/V$, where $V$ is the two-dimensional volume (surface area). These satisfy

$$\frac{\partial \tilde{n}_\alpha}{\partial t} = F_\alpha + D_\alpha \Delta \tilde{n}_\alpha - \frac{1}{\tau_\alpha} \tilde{n}_\alpha. \tag{7}$$

In the mono-component case, one would have just one equation of this type, and by supplementing this with appropriate boundary conditions, the stationary density profiles of adatoms around islands with radius $R_s$ can be calculated and the total adatom flux to the islands identified with the corresponding capture terms in Eqs. (1). This procedure yields self-consistent analytical expressions for the capture numbers and decay rates in the mono-component case.

For binary (multi-component) systems, the reaction between unlike adatoms needs a refined treatment. This has the following reason: In a naive extension of the mono-component case, the $B$ adatom density around an $A$ adatom would be characterized by an absorption length $\xi_B$, and the $A$ adatom density around a $B$ adatom by an absorption length $\xi_A$. However, the shape of both profiles is given by the pair density $n_{AB} (r, r')$ of $A$ and $B$ adatoms and hence the profiles must be characterized by the same capture length (if inversion symmetry holds). In fact, introducing the pair distribution function $G_{f g}(r)$

$$G_{AB}(r) = \frac{1}{V} \int_V d^2r' \int_V d^2r'' n_{AB} (r', r'') \delta (r - (r' - r'')). \tag{8}$$
allows one to treat unlike adatoms in a symmetric way, resulting in a symmetric expression for $\sigma_{AB}$. $G_{AB}(r)$ is the number of pairs of $A$ and $B$ adatoms at distance $r$ per area. Let us note that the approach based on pair distribution functions is well known in the kinetic theory of bimolecular chemical reactions.\textsuperscript{30,31} In our context, spatial correlations between adatoms for relative distances larger than the contact distance $R_1 = 2R_4$ play no role so that

$$n_{AB}(r, r') = \tilde{n}_A(r)\tilde{n}_B(r') , \quad |r - r'| > R_1 . \quad (9)$$

Combination with (7) yields an expression for the time derivative of $n_{AB}(r, r')$. Subsequent multiplication by $\delta(r - (r' - r''))$ and integration over all $r'$ and $r''$ gives

$$\frac{\partial G_{AB}(r)}{\partial t} = F_A n_A + F_B n_B + (D_A + D_B) \Delta G_{AB}(r) - \left( \frac{1}{\tau_A} + \frac{1}{\tau_B} \right) G_{AB}(r) . \quad (10)$$

Subtracting $d(n_{AB} n_B)/dt$ with the help of Eqs. (6) and going over to the quasi-stationary limit, we obtain

$$(D_A + D_B) \Delta G_{AB}(r) = \left( \frac{1}{\tau_A} + \frac{1}{\tau_B} \right) (G_{AB}(r) - n_A n_B) . \quad (11)$$

Alternatively,

$$\Delta G_{AB}(r) - \frac{1}{\xi_{eff}} (G_{AB}(r) - n_A n_B) = 0 , \quad (12)$$

where we introduced the effective absorption length

$$\xi_{eff}^{-2} = \frac{1}{D_A + D_B} \left( \frac{D_A}{\xi_A^2} + \frac{D_B}{\xi_B^2} \right) , \quad (13)$$

which is a weighted average of $\xi_{\alpha}^{-2}$, with weighting factors $D_{\alpha}/(D_A + D_B)$.

For $i = 1$, implying complete absorption at contact, and assuming isotropy, the boundary conditions to Eq. (12), are

$$G_{AB}(r) \to \begin{cases} n_A n_B & r \to \infty , \\ 0 & r \to R_1 , \end{cases} \quad (14)$$

where $r = |r|$ and we have replaced $G_{AB}(r)$ by $G_{AB}(r)$. The solution of Eq. (12) with the boundary conditions in Eq. (14) is $G_{AB}(r) = n_A n_B [1 - K_0(r/\xi_{eff})/K_0(R_1/\xi_{eff})]$, where $K_\nu$ is the modified Bessel function of order $\nu$.

