THE $P^*$ RULE IN THE STOCHASTIC HOLT-LAWTON MODEL OF APPARENT COMPETITION

SEBASTIAN J. SCHREIBER

Abstract. In 1993, Holt and Lawton introduced a stochastic model of two host species parasitized by a common parasitoid species. We introduce and analyze a generalization of these stochastic difference equations with any number of host species, stochastically varying parasitism rates, stochastically varying host intrinsic fitnesses, and stochastic immigration of parasitoids. Despite the lack of direct, host density-dependence, we show that this system is dissipative i.e. enters a compact set in finite time for all initial conditions. When there is a single host species, stochastic persistence and extinction of the host is characterized using external Lyapunov exponents corresponding to the average per-capita growth rates of the host when rare. When a single host persists, say species $i$, a explicit expression is derived for the average density, $P^*_i$, of the parasitoid at the stationary distributions supporting both species. When there are multiple host species, we prove that the host species with the largest $P^*_i$ value stochastically persists, while the other host species are asymptotically driven to extinction. A review of the main mathematical methods used to prove the results and future challenges are given.

1. Introduction

Volterra [1] proved that competition for a single, limiting resource results in competitive exclusion via the $R^*$ rule: the competing species that suppresses the resource to the lowest equilibrium density excludes the other competing species [2]. Volterra’s mathematical derivation was for ordinary differential equation models where the per-capita growth rates of the competing species are linear functions of resource availability [see discussion in 3]. Since this work of Volterra, MathSciNet lists 279 publications on the “competitive exclusion principle” of which 19 appeared in Discrete and Continuous Dynamical Systems: Series B [4–22]. These 19 papers proved new principles of competitive exclusion for a diversity of situations including spatial chemostat models [4], within-host competition of multiple viral types [13], competing technologies [14], epidemiological models of competing disease strains [20], stoichiometric models of tumor growth [21], and discrete-time, size-structured chemostat models [22].

Nearly fifty years after Volterra’s paper, Holt [23] inverted Volterra’s model by considering non-competing prey who share a predator. For ordinary differential equation models, Holt [23] showed that the addition of a new prey species to a predator-prey system could reduce the equilibrium density of the original prey species or even drive it extinct. This reduction or exclusion arises as an indirect effect by which the novel prey increases the predator density and, thereby, increases predation pressure on the original prey species. Holt [23] termed this indirect effect, “apparent competition” as to an observer unaware of the shared predator species, the prey appear to be competing. Despite the fundamental ecological importance of this interaction [24, 25], MathSciNet only list 18 publications on “apparent competition” of which 6 appear in mathematics journals [26–31]. All 6 of these publications use ordinary differential equation models which assumes overlapping generations of the prey and predator
species. However, some of the most important examples of apparent competition occur in host-parasitoid systems [24, 32–34].

Due to the tight coupling of their life-cycles, host-parasitoid systems can have discrete, synchronized generations and, consequently, are modeled using difference equations [35–37]. As the dynamics of these models can be exceedingly complex, there are few mathematical theorems about their dynamics [see, however, 38, 39]. To model apparent competition in host-parasitoid systems, Holt and Lawton [40] introduced stochastic difference equations with two, non-competing, host species sharing a common parasitoid. These host species experienced stochastic fluctuations in their intrinsic fitnesses, and the parasitoid species had a stochastic source of immigration. Using a mixture of time-averaging arguments and numerical simulations, Holt and Lawton [40] derived a $P^*$-rule: the host species that can support the higher, average parasitoid density excludes the other host species. Regarding their derivation, Holt and Lawton [40] wrote “we have doubtless ignored subtleties in specifying how the parameters must be constrained in their temporal evolution, so that densities are ensured to be bounded away from zero. Numerical simulations suggest that our conclusions hold for reasonable patterns of temporal variability.”

