Abstract. Correlations between the morphological features of lower buds and the developmental stages of the male gametophyte are of great practical interest as a reliable marker that accelerates and simplifies the selection of appropriate plant material for isolated microspore culture. Microspore culture enables one to quickly obtain many pure lines of different vegetable crops, but it has not yet been widely applied in the melon (Cucumis melo L.). To successfully apply this technique in a new culture, one has to optimize many of its elements: first, find the biological markers for selecting the lower buds containing the microspores of certain development stages. The paper presents the results of research estimating the correlations between the length and diameter of the flower buds, the length of the visual part of the corolla, the length of the anthers and the development stages of the male gametophyte in the F1 hybrid of the Kim Hong Ngoc melon. The strongest correlation (CC = 0.885) was found for the flower bud diameter and a strong correlation (CC = 0.880), for the bud length. The corolla’s visual part was a less reliable morphological feature, and the anther’s length should not be used as a parameter to predict the developmental stages of the melon’s male gametophyte. It was also found that one anther could contain the microspores and pollen grains of different developmental stages. In the flower buds less than 4 mm in length and 1.51 ± 0.02 mm in diameter prevailed tetrads, and in the buds 4.0–4.9 mm in length and 2.30 ± 0.02 mm in diameter, early microspores. The microspores of a middle stage of development prevailed in the flower buds 5.0–5.9 mm in length and 2.32 ± 0.00 mm in diameter; mid and late vacuolated microspores, in the buds 6.0–8.9 mm in length and 2.96 ± 0.37 mm in diameter; and two-celled pollen, in the buds more than 9 mm in length and more than 3.97 ± 0.34 mm in diameter.

Key words: male gametophyte; stages of microspore development; tetrad; pollen; flower bud; anther; Cucumis melo L.; melon.

Аннотация. Выявленная корреляция между морфологическими признаками бутонов и стадиями развития мужского гаметофита представляет большой практический интерес, так как наличие надежного маркера ускоряет и упрощает отбор подходящего растительного материала для культуры изолированных микроспор. Культура изолированных микроспор позволяет в короткие сроки получать чистые линии многолетних овощных культур, однако для дьины (Cucumis melo L.) эта технология пока не получила распространения. Чтобы успешно применить данную технологию для новой культуры, необходимо оптимизировать множество ее элементов, прежде всего подобрать морфологические маркеры, позволяющие отбирать бутонь, которые содержат микроспоры определенных стадий развития. В нашей работе приведена оценка корреляции между длиной бутонов, диаметром бутонов, длиной видимой части венчика, длиной пыльников и стадиями развития мужского гаметофита дьины F1 гибрид Kim Hong Ngoc. Наиболее сильная корреляция установлена для диаметра бутонов, коэффициент корреляции составил 0.885. Сильная корреляция выявлена также для длины бутонов, коэффициент корреляции 0.880. Длина видимой части венчика являлась менее надежным признаком, а длину пыльников не следует использовать в качестве параметра для прогнозирования стадий развития мужского гаметофита дьины. Отмечено, что в одном пыльнике одновременно находились микроспоры и пыльцевые...
The melon (Cucumis melo L.) is an economically important cultivated plant (Sebastian et al., 2010) grown in more than 1 mln ha of agricultural lands (FAOSTAT, 2019). The melon is a member of the cucumber family (Cucurbitaceae) and includes several species, including the commercial variety Cucumis melo var. moschatus. The melon is known for its sweet, juicy flesh and is widely cultivated for its fruits, which are used fresh, in salads, and for pickling. It is also used in the production of melon seeds, which are rich in oil and are used in the production of margarine and soap.

Introduction

The melon is a flowering plant with a variety of morphological characteristics that can be used to help identify different developmental stages. These characteristics include the length and width of the flower buds, the presence of aborted flowers, and the size and shape of the anthers. These characteristics can be used to help determine the stage of development of the melon plant and to identify the presence of abnormal developmental stages.