To obtain the reaction rate, we first select reactions along a particular direction $\hat{r} = r/|r|$, $r$ being the relative coordinate between an $A$ and $B$ atoms right before contact. The corresponding rate is given by

$$I(\hat{r}) = \lim_{|r| \to R_1} \frac{1}{V} \int d^2 r' \int d^2 r'' \hat{r} \cdot \left[ j_B(r'') \tilde{n}_A(r') - j_A(r') \tilde{n}_B(r'') \right] \delta(r - (r' - r'')) , \quad (15)$$

where $j_\alpha(r) = -D_\alpha \nabla \tilde{n}_\alpha(r)$. Substituting this expression into (15) and using (8), we can reexpress (15) as

$$I(\hat{r}) = (D_A + D_B)[\partial G_{AB}/\partial r] |_{R_1} .$$

After integration along the boundary at $r = R_1$, we obtain the total number of reactions per second and per unit area, which is identified with the corresponding term in the original rate equations, $(D_A + D_B)\sigma_{AB}^{1AB} n_{AB}$. Thus, we obtain

$$\sigma_{1AB}^{1AB} = 2\pi R_1 \frac{1}{n_A n_B} \left( \frac{\partial G_{AB}}{\partial r} \right) |_{R_1} . \quad (16)$$

Evidently, this result for $AB$-capture in a binary system has a structure analogous to the self-consistent capture number $\sigma_1$ for a one-component system of overall adatom density $n$ and diffusion coefficient $D$. That situation and the present one can be mapped onto each other by $n \leftrightarrow n_A n_B$; $2D \leftrightarrow D_A + D_B$; $\tilde{n}(r) \leftrightarrow G_{AB}(r)$ for the local densities in the SCF-treatment, and $\xi \leftrightarrow \xi_{eff}$, where $\xi_{eff}$ was defined by (13). Hence we can immediately translate known results for one-component systems to the present case, to obtain

$$\sigma_{1AB}^{1AB} = 2\pi R_1 \frac{K_1 (R_1/\xi_{eff})}{\xi_{eff}}. \quad (17)$$

The $\sigma_{1A}^{\alpha}$ are obtained by introducing the pair correlation function $G_{\alpha\alpha}(r)$ for like particles and repeating the above steps. For $\sigma_{1A}^{\alpha}$ we recover the form (17) with $\xi_{eff}$ replaced by $\xi_\alpha$. Moreover, we need $\sigma_\alpha$ for $s \geq 2$. Since islands with $s \geq 2$ do not move, the result is again equivalent to (17), where one type of adatoms has zero diffusion coefficient. For example, $\sigma_A^A$ is given by (17) with $D_B = 0$, hence $\xi_{eff} = \xi_A$, and $R_1$ replaced by $R_s = R_s + R_1$. Clearly, our treatment also covers one-component systems through the limit where $A$ and $B$ atoms become indistinguishable.

\section{IV. DECAY PROCESSES}

In this section we extend the above scheme to include detachment processes. First, we focus on unstable $AB$-dimers, characterized by some finite binding energy $E_{AB}$. This situation can be incorporated into the treatment of Sec. II\textsuperscript{1} by a modification of the boundary condition (14). Consider detachment and re-attachment reactions between an $A$ and $B$ adatom. Within a lattice model and $E_{AB}$ a nearest neighbor binding energy, the bound state corresponds to an $AB$-pair located on nearest neighbor sites, whereas in the detached state the $A$ and $B$ adatoms are separated by one vacant site. By $n_{AB}$ and $n_{AB}^*$ we denote the densities of bound and detached states of this type. Assuming local equilibrium, both densities are related by

$$n_{AB}^* = n_{AB} \mu_{AB} \exp(-E_{AB}/k_B T) . \quad (18)$$

The factor $\mu_{AB}$ is determined by the degeneracies of the bound and dissociated states in a circularly averaged description, and depends on the geometry of $A$.
and $B$ adsorption sites on the surface. We do not go into the underlying counting problem for specific lattice geometries, but merely treat $\mu_{AB}$ as a parameter. Writing $\mu_{AB} \exp(-E_{AB}/k_B T) = \kappa_{AB}$ we arrive at the local equilibrium boundary condition

$$G_{AB}(r) \rightarrow \kappa_{AB} n_{AB}, \quad r \rightarrow R_2. \quad (19)$$

As before, see Eq. (11), $G_{AB}(r) \rightarrow n_{AB} n_B$ as $r \rightarrow \infty$. Solving Eq. (12) for these boundary conditions yields $G_{AB}(r) = n_{AB} n_B \left[1 - (\kappa_{B}(r/\xi_S)/K_0(R_1/\xi_S))\right]$ with $\kappa = (1 - \kappa_{AB} n_{AB}/n_{A} n_B)$.