Here, we provide a mathematically rigorous analysis of an extension of Holt and Lawton [40]’s model to allow for any number of host species and stochastic variation in the parasitism rates. The analysis includes mathematical proofs of the stabilizing effect of parasitoid immigration, a characterization of persistence for a single host species and the associated $P^*$ value, and the $P^*$ rule. The stochastic, difference-equation model is introduced in Section 2. The main results about this model are presented in Section 3. The results are also illustrated numerically and followed by a discussion of future challenges. To prove the results, we use methods developed by Benaïm and Schreiber [41] whose key elements are summarized in Section 4. The proofs of the two main theorems for the host-parasitoid models are given in Sections 5 and 6.

2. The Model and Assumptions

We assume that there are $k \geq 1$ host species with densities $x = (x_1, \ldots, x_k)$ and one parasitoid species with density $y$. Let $z(t) = (x(t), y(t))$ be the state of the host-parasitoid community in the $t$-th generation. Each individual of host species $i$ escapes parasitism with probability $\exp(-a_i(t)y(t))$ in the $t$-th generation i.e. the parasitoid attacks are Poisson distributed with mean $a_i(t)y(t)$ on host $i$ where $a_i(t)$ is the attack rate of the parasitoid on host $i$ in the $t$-th generation. Each individual of host species $i$ that escapes parasitism produces $R_i(t)$ offspring that emerge in the next generation. Hosts that do not escape parasitism become parasitoids in the next generation. In addition to this production of parasitoids, there is “recurrent immigration by the parasitoid from outside the local community”[40] with $I(t)$ immigrants entering the parasitoid population at the end of the $t$-th generation. Thus, the community dynamics are

$$
\begin{align*}
  x_i(t+1) &= R_i(t) \exp(-a_i(t)y(t)) \quad i = 1, 2, \ldots, k \\
  y(t+1) &= \sum_{i=1}^{k} x_i(t)(1 - \exp(-a_i(t)y(t))) + I(t).
\end{align*}
$$

This model generalizes Holt and Lawton [40]’s model by allowing for more than two host species and by allowing the attack rates $a_i(t)$ to stochastically vary.

To complete the specification of the model, we make the following assumptions about the $R_i(t)$, $a_i(t)$ and $I(t)$:
Figure 1. Stochastic persistence and the $P^*$ rule for the host-parasitoid model (1). In A, there is $k = 1$ host species and the condition for stochastic persistence is met. In B, there are $k = 4$ host species which only differ in the variance of their $R_i(t)$ terms. Parameter values: $a_i(t) = 0.1$ for all $i$ and $t$, $R_i(t) = 0.9 + 1.1\beta_i^R(t)$ where $\beta_i^R(t)$ are $\beta$ distributed with both scale parameters $= k + 1 - i$, and $I(t) = 0.1 + 0.9\beta^I(t)$ where $\beta^I(t)$ are $\beta$ distributed with both scale parameters $= 2$.

A1: For each $1 \leq i \leq k$, $R_i(0), R_i(1), R_i(2), \ldots$ is a sequence of independent and identically distributed (i.i.d.) random variables taking values in $[R, \bar{R}]$ where $\bar{R} \geq R > 0$.

A2: For each $1 \leq i \leq k$, $a_i(0), a_i(1), a_i(2), \ldots$ is a sequence of i.i.d. random variables taking values in $[a, \bar{a}]$ where $\bar{a} \geq a > 0$.

A3: $I(0), I(1), I(2), \ldots$ is an i.i.d. sequence taking values in $[I, \bar{I}]$ where $\bar{I} \geq I > 0$.

3. Results and Discussion

Our first result is to show that solutions of (1) enter a compact set after a finite amount of time. In contrast, without parasitoid immigration, $k = 1$ host species, and constant $R_i$ and $a_i$, equation (1) is the Nicholson-Bailey model whose solutions exhibit unbounded oscillations whenever both species are present [39]. The following proposition proves that immigration stabilizes these unbounded oscillations.

Proposition 3.1. There exists a compact set $S \subset [0, \infty)^k \times [I, \infty)$ such that

$$ (x(t), y(t)) \in S \text{ for all } t \geq 4 $$

whenever $(x(0), y(0))$ is non-negative.