Materials and methods

The flower buds of the melon were collected from plants of the Kim Hong Ngoc hybrid variety, which is grown in Thailand. The buds were collected at 5:30-6:30 a.m. and were stored for 24 hours at 4 °C. At least 10 buds were accounted for each of the intervals.

For the purpose of fluorescent staining, the microspores were isolated from the anthers. The microspores were treated with an acetylation solution (2 % acetocarmine) and then stained with DAPI (4′,6-diamidino-2-phenylindole) to identify the presence of fluorescing cells. The microspores were then observed using a Zeiss Stemi 2000-C stereomicroscope (Suzhou Co., Ltd.). The microspores were analyzed to determine the presence of fluorescing cells and to identify the stage of development of the melon plant.
Flower bud morphology and developmental stages of the male gametophyte of melon

Fig. 1. DAPI- and acetocarmine-dyed microspore development stages of *Cucumis melo* L.: a – tetrads, b – early microspores, c – mid microspores, d – late vacuolated microspores, e – early two-celled pollen, f – late two-celled pollen. Bar = 20 µm.

2003; Blackmore et al., 2007; Zhang et al., 2013). In each specimen, the development stages of 100 microspores were observed. Such parameters as the presence of tetrads, early/middle/late microspores and two-cell pollen were considered. The percentage of each development stage in a particular specimen was calculated as the ratio of the number of microspores related to a certain development stage to the total number of observed microspores multiplied by 100 %.

The statistical significance of the performed calculations was confirmed with ANOVA analysis and the Tukey test for α = 0.05. The correlation between the measured parameters and microspore development stages was determined using the linearity regression (R) and correlation (CC) coefficients.

The collected data were described and processed with the R software.

**Results and discussion**

During the cytological analysis of melon flower buds, 6 stages of microspore development were observed. These included tetrads, early/middle/late vacuolated microspores, early/late two-celled pollen (Fig. 1).

The diameter of the microspores increased as they developed and reached their maximum at the stage of late two-celled pollen (Fig. 2). It has been noted that each stage was characterized by a certain shape and size of the cells. The diameter of the early microspores formed after tetrad degradation was $33.41 \pm 4.34 \, \mu m$; they were of uneven circular shape and had thin walls and large nuclei. The middle microspores were $39.06 \pm 2.33 \, \mu m$ in diameter, had a round shape and a centered nucleus. The late microspores were round and had a well-expressed three-lobed exine wall with the nucleus pressed to it by a big vacuole. Their diameter was $40.45 \pm 3.26 \, \mu m$.

The cells of early two-celled pollen had $44.94 \pm 2.65 \, \mu m$ in diameter with well-expressed two nuclei. The vegetative

* Data marked with the same letters do not differ at \( p = 0.05 \).

Fig. 3. Changing the morphological characteristics of melon buds (1, bar = 20 µm) and anthers (2, bar = 10 µm) in relation to flower-bud sizes:

\( a \) – 3.6–4.0 mm; \( b \) – 4.0–4.9 mm; \( c \) – 5.0–5.9 mm; \( d \) – 6.0–6.9 mm; \( e \) – 7.0–7.9 mm; \( f \) – 8.0–8.9 mm; \( g \) – 9.0–9.9 mm; \( h \) – 10.0–10.9 mm; \( i \) – 11.0–11.9 mm; \( j \) – 12.0–12.9 mm; \( k \) – 13.0–13.9 mm; \( l \) – more than 14.0 mm.

and a more vividly-colored generative one. The diameter of the late two-celled pollen comprised 56.93 ± 4.81 µm, its cell shapes varying from round to oval, so one anther could contain pollen grains of different shapes. The pollen’s cytoplasm became dense and nontransparent making it more difficult to observe the nucleus.

The results of the correlation analysis to bring together the morphological features of melon flower buds and corresponding microspore development changes enabled us to subdivide the buds into 6 groups. Each group could include microspores of different stages, so at least one of these stages prevailed (see the Table). It was noted that a single anther could have microspores that belonged to different development stages, which corresponds to the observations of other researchers who studied this issue in other cultures.