The total reaction rate can be then written as$^{23}$$I_{\text{tot}} = I_{\text{capture}} - I_{\text{decay}}, \quad (20)$

where $I_{\text{capture}} = (D_A + D_B) \sigma_1^{AB} n_{AB}$ is defined with $\sigma_1^{AB}$ from Eq. (10), and

$$I_{\text{decay}} = \frac{n_{AB}}{n_A n_B} \kappa_{AB} I_{\text{capture}}. \quad (21)$$

Identification with the corresponding decay term $K_2^{AB} n_{AB}$ in Eq. (11), we find

$$K_2^{AB} = (D_A + D_B) \kappa_{AB} \sigma_1^{AB}. \quad (22)$$

In the same way we obtain

$$K_2^{AB} = 2D_A \kappa_{AA} \sigma_1^{AA}, \quad (23)$$

with $\kappa_{AA} = \mu_{AA} \exp(-E_{AA}/k_B T)$. Again, the degeneracy factors $\mu_{AA}$ are treated as parameters.

Note that when we use these results for the self-consistent capture and decay numbers in the two-component Walton relations$^{23}$, $(D_A + D_B) \sigma_1^{AB} n_{AB} \approx K_2^{AB} n_{AB}$, it follows that $I_{\text{capture}} \simeq I_{\text{decay}}$. This is consistent with the quasi-stationarity assumption underlying the Walton relations$^{23}$, which implies that the capture and decay rates nearly balance. Let us further note that reaction barriers for formation and dissociation of dimers can also be incorporated in the treatment. They lead to a modification of the boundary condition (11), corresponding to a partially reflecting boundary, sometimes called “radiative boundary condition.”$^{23,31,33}$

**V. NUMERICAL RESULTS AND DISCUSSION**

The coupled set of rate equations (11)-(13) along with the self-consistent expressions for the capture numbers must be solved numerically by using an iterative integration scheme. An adequate but time-consuming numerical integration requires to solve a large number of equations for an $s$-range in Eqs. (11) significantly exceeding the mean island size $\bar{s} = \Theta/N$. A much simpler approach of almost the same quality has been proposed for one-component systems by Venables$^{34}$ and can be taken over to binary mixtures considered here. In the case $i = 1$, where $K_2^{AB} = 0$, this approach amounts to setting

$$\sum_{s \geq 2} \sigma_2^{AB} n_s = \bar{s}\alpha N. \quad (24)$$

in Eq. (6), to be combined with Eq. (5). Here, $\bar{s}\alpha$ is the average capture number of stable clusters. Inserting the results from Sec. III for $\sigma_2^{AB}$ [see the discussion following Eq. (17)] and assuming that $n_s$ is sufficiently peaked around the mean island size $\bar{s}$, one obtains

$$\bar{s}\alpha = 2\pi \frac{R}{\bar{s}} \kappa_{A} \left( \frac{\bar{s}/\xi_S}{\xi_S} \right) \frac{R_{1}/\xi_S}{\kappa_{0}(R_1/\xi_S)}.$$

where $\bar{R} = R_s = (\bar{s}/2 + 1)/R_1$. The self-consistency problem then reduces to solving three coupled equations, Eq. (5) for $\alpha = A$ and $B$, and the equation for nucleation of stable clusters,

$$\frac{dN}{dt} = \sum_{\alpha} D_{\alpha} \sigma_1^{\alpha A} n_{A}^{2} + (D_{A} + D_{B}) \sigma_1^{AB} n_{AB} n_{B}. \quad (26)$$

Capture numbers $\sigma_2^{AB}$ and $\bar{s}\alpha$ entering these equations become functions of $n_{A}$ and $N$.