Proof. Let $x(0) = (x_1(0), \ldots, x_k(0)), y(0)$ be non-negative. Then

$$ y(t) \geq I \text{ for all } t \geq 1 \text{ and } y(t) \geq \sum_{j=1}^{k} x_j(t-1)(1 - \exp(-aI)) \text{ for } t \geq 2. $$
Define \( \alpha = (1 - \exp(-aI)) \). For \( t \geq 3 \),
\[
x_i(t) \leq \bar{R}x_i(t-1) \exp \left( -a_i(t-1)\alpha \sum_{j=1}^{k} x_j(t-1) \right)
\leq \bar{R}x_i(t-1) \exp \left( -a\alpha x_i(t-1) \right)
\leq \frac{\bar{R}}{a\alpha e}
\]
Thus, for \( t \geq 4 \),
\[
y(t) \leq k \frac{\bar{R}}{a\alpha e} + \bar{I}.
\]
Setting
\[
S = \left[ 0, \frac{\bar{R}}{a\alpha e} \right]^k \times \left[ I, k \frac{\bar{R}}{a\alpha e} + \bar{I} \right]
\]
completes the proof of the proposition.

To characterize whether the host persists or not in the presence of the parasitoid, we use two notions of stochastic persistence [see reviews in 42, 43]. The first notion corresponds to what Chesson [44] called stochastically bounded coexistence and takes an ensemble point of view. This form of persistence, as shown in equation (2) below, implies that probability of a small species density far into the future is small. The second form of stochastic persistence, introduced in [45], takes the perspective of a single, typical realization of the Markov chain. This form of persistence, as shown in equation (3) below, implies that the fraction of time spent below small species densities is small. Figure 1A illustrates the host-parasitoid dynamics in the case of stochastic persistence.

**Theorem 3.1.** Assume \( k = 1 \) and assumptions \( A1 - A3 \) hold. If \( \mathbb{E}[\ln R_1(t)] < \mathbb{E}[a_1(t)]\mathbb{E}[I(t)] \) and \( x_1(0) > 0 \), then
\[
\limsup_{t \to \infty} \frac{1}{t} \ln x_1(t) < 0 \text{ with probability one.}
\]
If \( \mathbb{E}[\ln R_1(t)] > \mathbb{E}[a_1(t)]\mathbb{E}[I(t)] \), then there exist \( \alpha, \beta > 0 \) such that
\[
(2) \quad \limsup_{t \to \infty} \mathbb{P} \left[ x_1(t) \leq \delta \right] \leq \alpha \delta^\beta
\]
and
\[
(3) \quad \limsup_{t \to \infty} \frac{\# \{ 1 \leq s \leq t : x_1(s) \leq \delta \} }{t} \leq \alpha \delta^\beta \text{ with probability one}
\]
whenever \( x_1(0) > 0 \) and \( y(0) \geq 0 \). Moreover,
\[
(4) \quad \int y \mu(dx, dy) = \mathbb{E}[\ln R_1(t)]/\mathbb{E}[a_1(t)]
\]
for any invariant measure \( \mu(dx, dy) \) supported on \( (0, \infty)^2 \).

Beyond characterizing host persistence, Theorem 3.1 via (4) provides a mathematical proof of one of Holt and Lawton [40]'s conclusions even when the attack rates fluctuate: “in a fluctuating environment the long-term average parasitoid density \( [P^*] \) is proportional to the long-term average logarithmic host growth rate.” The definition of an invariant measure is given in section 4.
Provided that each host species can persist with the parasitoid, our next theorem shows that these long-term average parasitoid densities determine the winner of apparent competition.