The tetrads were found in green oval-shaped pubescent flower buds that were fully covered in sepals and had a length of less than 4 mm and a diameter of 1.85 mm (Fig. 3, \( a \)). The buds’ anthers were of light-beige color and had 1.6–1.63 mm in length.
The early microspores were found in flower buds of 3.8–7.0 mm in length, their biggest portion (30 ± 14.14 %) concentrated in buds of 4.0–4.9 mm. The buds’ anthers changed their color to green-yellow, their length comprised 1.63–2.74 mm (see Fig. 3, b). The early microspores were found in smaller amounts compared to the other development stages.

The middle microspores concentrated in flower buds of 4.0 to 10.9 mm in length. The buds’ anthers were 2.15 ± 0.05 mm in length and had a yellowish glazing surface (see Fig. 3, c). The microspores prevailed (50 ± 14.14 %) in the buds of 5.0–5.9 mm in length. Such buds had a clear morphological difference from younger buds: their sepals were open, so one could see the corolla tip.

The late vacuolated microspores prevailed in buds of 6.0–8.9 mm in length. At this stage, the buds kept growing in size, so the corolla extended beyond the sepals. However, the anthers’ morphology remained unchanged (see Fig. 3, d–f) as did their length.

The early two-celled pollen prevailed in buds of 9.0–12.0 mm in length (see Fig. 3, g–i). Their anthers’ length, compared to the previous stage, remained unchanged, their surfaces containing mature pollen grains.

As for buds larger than 12 mm in length, they contained only two-celled pollen. The transition from the late to mature stage was characterized by a small increase in bud size, its petals starting to open (see Fig. 3, j–l). The anthers increased in size and opened too, so a large number of pollen grains could be seen on their surface.

Statistical analysis of anther lengths gave us linear regression coefficient $R^2 = 0.52$, which meant that this parameter could not be used as a predictor of microspore development stages in the melon, which corresponded to the results obtained for some other cultures such as the tomato and aubergine (Segui-Simarro, Nuez, 2005; Salas et al., 2012). In (Adhikari, Kang, 2017), the authors obtained a similar coefficient ($R^2 = 0.59$) when studying a relation between anther length and microspore development stages in the tomato.

Many researchers recommend using flower-bud length to select proper plant material to cultivate isolated microspores for it is a convenient and reliable morphological parameter for many plant species. They also recommend bud diameter as an indicator for flower bud selection. A study published in 2019 demonstrated that the best results in the embryogenesis of lucerne microspores were obtained when cultivating late microspores from flower buds of 6.02–6.20 mm in length and 1.50–1.72 mm in diameter (Yi et al., 2019). In 2017, a correlation between flower-bud size (length and diameter), anther length and microspore development stages in the tomato was published (Adhikari, Kang, 2017).

In our study, a linear regression analysis showed there was a clear linear dependence ($p < 0.05$) between the flower-bud characteristics and microspore development stages. The regression coefficients ($R^2$) varied from 0.767 to 0.783. The strongest correlation was for flower-bud diameter ($r = 0.885$, $R^2 = 0.783$) (Fig. 4), followed by flower-bud ($r = 0.880$, $R^2 = 0.775$) (Fig. 5) and anther ($r = 0.876$, $R^2 = 0.763$) lengths, the last being the least reliable feature.

**Conclusion**

The correlation between the morphological characteristics of the flower buds and anthers of the melon (*Cucumis melo L.*) and the development stages of its microspores enables one to select a proper material for cultivation of isolated microspores *in vitro*. The characteristics in question are flower-bud diameter and length and the length of visible corolla. Since the correlation coefficient is higher for the diameter and length of flower buds, these parameters are easier to use.

The obtained results can be applied for further development of the technology to produce melon DHs in isolated microspore culture.