In the more general case of Sec. IV allowing dimer decay processes, we must distinguish between stable and unstable dimers. The example considered below refers to unstable $BB$ dimers but stable $AA$ and $AB$ dimers, which entails the decomposition

$$\sum_{s \geq 2} \sigma_2^{\alpha} n_s = \sigma_2^{AB} n_{BB} + \bar{\sigma}\alpha N. \quad (27)$$

The relevant rate equations now include Eq. (2) for $\alpha = B$ and

$$\frac{dN}{dt} = D_{A} \sigma_1^{A A} n_{A}^{2} + (D_{A} + D_{B}) \sigma_1^{AB} n_{A} n_{B} + (D_{A} \sigma_1^{B} n_{B} + D_{B} \sigma_1^{A} n_{B}) n_{BB} \quad (28)$$

instead of (26).

To test the self-consistent theory based on that reduced set of coupled rate equations, we have performed KMC simulations for codeposition of $A$ and $B$ atoms onto a triangular lattice with $500 \times 500$ sites at various compositions and $D_{A}/D_{B}$ ratios, and for different situations of cluster stabilities with respect to their size and composition. Atoms are deposited at random to vacant substrate sites and diffuse via nearest-neighbour hops, excluding multiple site occupation. Attachment of monomers to islands is accompanied by instantaneous relaxation to highly coordinated edge sites, yielding compact cluster structures. For each parameter set, the number densities were averaged over 50 realizations.

First, we study the situation of irreversible growth, $i = 1$. Results for $N$ and $n_s$ are plotted in Fig. 1 as a function of the coverage $\Theta = Ft$ for two concentrations $x_A = 0.75$ and $x_A = 0.25$. In the simulations for both concentrations, $D_B/F = 10^7$ was fixed, and two values $D_A = 10D_B$ and $D_A = 0.1D_B$ were considered. The reduced self-consistent theory without fitting parameters (solid lines) evidently is in good quantitative agreement with the KMC simulations (open symbols). At low coverages (short times), $n_s = x_{\alpha} \Theta$, whereas
in the scaling regime (see discussion in Refs. 4 and 8),
\( n_\alpha \approx x_\alpha F/D_\alpha N^{13/28} \) By going from Fig. 1(a) to (b),
the diffusion coefficient of the majority component \( A \) is
lowered by a factor \( 10^2 \), which explains the fact that \( n_A \)
gets much larger than \( n_B \) and the corresponding curves
do not intersect anymore. Inspection of Eq. (28) in turn
shows that nucleation of stable islands in Fig. 1(a) is
mostly due to the second term, i.e., nucleation of \( AB \)
dimers prevails, whereas in Fig. 1(b) both \( AA \) and \( AB \)
dimers will appear with similar densities. In Fig. 1(b),
\( N \) close to saturation becomes significantly larger than
in Fig. 1(a), which is consistent with the scaling form
\( N \propto (\Gamma_{\text{eff}})^{-1/3} \) with \( \Gamma_{\text{eff}} = (\sum_\alpha x_\alpha F/D_\alpha)^{-1/3} \). For
\( x_A = 0.25 \) [Figs. 1(c) and (d)] the influence of the mobility
ratio \( D_A/D_B \) on \( N \) is less pronounced. Nucleation in
Fig. 1(c) proceeds mainly by formation of \( BB \) dimers.

Next we include detachment kinetics. Specifically, we
assume that the stability of dimers depends on their composition:
\( AA \) and \( AB \) dimers are stable \( (K_{AA}^{AB} = K_{AB}^{AA} = 0) \), while \( BB \) dimers are unstable with zero binding energy.
The number density of stable islands is given by
\( N = n_{AA} + n_{AB} + \sum_{s>2} n_s \) and its time evolution obeys
Eq. (28). Again, numerical results based on our self-
consistent rate equations for mixtures are in good quanti-
tative agreement with the KMC simulations. This is
shown in Figs. 2(a)-(c) and Figs. 3(a)-(b) for the same values of \( x_A \) and \( D_\alpha \) as considered in Fig. 1.