**Theorem 3.2.** Assume assumptions A1–A3 hold and
\[ \mathbb{E}[\ln R_i(t)] > \mathbb{E}[a_i(t)] \mathbb{E}[I(t)] \text{ for } i = 1, 2, \ldots, k. \]

Define
\[ P^*_i := \frac{\mathbb{E}[\ln R_i(t)]}{\mathbb{E}[a_i(t)]} \text{ for } i = 1, 2, \ldots, k. \]

If \( P^*_1 > P^*_i \) for \( i = 2, \ldots, k \), then there exist \( \alpha, \beta > 0 \) such that
\[ \limsup_{t \to \infty} \frac{1}{t} \ln \max_{2 \leq i \leq k} x_i(t) < 0 \text{ with probability one} \]

and
\[ \limsup_{t \to \infty} \frac{\#\{1 \leq s \leq t : x_1(s) \leq \delta\}}{t} \leq \alpha \delta^\beta \text{ with probability one for } \delta \leq 1 \]

and
\[ \limsup_{t \to \infty} \mathbb{P}[x_1(t) \leq \delta] \leq \alpha \delta^\beta \text{ for } \delta \leq 1 \]

whenever \( \prod_{i=1}^k x_i(0) > 0 \).

Thus, this theorem mathematically confirms Holt and Lawton [40]'s conclusion: “regardless of the exact cause of the fluctuations, the outcome should be no different than that expected in a constant environment with stable populations: one host tends to displace alternative hosts from the assemblage, and the winner is the host sustaining the highest average parasitoid density.”

**Discussion.** As noted by Holt and Lawton [40], fluctuations in \( R_i(t) \) can influence the winner of apparent competition. For example, suppose that there are two host species with the same mean intrinsic fitness and experiencing the same attack rates i.e. \( \mathbb{E}[R_1(t)] = \mathbb{E}[R_2(t)] \) and \( a_1(t) = a_2(t) \) for all \( t \). However, host 2 experiences variation in its intrinsic fitness (i.e. \( \text{Var}[R_2(t)] > 0 \)) while host 1 experiences no variation (i.e. \( \text{Var}[R_1(t)] = 0 \)). As \( \ln \) is a concave function, Jensen’s inequality implies that \( \mathbb{E}[\ln R_1(t)] > \mathbb{E}[\ln R_2(t)] \). Thus, \( P^*_1 > P^*_2 \) and Theorem 3.2 implies that host species 2 is excluded due to having greater variation in its intrinsic fitness. This phenomena is illustrated in Figure 1B with \( k = 4 \) host species that only differ in the variances of their intrinsic fitness, \( \text{Var}[R_i(t)] \).

Theorems 3.1 and 3.2 are largely possible due to the exponential form of the Poisson escape function (i.e. \( \exp(-a_i y) \) due to Nicholson and Bailey [46]) and the absence of host-density dependence. In particular, the Poisson escape function assumes that parasitoids are not time-limited and their attacks are randomly distributed among the hosts. Thus, future mathematical challenges include understanding whether or not the \( P^* \) rule holds when the escape function accounts for aggregated parasitoid attacks (e.g. the negative binomial form \((1 + a_i y/k)^{-k}\) introduced by May [47]), the escape function accounts for parasitoid time-limitation (e.g. \( \exp(-a_i y/(1 + b_i x_i)) \) as introduced by Hassell et al. [48]), or the hosts experience direct density-dependence (e.g. \( R_i(t) \exp(-c_i x_i - a_i y) \) as developed by May et al. [49]).

Another avenue for future research is to account for feedback between ecology and evolution in the model [50]. For deterministic, continuous-time models of two prey sharing a predator, evolution of the predator’s attack rate can, by reducing the effects of apparent competition, mediate coexistence but could also lead to oscillatory and chaotic dynamics [51, 52].
Whether similar phenomena arise for the discrete-time, stochastic host-parasitoid models considered here remains to be seen.

4. Main Tools from Benaîm and Schreiber [41]

To prove Theorems 3.1 and 3.2, we used methods developed by Benaîm and Schreiber [41]. These methods apply to models with a mixture of ecological and auxiliary variables (see Remark 1 and the proofs in Sections 5, 6 for more details). The ecological variables correspond to the densities of species given by \( u = (u_1, u_2, \ldots, u_n) \in [0, \infty]^n =: \mathbb{R}_+^n \). The species dynamics interact with the auxiliary variable \( v \) which lies in \((-\infty, \infty)^m =: \mathbb{R}^m\). In the proofs of both Theorem 3.1 the parasitoid density is treated as an auxiliary variable, while in the proof of Theorem 3.2 the densities of host species 2 through \( k \) also are used as auxiliary variables.

