Abstract
A recent outbreak of a novel Coronavirus responsible for a Severe Acute Respiratory Syndrome (SARS-CoV-2) is spreading globally. The aim of this study was to systematically review the existing evidence on SARS-CoV-2 infections in pediatric age.

An electronic search was conducted in PubMed database. Papers published between the 1st of January and the 7th of April, 2020 including children aged 0-18 years were selected.

Fifty-two studies and two reviews were included, with a total sample size of 4,612 children (2,366 males, 51.3%, weighted mean age 7 years). Patients showed mainly mild (1285/2679, 48.5%) and moderate (1035/2679, 39.1%) signs of the infection. Less than 2% of children were admitted to the Pediatric Intensive Care Unit. The most commonly described symptoms were fever (49.2%) and cough (44.1%). Laboratory findings were often unremarkable. Children underwent a chest CT-scan in 85.7% of all cases, and 36% resulted normal. Overall, the estimated mortality was 0.07%. A higher proportion of newborns was severely ill (17%) and dyspnea was the commonest reported sign (40%).

Conclusion: SARS-CoV-2 affects children less severely than adults. Laboratory and radiology findings are mainly nonspecific. Larger epidemiological and clinical cohort studies are needed to better understand possible implications of COVID-19 infection in children.

Introduction
In early January 2020, a novel type of Coronavirus (CoV) was identified in the bronchoalveolar lavage sample of a subject affected by pneumonia of unknown origin[1]. The virus was provisionally named novel coronavirus (2019-nCoV)[2] to differentiate it from the Severe Acute Respiratory Syndrome Coronavirus (SARS-CoV)[3] and the Middle East Respiratory Syndrome Coronavirus (MERS-CoV)[4], responsible for two previous outbreaks, in 2002 and 2012 respectively[5]. Successively, the International Committee on Taxonomy of Viruses defined it as SARS-CoV-2[6] and the associated disease has been called 2019 Coronavirus Disease (COVID-19). SARS-CoV-2 rapidly spread worldwide, forcing the World Health Organization (WHO) to declare the outbreak as a pandemic on 11 March[7, 8].

As of April 7, 1,511,104 cases have been reported in 184 countries in all continents except for
Antarctica, with 88,338 deaths and 328,661 recovered[9]. Children seem to be less affected than adults, but data regarding epidemiologic characteristics and clinical features of COVID-19 in pediatric age are very poor and essentially based on limited case series[10, 11]. In a report of 72,314 cases from Chinese Center for Disease Control and Prevention (CDC), about 2% of all patients were aged <19 years, but no specific clinical information was available[12].

Italy has the second largest number of COVID-19 cases in the world, with 1.2% of all patients represented by children[9, 13, 14]. The estimated overall case-fatality rate in Italy resulted higher than in China (7.2% vs 2.3%)[15], but no death in the pediatric age has been reported, confirming that the mortality remains low and no specific risk factor could be identified[16].

Neonatal SARS-CoV-2 infections are also extremely rare and, to date, there is no evidence of intrauterine infection caused by vertical transmission[17, 18]. As described in a case series by Chen et al., amniotic fluid, cord blood, neonatal throat swab and colostrum samples collected from infected mothers were negative for COVID-19[19]. However, as the virus is transmitted via droplets or direct contact, currently in China all newborns are separated from their infected mothers for at least 14 days[20].

Despite the global interest and concern about COVID-19, clinical pattern is still unclear for the pediatric health community. The aim of our review is to provide a concise and systematic overview of the available evidence on clinical, laboratory and radiological findings in children with SARS-CoV-2 infection.

**Materials And Methods**

This study is in compliance with the Preferred Reporting Items for Systematic Reviews and Metaanalyses (PRISMA) guidelines[21].

An electronic search was conducted on studies published from the 1st of January, 2020 to the 7th of April, 2020 in PubMed database. We used the search terms “2019 novel coronavirus OR COVID-19 OR SARS-CoV-2 AND child* OR pediatric* OR newborn OR infant” with no language restriction to include as much data as possible. However, since full texts available only in Chinese language could not be evaluated, we had to rely on English-language abstracts. For the purpose of this review, studies on
children aged 0 to 18 years old were included. Case reports, case series, retrospective or observational studies were all considered eligible.