A feature worth noting in Fig. 2(b) is the occurrence of
a local minimum of \( n_A \) as a function of \( \Theta \) for \( x_A = 0.25 \)
and \( D_A/D_B = 0.1 \). It can be understood as follows. For
these parameters and throughout the nucleation regime,
\( AB \) nucleation is the dominating process for capture of
\( A \)-atoms, see Figs. 3(a) and (c) below. The reason is that
\( BB \) dissociation entails a large number of \( B \) adatoms, as
can be seen in Fig. 2(c): The peak in \( n_B \) near \( \Theta \approx 10^{-3} \)
is about 2.5 times higher than the corresponding peak in
Fig. 1(d) in the absence of dissociation. When, with increas-
ing \( \Theta \), the \( B \) adatom density \( n_B \) approaches its max-
imum, \( AB \) nucleation becomes strong enough to over-
come the gain of \( n_A \) by the external flux \( F_A \), hence \( n_A \)
gets depleted. Beyond \( \Theta \approx 10^{-3} \), on the other hand,
\( n_B \) quickly decreases due to reactions with stable islands
so that \( n_A \), after going through a minimum, can increase
again through deposition with \( F_A \). Upon further increasing
\( \Theta \), it passes a second maximum and finally drops
through absorption by stable islands.

Shortly speaking, the consumption of \( n_A \) after its first
maximum in Fig. 2(b) is governed by \( AB \) nucleation,
and after its second maximum by attachments to stable
islands. The rise of the \( A \) adatom density after the mini-
mum is due to missing \( B \) adatoms for \( AB \) nucleation and
the small \( D_A \) value. From this discussion it should be
come clear, why the minimum is not seen for the curves
with the larger value \( D_A/D_B = 10 \) (shorter mean time
to traverse the mean free path) or the larger \( x_A = 0.75 \)
(smaller mean free path for \( AA \) nucleation).

FIG. 1. (Color online) Number densities of \( A \) and \( B \) adatoms, and stable islands as a function of the coverage \( \Theta = Ft \) for \( i = 1 \)
and various combinations of \( x_A \) and \( D_A/D_B \). Results from the self-consistent rate theory are given by solid lines.
To discuss nucleation rates based on Eq. (28) and the self-consistent theory, note first that in all our examples nucleation of trimers via $BB$ dimers is rare, because $n_{BB}$ is small due to decay processes. Therefore the last term in Eq. (28) is negligible. The remaining two terms, giving the partial rates for nucleation via $AA$ and $AB$ dimers, are represented in Fig. 2(c) by open and filled symbols, respectively. For example, for $x_A = 0.75$ and $D_A/D_B = 0.1$, the term $2D_A\sigma_1^{AA}(n_A)^2$ (open diamonds) becomes larger than the term $(D_A + D_B)\sigma_1^{AB}n_An_B$ (filled diamonds). The formation of stable islands [open diamonds in Fig. 2(a)] is therefore caused mostly by the nucleation path via $AA$ dimers. By contrast, for $x_A = 0.25$ and $D_A/D_B = 10$ we observe the opposite scenario [see open and filled triangles in Fig. 2(c)], which means that $AB$ nucleation prevails. In the remaining two cases in Figs. 2 and 3 both the $AA$ and the $AB$ dimer route contribute with similar strength to the formation of stable islands.
VI. CONCLUSIONS

We have shown that a self-consistent treatment of capture numbers in the rate equations for surface growth of binary systems yields a very good quantitative description of island and adatom densities. Essential for this theory is the effective absorption length $\xi_{\text{eff}}$ in Eq. (13), which is symmetric in the two components $A$ and $B$. Its derivation requires the introduction of pair densities. Note that the weighting factors $D_{\alpha}/(D_A + D_B)$ appearing in that equation can strongly vary with temperature as the underlying activation energies for the two species generally differ. By this, $\xi_{\text{eff}}$ acquires an additional temperature dependence which we expect to become important in measurements of island and adatom densities.

Different scenarios for dimer stabilities and prevailing nucleation routes were studied. In all cases, only a reduced set of few coupled rate equations needs to be solved, which can easily be done on a PC.

Extensions of our theoretical treatment to larger unstable clusters is straightforward by first generalizing the rate equations as described in Ref. [13]. Reduced sets of coupled rate equations comprise the densities of stable islands, monomers and all unstable clusters. Extensions to systems with more than two components and (as before) pairwise reactions follows directly from the above scheme by introducing pair densities $G_{\alpha\beta}(r)$ among all mobile adatom species $\alpha$ and associated effective absorption lengths $\xi_{\alpha\beta}$. More generally, in the case of non-vanishing cluster mobilities, pair densities need to be introduced for all pairs of mobile species.