The ecological and auxiliary variables may be influenced by stochastic forces captured by a sequence of independent and identically distributed (i.i.d.) random variables \( \xi(1), \xi(2), \ldots \) taking values in a Polish space \( \Xi \) i.e. a separable completely metrizable topological space. The stochastic difference equations considered by Benaîm and Schreiber [41] are of the form:

\[
\begin{align*}
    u_i(t + 1) &= u_i(t) f_i(u(t), v(t), \xi(t)) & \text{(species densities)} \\
    v(t + 1) &= G(u(t), v(t), \xi(t)) & \text{(auxiliary variables)}.
\end{align*}
\]

with standing assumptions:

**B1:** For each \( i = 1, 2, \ldots, n \), the fitness function \( f_i(z, \xi) \) is continuous in \( z = (x, y) \), measurable in \( (z, \xi) \), and strictly positive.

**B2:** The auxiliary variable update function \( G \) is continuous in \( z = (x, y) \) and measurable in \( (z, \xi) \).

**B3:** There is a compact subset \( \mathcal{S} \) of \( \mathbb{R}_+^n \times \mathbb{R}^m \) such that all solutions \( z(t) = (u(t), v(t)) \to (1) \) satisfy \( z(t) \in \mathcal{S} \) for \( t \) sufficiently large.

**B4:** For all \( i = 1, 2, \ldots, n \), \( \sup_{z,\xi} |\log f_i(z, \xi)| < \infty \).

**Remark 1.** For the proofs of Theorems 3.1 and 3.2, host species 1 of (1) is always treated as a species density (e.g. \( u_1 = x_1 \)), the parasitoid density is always treated as an auxiliary variable (e.g. \( v_1 = y \)), the host species 2 through \( k \) are treated either as species densities (e.g. \( u_i = x_i \) for \( i = 2, \ldots, k \)) or as auxiliary variables (e.g. \( v_i = x_i \) for \( i = 2, \ldots, k \)), and the i.i.d. random variables \( \xi(t) \) equal \( (R_i(t), a_i(t), I(t)) \). Our assumptions **A1–A3** and Proposition 3.1 ensure that assumptions **B1–B4** hold for (1).

To evaluate whether species are increasing or decreasing when rare, we consider their per-capita growth rate averaged over the fluctuations in \( u(t), v(t) \), and \( \xi(t + 1) \). To this end, recall that a Borel probability measure \( \mu \) on \( \mathcal{S} \) is an invariant probability measure if for all continuous functions \( h : \mathcal{S} \to \mathbb{R} \)

\[
\int_{\mathcal{S}} h(z) \mu(dz) = \int_{\mathcal{S}} \mathbb{E}[h(Z(1))|Z(0) = z] \mu(dz)
\]

An invariant probability measure \( \mu \) is an ergodic, probability measure if it can not be written as a non-trivial convex combination of invariant probability measures. For any invariant probability measure \( \mu \), define \( r_i(\mu) \) as the realized per-capita growth rate of population \( i \):

\[
    r_i(\mu) = \int_{\mathcal{S}} \mathbb{E}[\log f_i(z, \xi(t))]|\mu(dz).
\]
For any ergodic probability measure \( \mu \), define the species supported by \( \mu \), denoted \( S(\mu) \), to be the unique subset \( I \subset \{1, 2, \ldots, n\} \) such that \( \mu(\{(u, v) \in S : u_i > 0 \text{ iff } i \in I\}) = 1 \).

The following proposition implies that \( r_i(\mu) = 0 \) for all \( i \in S(\mu) \). Alternatively, for \( i \not\in S(\mu) \), \( r_i(\mu) \) need not be zero in which case \( r_i(\mu) \) measures the rate of growth of species \( i \) when introduced at infinitesimally small densities. For \( i \not\in S(\mu) \), \( r_i(\mu) \) is also known as the external Lyapunov exponent of \( \mu \). The following result is proven in [41, Proposition 1].