Articles were first screened by title and abstract: duplicates and those with no available English summary were excluded. Eligible full texts were then assessed for pediatric clinical, laboratory and radiological data. Papers reporting information on both children and adults were included only if pediatric data could be retrieved. To identify missing studies, we also checked the reference list for each selected paper.

Three reviewers extracted data independently. A standardized table with the following information was used for data extraction: first author, date and journal of publication, study design (cohort study, case series, case report), sample size, age, mortality and morbidity rate, clinical features, laboratory and radiological results and treatment information. All included studies were differentiated in tables for newborns and infants ≤ 3 months and for children aged > 3 months.

During the data analysis process, clinical patterns were grouped according to the pediatric scoring for patients with COVID-19 (recommendations issued by the pediatric branch of the Chinese Medical Association[22]). In particular, cases described as “upper respiratory tract infection” (i.e. pharyngeal congestion, sore throat, and fever) with no abnormal radiographic and septic presentation were included in the “mild” symptomatic category. Children with “pneumonia” and no complications were categorized as “moderate”. Patients with mild or moderate clinical patterns, plus any manifestations suggesting disease progression (i.e. tachypnoea, hypoxia, neurological deterioration, dehydration, myocardial injury, coagulation dysfunction, rhabdomyolysis) were considered “severe”. Critically-ill children were those with a rapid disease progression, plus any other of the following conditions: respiratory failure with need for mechanical ventilation (i.e. acute respiratory distress syndrome, persistent hypoxia), septic shock or multiple organ failure (MOF)[22].

Laboratory data were presented as abnormally high or low according to the reference value reported by the paper, if available. Similarly, radiological findings were categorized according to the available description.

A quantitative synthesis of the included studies was performed. For continuous variables, weighted
mean (range) was calculated as appropriate, while categorical variables were expressed as percentages or frequencies in relation to the total or subtotal sample size, according to the number of missing data.

Results

We initially identified 191 papers on SARS-CoV-2 infection in children published from the 1st of January 2020 to the 7th of April 2020. After screening the title and abstract, 101 full articles were evaluated for eligibility. At the end of the selection process (Figure 1), 52[10, 11, 14, 16, 23–70] studies and two previously published reviews[71, 72] with a total sample size of 4.612 children (2.366 males, 51.3%) were included in the systematic review (Table 1). The weighted mean age of patients was 7 years, ranging from 0 to 18 years old. Children included were mainly Chinese (2700/4612; 58.6%) and Italian (1708/4612; 37%). The most extensive retrospective study[16] described clinical characteristics of 2.143 children with confirmed (n=713) or suspected (n=1430) SARS-CoV-2 infection. Overall, 3382/4612 (73.3%) were discharged after a weighted mean hospitalization of 11.6 days (range 2-23). The estimated mortality was 0.07%, with 3 reported deaths: a 10 months baby with intussusception who developed MOF[10], a 14-year-old boy from Hubei province[16], and a preterm newborn who died from complications of sepsis[59]. Significant comorbidities were reported in 11 patients: 3 who were on immunosuppressive treatment for previous liver transplantation[24], 3 with a diagnosis of congenital heart disease[26, 55], 2 with asthma[55, 56], 1 child had acute lymphoblastic leukemia (ALL)[25], 1 with duplicate kidneys[56], and 1 with nephroblastoma[55]. None of them had a severe course of the disease.

Clinical features

Clinical findings were available in 2.679 children aged 3 months-18 years (38 studies)[10, 11, 16, 24–56, 67, 68] (Table 2). Severe and critically ill children accounted for 4.5% (118/2679) and 0.7% (18/2679) of the total sample size respectively. The most commonly described symptoms in pediatric age were fever (49.2%), cough (44.1%) and sore throat (19%). Rarely children were also dyspneic (4.5%) and required oxygen supplementation for SpO₂ below 92% (10.4%)[10, 25]. Extrarespiratory symptoms were mainly represented by diarrhea (8.9%) and vomiting (5.5%). A familial history of
positive contact could be identified in 85% of the cases. One child with ALL on chemotherapy contracted SARS-CoV-2 infection during hospitalization, but then recovered[25].

**Laboratory investigations**

Table 3 summarizes the main laboratory investigations reported in 474 children (29 studies)[10, 11, 25–28, 30–44, 49, 52–56, 67, 68]. The full blood cell count was unremarkable in most patients, with less than one-fifth of them (18.9%) showing low white blood cell (WBC) and lympho- or neutropenia (12.3%). Elevated inflammatory indexes such as C-reactive protein (CRP) and procalcitonin (PCT) were shown by 38.7% of children. Creatine kinase (CPK) and liver enzymes were also altered, as shown by 13.1% and 12.9% of all patients respectively.

**Radiology findings**

Of the 493 children who had radiological exams (31 studies)[10, 11, 25–28, 30–44, 47, 49, 51–56, 67, 68], up to 52.1% of them showed abnormalities, even if asymptomatic (Table 4). Most patients underwent a chest CT-scan (85.7%) that resulted normal in 163 out of 453 patients (36%), whereas typical ground-glass opacities (GGO), nonspecific unilateral and bilateral lesions were identified in 33.7%, 21% and 15.4% of patients, respectively.

**Treatment**

Of all patients, less than 2% were admitted in the Pediatric Intensive Care Unit (PICU) and required mechanical ventilation (MV) (Table 5)[10, 11, 25–27, 30–32, 34, 35, 37, 38, 43, 45, 47, 49, 51–56, 67, 68]. Most authors described the use of nebulized Interferon (IFN) (47.5%), and of other antiviral agents (38.5%) or antibiotics (22.3%). The use of intravenous immunoglobulin (IVIg) and corticosteroids (CCS) was less frequently described (5% and 6%, respectively).

**Neonatal cases**

A few case reports[43, 57, 58, 62–65, 69, 70] and case series[59, 60, 66] including a total of 25 newborns (15 males, 60%) with SARS-CoV-2 were identified (Table 6). Neonates were usually screened because of a history of primary maternal infection (80%). Similarly to older children, most of them were asymptomatic (12%) or had mild (52%) and moderate (20%) signs of clinical infection. However, a slightly higher proportion of them was severely ill (17%). Dyspnea was the commonest
reported sign in neonatal age (40%). Fever (32%) and feeding intolerance (24%) were also described. Blood tests showed high WBC (28%), CRP and/or PCT (20%), CPK (28%) and liver enzymes (20%).

Unlike older children, newborns underwent a chest X-ray in most cases (64%) (Table 7). Abnormal radiological findings could be recognized in more than half of them (56%), but specific lesions were not so frequently described: 8% had GGO, 24% unilateral patchy area, and 12% bilaterally. Poor information on treatment options was obtainable from the included reports, and most patients (48%) received only symptomatic therapies.

Discussion
This systematic review fully assesses epidemiological and clinical characteristics of SARS-CoV-2 infections reported in pediatric age.

Children are less likely to develop severe symptoms of COVID-19 than adults, with 95% of all cases ranging from asymptomatic to mild-moderate clinical patterns, as described by different case series[10, 11, 24, 27-56, 67, 68]. Moreover, less than 2% of patients were admitted to PICU or required MV[10, 25, 26]. Overall, three deaths were reported (mortality rate 0.07%): all patients developed complications[10, 16], including a preterm newborn who died from sepsis[59]. In adulthood, over two-third of those who died from COVID-19 had a comorbidity[73], while a very limited number of children with underlying disease could be identified, and none of them showed worse clinical course of the infection in comparison to previously healthy patients[10, 24, 26, 55, 56]. However, children might not be tested for SARS-CoV-2 as frequently as adults. Moreover, the current gold standard for the diagnosis of SARS-CoV-2 infection is Real Time-Polymerase Chain Reaction (RT-PCR) on respiratory tract specimen. The diagnostic accuracy of RT-PCR highly depends on the virus-specific diagnostic window, and the analytical sensitivity of this assay is potentially plagued by false SARS-CoV-2 negativity attributable to the low viral loads, especially in asymptomatic or mild symptomatic patients that might transmit the disease as well[74].