**Proposition 4.1.** Let \( \mu \) be an ergodic probability measure. Then \( r_i(\mu) = 0 \) for all \( i \in S(\mu) \).

Following the approach introduced by Josef Hofbauer [3, 53], the following Theorem from [41, Theorem 1] gives a sufficient condition for stochastic persistence. We make use of this theorem for the proofs of both Theorems 3.1 and 3.2. To state this theorem, define the extinction set as

\[
S_0 = \{(u, v) \in S : \prod_{i=1}^{n} u_i = 0\}.
\]

**Theorem 4.1.** If

\[
(7) \quad \text{there exist positive } p_1, \ldots, p_n \text{ s.t. } \sum_i p_i r_i(\mu) > 0 \text{ for all ergodic } \mu \text{ with } \mu(S_0) = 1.
\]

holds, then there exists \( a, b > 0 \) such that for all \( \delta \leq 1 \) and \( Z(0) = z \in S \setminus S_0 \)

\[
\text{(persistence in probability)} \quad \limsup_{t \to \infty} \mathbb{P} \left[ \min_{1 \leq i \leq n} u_i(t) \leq \delta \right] \leq a(\delta)^b
\]

and

\[
\text{(almost-sure persistence)} \quad \limsup_{t \to \infty} \frac{\#\{1 \leq s \leq t : \min_{1 \leq i \leq n} u_i(s) \leq \delta\}}{t} \leq a(\delta)^b \text{ almost surely.}
\]

To identify when species are driven extinct, we consider the case when there is a subset \( I \subset \{1, 2, \ldots, n\} \) of species that can not be invaded. Define

\[
S^I := \{(u, v) \in S | u_j = 0 \text{ whenever } j \not\in I\}
\]

and for \( \delta > 0 \), define

\[
S^{I, \delta} := \{(u, v) \in S | u_j \leq \delta \text{ whenever } j \not\in I\}.
\]

We say \( S^I \) is accessible if for all \( \delta > 0 \), there exists \( \gamma > 0 \) such that

\[
\mathbb{P}[z(t) \in S^{I, \delta} \text{ for some } t \geq 1] \geq \gamma
\]

whenever \( Z(0) = (u, v) \) satisfies \( \prod_i u_i > 0 \). Intuitively, this accessibility conditions states that with probability one, the process will eventually enter any neighborhood of \( S^I \). As the process is Markov, this implies that the process will enter this neighborhood infinitely often.

**Theorem 4.2.** Let \( I \) be a strict subset of \( \{1, 2, \ldots, n\} \). Assume

(i) (1) restricted \( S^I \) satisfies that there exists \( p_i > 0 \) for \( i \in I \) and \( \sum_{i \in I} p_i r_i(\mu) > 0 \) for ergodic \( \mu \) with \( \mu(S_0^I) = 1 \) where \( S_0^I := \{z = (u, v) \in S^I : \prod_{i \in I} u_i = 0\} \),

(ii) \( r_j(\mu) < 0 \) for any \( j \not\in I \) and ergodic \( \mu \) satisfying \( S(\mu) = I \), and

(iii) \( S^I \) is accessible.

Then

\[
(8) \quad \mathbb{P} \left[ \limsup_{t \to \infty} \frac{1}{t} \log \text{dist}(z(t), S_0) < 0 \right] = 1 \text{ whenever } Z(0) = z \in S.
\]
Condition (i) in Theorem 4.2 ensures the set of species in $I$ coexist in the sense of stochastic persistence. Condition (ii) implies that the per-capita growth rates are negative for all of the species not in $I$. Conditions (i) and (ii) are sufficient to ensure the local attractivity of $S^f$ in a stochastic sense–see Theorem 2 in [41]. Condition (iii) ensures the global attractivity with probability one.

5. Proof of Theorem 3.1

Assume that $\alpha := \mathbb{E}[\ln R_1(t)] - \mathbb{E}[a_1(t)]\mathbb{E}[I(t)] < 0$. As $y(t) \geq I(t-1)$ for all $t \geq 1$, it follows that for all $t \geq 1$

$$x_1(t+1) \leq R_1(t)x_1(t)\exp(-a_1(t)I(t-1))$$

$$\leq x_1(0)\hat{R}\prod_{s=1}^{t} R_1(s)\exp(-a_1(s)I(s-1)).$$

The strong law of large numbers implies that with probability one

$$\limsup_{t \to \infty} \frac{\ln x_1(t+1)}{t+1} \leq \lim_{t \to \infty} \frac{1}{t+1} \left( \ln \hat{R}x_1(0) + \sum_{s=1}^{t} (\ln R_1(s) - a_1(s)I(s-1)) \right) = \alpha < 0.$$

Now assume $\alpha := \mathbb{E}[\ln R_1(t)] - \mathbb{E}[a_1(t)]\mathbb{E}[I(t)] > 0$. We will use Theorem 4.1 with $n = 1$, $u_1 = x_1$ and $v_1 = y$ in (5). On $S_0 = \{(x_1, y) \in S : x_1 = 0\}$, the dynamics are given by $x_1(t) = 0$ for all $t$ and $y(t) = I(t)$ for all $t \geq 0$. As the $I(t)$ are i.i.d., the only ergodic invariant measure $\mu(dx, dy)$ for the dynamics on $S_0$ is determined by the law $m(dy)$ of $I(t)$ i.e. $\int_{S_0 \times A} \mu(dx, dy) = \int_A m(dy)$ for any Borel set $A \subset [0, \infty)$. For this invariant measure, the per-capita growth rate of the host equals

$$r_1(\mu) = \int_{\mathbb{R}} \mathbb{E}[\ln R_1(t)] - a_1(t)y \cdot m(dy) = \alpha > 0.$$

Hence, Theorem 4.1 implies the first two conclusions for the case of $\alpha > 0$. For the final conclusion, let $\nu(dx_1, dy)$ be any ergodic measure such that $\nu(S \setminus S_0) = 1$. Then, Proposition 4.1 implies

$$0 = r_1(\nu) = \int_{S_0 \times A} \mathbb{E}[\ln R_1(t)] - a_1(t)y \cdot \nu(dx_1, dy) = \mathbb{E}[\ln R_1(t)] - \mathbb{E}[a_1(t)] \int_{S_0 \times A} \nu(dx_1, dy).$$

By the ergodic decomposition theorem [54, Theorem 4.1.12], every invariant probability measure $\mu$ satisfying $\mu(S \setminus S_0) = 1$ is a convex combination of ergodic measures $\nu$ satisfying $\nu(S \setminus S_0) = 1$. (9) applied to each of these ergodic measures $\nu$ in the decomposition of $\mu$ implies the final conclusion of the case $\alpha > 0$.

6. Proof of Theorem 3.2

First, we show that host species 1 is stochastically persistent. To this end, we use Theorem 4.1 with $u = x_1$ and $v = (x_2, \ldots, x_k, y)$ in (5) i.e. the other host species and the parasitoid are treated as auxiliary variables. For these choices, the extinction set is $S_0 = \{(x, y) \in S : x_1 = 0\}$. Let $\mu(dx, dy)$ be an ergodic, invariant probability measure on $S_0$. Then there either $\mu(dx, dy)$ supports no host species in which case $r_1(\mu) = \mathbb{E}[\ln R_1(t)] - \mathbb{E}[a_1(t)]\mathbb{E}[I(t)] > 0$ or $\mu(dx, dy)$ supports at least one host species $i \geq 2$. In the latter case, Proposition 4.1 implies that

$$0 = r_i(\mu) = \mathbb{E}[\ln R_i(t)] - a_i(t) \int_{S_0} y \cdot \mu(dx, dy).$$
and therefore $\int y \mu(dx, dy) = E[\ln R_i(t)]/E[a_i(t)]$. On the other hand,

$$r_1(\mu) = \frac{E[\ln R_1(t)] - E[a_1(t)]}{E[a_1(t)]} \int y \mu(dx, dy) = \frac{E[\ln R_1(t)]}{E[a_1(t)]}$$

As $P^*_1 = \frac{E[\ln R_1(t)]}{E[a_1(t)]} > \frac{E[\ln R_1(t)]}{E[a_1(t)]} = P^*_1$, it follows that $r_1(\mu) > 0$. As we have shown that $r_1(\mu) > 0$ for all ergodic measures supported by $S_0$, Theorem 4.1 with $p_1 = 1$ implies stochastic persistence as claimed.