Clinical features
Infected children usually show typical symptoms of acute respiratory infections including fever (49.2%) and cough (44.1%)[10, 11, 16, 25-29, 31–33, 35–37, 41, 45, 47, 49, 53–56]. In particular,
some authors reported that up to one-third of symptomatic children may have high fever[10], but generally below 39°C[32]. Differently from adults, children are more likely to present with extrarespiratory symptoms[75]: diarrhea (8.9%) and vomiting (5.5%) are the most frequently reported ones. It has been showed that, when present, gastrointestinal symptoms usually anticipate the typical respiratory pattern[76]. Previous studies on SARS-CoV cases demonstrated the viral detection in gut biopsy specimens and stool of recovered patients, indicating a possible gastrointestinal tract tropism that may partially provide explanations for extrarespiratory symptoms and persistent viral shedding through fecal-oral route[77]. There is growing evidence that this mechanism of excretion may be typical also for SARS-CoV-2[2, 31]. As described in a case series of ten infected children, SARS-CoV-2 remained detectable in rectal swabs after nasopharyngeal swabs turned negative[31]. However, the extrapulmonary detection of viral RNA does not mean infectious virus is present, but two independent laboratories from China declared that they have successfully isolated live 2019-nCoV from the stool of patients (unpublished)[76]. Moreover, given the fact that pathogenesis of human coronavirus mainly depends on the interactions between its transmembrane spike glycoprotein (S-protein) and specific cell receptors of angiotensin converting enzyme II (ACE2) [78], recent analysis revealed that ACE2 was expressed also in upper esophagus and absorptive enterocytes from ileum and colon[55].

According to evaluated studies, clinical presentation in newborns and infants below 3 months could be slightly different than in older children, with a higher proportion of them (17%) presenting with a severe pattern[59, 60]. Even if the vertical transmission for SARS-CoV-2 has not been demonstrated[19, 79], in 80% of neonatal cases the mother was infected[57–60, 63, 66]. Moreover, nosocomial infection may also occur, and strict measures to reduce this risk should be always observed[20]. However, some authors hypothesized that 2019-nCoV infection and morbidity in newborns may be related to possible hypoxemia in the infected mother that increases the risk of perinatal adverse events such as birth asphyxia and premature birth[59, 80]. Evidence remains still too limited.

*Laboratory findings*
Twenty-nine studies accounting for a total of 474 patients reported information on blood investigations in pediatric cases with COVID-19. Overall, no significant abnormalities were observed and this was consistent with the results of a previously published review including a total sample size of 66 children with confirmed SARS-CoV-2 infection[71]. In particular, full blood cell count was normal in most patients. Two case series reported high rates of lymphopenia (10/25, 40%[26] and 11/36, 30.1%[54] respectively). However, this finding seems to be in contrast with adult data, as low lymphocyte count has been noted in up to 80% of infected critically-ill subjects[74, 81]. The limited number of severe COVID-19 infection may in part explain the lack of significant lymphopenia in children.

Our results suggested that inflammatory indexes may be abnormal in more than one-third of children with SARS-CoV-2 infection (38.7%), while Henry et al. described only 10-13% of cases with high CRP and/or PCT[71]. This controversial finding could be explained by the high heterogeneity in defining a cut-off of abnormal values across all the included studies. However, in adults a PCT value of ≥0.5 ng/ml was observed to be associated with a near 5-fold increase in risk of severe clinical course of COVID-19 infection[82].