Next, we verify condition (ii) i.e.

$\sum_{k=1}^K x_k > 0$ whenever $x_i(0)x_1(0) > 0$. To prove this conclusion, we verify the conditions of Theorem 4.2 with $u = (x_1, \ldots, x_k)$ and $v = y$ (i.e. only the parasitoid is an auxiliary variables) in (5), and $I = \{1\}$ in conditions (i)–(iii) in Theorem 4.2. For these choices, $S' = \{(x, y) \in S : x_2 = \cdots = x_k = 0\}$. Theorem 3.1 applied to the $x_1 - y$ subsystem implies condition (i) of Theorem 4.2. Next, we verify condition (ii) i.e. $r_2(\mu) < 0$ for all $2 \leq i \leq n$ and ergodic, probability measures $\mu$ such that $S(\mu) = \{1\} = I$. Let $\mu$ be such an ergodic measure. Theorem 3.1 implies that for $i \geq 2$

$$r_i(\mu) = \frac{E[\ln R_i(t)] - E[a_i(t)]}{E[a_i(t)]} = \frac{E[\ln R_i(t)]}{E[a_i(t)]}(P^*_i - P^*_1) < 0$$

as we have assumed that $P^*_1 > P^*_1$. Next we verify assumption (iii) of Theorem 4.2. Consider any initial condition $(x(0), y(0)) \in S$ such that $x(0) > 0$ and $\sum_{i=1}^K x_i(0) > 0$. Define the occupational measure

$$\Pi_t = \frac{1}{t} \sum_{s=1}^t \delta_{z(s)}$$

where $\delta_z$ is a Dirac measure at $z$ i.e. for any Borel set $A \subset S$, $\delta_z(A) = 1$ if $z \in A$ and 0 otherwise. By Lemma 4 of [41] and the stochastic persistence of host species 1 from the first part of this proof, the weak* limit points $\mu$ of $\Pi_t$ as $t \to \infty$ are, with probability one, invariant probability measures that satisfy $\mu(\{(x, y) \in S : x_1 = 0\}) = 0$ and $r_1(\mu) = 0$. Hence, for these weak* limit points $\mu$, we have $\int y \mu(dx, dy) = P^*_1$. For such a $\mu$, we claim that $\mu(\{(x, y) : x_1 > 0, x_2 = \cdots = x_n = 0\}) = 1$. Suppose, to the contrary, that for some $i \geq 2, \mu(\{(x, y) \in S : x_1 > 0, x_i > 0\}) > 0$. Then, by the ergodic decomposition theorem [54, Theorem 4.1.12], there is an ergodic, probability measure $\nu$ such that $\nu(\{(x, y) \in S : x_1 > 0, x_i > 0\}) = 1$. By Proposition 4.1,

$$0 = r_1(\nu)/E[a_i(t)] = \frac{E[\ln R_1(t)]}{E[a_i(t)]} - \frac{E[\ln R_1(t)]}{E[a_1(t)]} = P^*_i - P^*_1,$$

a contradiction to our assumption that $P^*_1 > P^*_1$. Hence, with probability one, the weak* limit points $\mu$ of $\Pi_t$ as $t \to \infty$ satisfy $\mu(\{(x, y) \in S : x_1 > 0, x_2 = \cdots = x_n = 0\}) = 1$ as claimed. In particular, this implies for any neighborhood $U$ of $\{(x, y) \in S : x_1 > 0, x_2 = \cdots = x_n = 0\}$, $z(t)$ enters $U$ infinitely often with probability one. Hence, condition (iii) of Theorem 4.2 is satisfied and (8) implies

$$\limsup_{t \to \infty} \frac{1}{t} \ln \max_{2 \leq i \leq k} x_i(t) < 0$$

with probability one, as claimed. \(\square\)