Other significant reported laboratory investigations were represented by high CPK values (13.1%) and liver enzymes (12.9%). These enzymes could be often altered during viral infections[83]. In particular, high CPK levels or aspartate aminotransferase activity correlated with more severe clinical patterns in adult patients with SARS-CoV-2 infection[84]. Abnormal transaminases levels may also express a sign of direct liver damage. Recently published data demonstrated enrichment of ACE2 expression in cholangiocytes (59.7% of cells) suggesting that SARS-CoV-2 might lead to direct damage of intrahepatic bile ducts[85].

Radiology findings

A total of 493 children had radiological exams, with half of them showing abnormalities. The sensitivity of chest X-ray is supposed to be inferior to that of CT-scan: in adults, nonspecific patchy peripheral and peribronchovascular opacities may be shown in all lung zones, according to the severity of the infection[86]. As children usually develop milder patterns of the disease, chest X-ray
may fail to identify typical lesions, and it is mainly adopted in newborns and younger infants[59, 63, 66]. CT-scan is frequently performed in children with suspected or confirmed SARS-CoV-2 infection (up to 85% of all cases reported). The most frequently recognizable lesions are represented by GGO, with unilateral or bilateral distribution [27–29]. However, it should be noted that CT-scan was performed also in asymptomatic patients[10, 27–30, 38, 39, 49, 57], and that more than one third of all patients who underwent this exam resulted completely normal. The use of CT-scan as a diagnostic screening tool in confirmed or suspected COVID-19 patients is supported by recent evidence showing that its sensitivity could be greater than that of real time-PCR in detecting the virus (98% vs. 71%, respectively)[87]. However, routine use of CT-scan has several obvious implications, in particular in a pediatric setting where concern about unnecessary exposure to radiation source should be raised. Therefore, other possible diagnostic imaging tools may be used. Lung ultrasound has been successfully adopted in adult subjects with SARS-CoV-2 infection[88], but, to date, there is no data in children.

Treatment
Currently, there is no ongoing drug trial specifically aimed at children. Symptomatic treatment alone was used in most cases, in particular in newborns[59]. The only therapeutic recommendation in pediatric age is to use nebulized IFN and oral antiviral agents (i.e., lopinavir/ritonavir), with CCS for complications (acute respiratory distress syndrome, encephalitis, hemophagocytic syndrome or septic shock) and IVIg for severe cases[22]. However, none of these therapies have shown a clear benefit in the treatment of SARS-CoV-2.

The main limitation of our review is represented by the difficulty to retrieve the full text of some Chinese studies, and we had to rely on English-language summaries, or publications that referenced papers published in Chinese. Moreover, our findings are essentially based on limited case-series and case reports, therefore laboratory parameters of interest were not consistently reported and reference ranges were not always clearly defined. Similarly, radiological patterns were difficult to compare, as the description of the included cases was not standardized. However, despite the scarce and extremely heterogeneous evidence on pediatric patients with
COVID-19, the use of systematic databases allowed us to review at a glance and interpret the majority of published studies up to 7 April 2020.

Conclusion

SARS-CoV-2 affects children less commonly and severely in comparison to adults, with an estimated very low mortality rate. This could be due either to the fact that children are less frequently exposed to the main sources of transmission (in particular, nosocomial), and that they tend to show milder symptoms, therefore may be less often tested. In symptomatic patients, laboratory and radiology findings are mainly nonspecific, but could help identifying those who are severely ill. Larger epidemiological and clinical cohort studies are needed to better understand possible implications of COVID-19 infection in children.

Declarations

Author Contribution

IL conceptualized the systematic review, performed the electronic search, evaluated articles for eligibility, extracted relevant data, interpreted the results, and drafted sections of the manuscript.

CP contributed to study design, screened search results, reviewed all included studies and reviewed and revised the manuscript.

MB and MF contributed to study design, developed search terms and performed the electronic search, and reviewed and revised the manuscript.

AN contributed to study design, reviewed and revised the manuscript, and provided mentorship;

AP, EV and PC conceptualized and designed the study, coordinated and supervised data collection, and critically reviewed the manuscript for important intellectual content.

All authors approved the final manuscript as submitted and agree to be accountable for all aspects of the work.
