The imminent threat of viral epidemics and pandemics dictates a need for therapeutic approaches that target viral pathology irrespective of the infecting strain. Reactive oxygen species are ancient processes that protect plants, fungi and animals against invading pathogens including bacteria. However, in mammals reactive oxygen species production paradoxically promotes virus pathogenicity by mechanisms not yet defined. Here we identify that the primary enzymatic source of reactive oxygen species, NOX2 oxidase, is activated by single stranded RNA and DNA viruses in endocytic compartments resulting in endosomal hydrogen peroxide generation, which suppresses antiviral and humoral signaling networks via modification of a unique, highly conserved cysteine residue (Cys98) on Toll-like receptor-7. Accordingly, targeted inhibition of endosomal reactive oxygen species production abrogates influenza A virus pathogenicity. We conclude that endosomal reactive oxygen species promote fundamental molecular mechanisms of viral pathogenicity, and the specific targeting of this pathogenic process with endosomal-targeted reactive oxygen species inhibitors has implications for the treatment of viral disease.
The production of reactive oxygen species (ROS) is a highly coordinated process achieved by enzymes of the NADPH oxidase (Nox) family. Nox enzymes are not present in prokaryotes but evolved ~1.5 billion years ago in single cell eukaryotes and are present in most eukaryotic groups including ameba, fungi, algae and plants, nematodes, echinoderms, urochordates, insects, fish, reptiles and mammals. The functions of NADPH oxidases within eukaryotes are diverse, however, a common function is the generation of ROS by innate immune cells in response to pathogens. Indeed, orthologs of NADPH oxidase in plants (ArtbohD and ArtbohF), fungi (Noxa/B), and invertebrates Caenorhabditis elegans (Duox orthologs), Drosophila melanogaster (Nox5 homolog, d-Nox), and mosquito Aedes aegypti (NoxM and DUOX) generate ROS with bactericidal activity that protects the host. Vertebrates including teleosts, amphibians, birds, and mammals possess a Nox2 NADPH oxidase that generates a burst of ROS within phagosomes to kill invading pathogens especially bacteria. However, the impact of ROS on virus infection is largely unknown.

To address the potential role of endosomal ROS in virus pathology we first focussed on influenza A viruses, which belong to the Orthomyxoviridae family and are internalized by endocytosis. Exposure of mouse alveolar macrophages (AMs), mouse peritoneal RAW264.7 cells or bone marrow-derived macrophages (BMDMs) to influenza A virus strain H5N1 (H3N2) resulted in a dose and time-dependent increase in influenza nucleoprotein (NP) fluorescence (Supplementary Fig. 1a), which was almost abolished by the dynamin inhibitor, Dynasore (100 μM) indicating a clathrin-coated pit or caveolin-dependent mechanism of internalization (Supplementary Fig. 1b). Internalized virus displayed a strong co-localization with the early endosomal marker EEA1 (Fig. 1c, d, Supplementary Fig. 2a, b, e, f) and in autoimmune disease, mediate similar Type I IFN responses, and stimulate antibody production against self-RNA and antigen. Notably, mice that are chronically deficient in Nox2 oxidase have an increased tendency to develop self-antibodies and patients with chronic granulomatous disease, who have a defective capacity to generate ROS via the Nox2 oxidase, have elevated circulating Type I IFNs and autoantibodies. These observations are supportive of the notion that low levels of ROS result in an enhanced immune response. However, it remains unknown how viruses cause ROS production and how these reactive oxygen molecules, which appear to be largely confined to their site of generation, contribute to disease.

After binding to the plasma membrane, viruses enter cells and ultimately endosomes by a variety of mechanisms resulting in viral RNA detection by endosomal pattern recognition receptors, including toll-like receptor 3 (TLR3), TLR7, and TLR8. The specific receptor interaction depends upon either the Group I–V or genomic orientation (i.e., ssRNA, dsRNA or DNA) of the virus and triggers an immune response characterized by Type I IFN or IL-1β production, and B-cell-dependent antibody production. Host nucleic acids and self-antigens are also detected by endosomal TLRs, and in autoimmune disease, mediate similar Type I IFN responses and stimulate antibody production against self-RNA and antigen. Notably, mice that are chronically deficient in Nox2 oxidase have an increased tendency to develop self-antibodies and patients with chronic granulomatous disease, who have a defective capacity to generate ROS via the Nox2 oxidase, have elevated circulating Type I IFNs and autoantibodies. These observations are supportive of the notion that low levels of ROS result in an enhanced immune response. However, it remains unknown how viruses cause ROS production and how these reactive oxygen molecules, which appear to be largely confined to their site of generation, contribute to disease.

Here we hypothesize firstly, that the internalization of virus into endosomes results in ROS production and that this subdues essential immune pathways that would otherwise clear the virus; and secondly that the targeted inhibition of endosomal ROS markedly reduces viral pathogenicity. The identification of a mechanism to explain the paradoxical effect of ROS on viruses vs. other pathogens such as bacteria has the potential to facilitate the development of specific endosome-targeted antiviral therapies. Our results demonstrate that, Nox2 oxidase is expressed in endosomes in mouse and human cells, and is activated following infection with a) single stranded RNA viruses irrespective of their classification including influenza A viruses, respiratory syncytial virus, rhinovirus, Dengue virus and HIV, as well as b) the DNA viruses vaccinia virus and herpes simplex virus. Activation of endosomal Nox2 is dependent on TLR7 for ssRNA viruses or TLR9 for DNA viruses and is the result of PKC activation. Endosomal Nox2 oxidase activity results in the spatially targeted generation of H2O2, which suppresses key antiviral and humoral signaling processes via the modification of a unique, highly conserved single cysteine residue (Cys98) on the ectodomain of TLR7. Accordingly, targeting endosomal ROS production with a Nox2 oxidase inhibitor suppresses influenza A virus pathogenicity. Finally these findings identify four conceptual advancements centered on ROS biology including: (1) identification of the endosome as a critical sub cellular compartment of ROS generation to virus infection, irrespective of strain; (2) molecular targets of ROS reside within the endosome revealing a paradigm in cell lineage-specific cell signaling; (3) endosomal ROS suppress antiviral signaling, and (4) endosome specific delivery of a ROS inhibitor is an effective treatment strategy for influenza viral disease.

Results
Influenza viruses drive endosomal ROS. To address the potential role of endosomal ROS production in virus pathology we first focussed on influenza A viruses, which belong to the Group IV negative sense, ssRNA viruses of the Orthomyxoviridae family and are internalized by endocytosis. Exposure of mouse alveolar macrophages (AMs), mouse peritoneal RAW264.7 cells or bone marrow-derived macrophages (BMDMs) to influenza A virus strain H5N1 (H3N2) resulted in a dose and time-dependent increase in influenza nucleoprotein (NP) fluorescence (Supplementary Fig. 1a), which was almost abolished by the dynamin inhibitor, Dynasore (100 μM) indicating a clathrin-coated pit or caveolin-dependent mechanism of internalization (Supplementary Fig. 1b). Internalized virus displayed a strong co-localization with the early endosomal marker EEA1 (Fig. 1a). However, not all of the NP was co-localized with internalized virus (Fig. 1a) and might have already entered late endosomes and/or lysosomes. Nox2 co-localized with EEA1 in control and influenza infected cells (Fig. 1b, Supplementary Fig. 1c). Thus, the enzymatic machinery for ROS generation is present in early endosomes and this is significantly enhanced in influenza A virus infection, promoting co-localization with internalized virus.

Endosomal ROS production in response to viral uptake was assessed with OxyBURST. Exposure to a series of low to high pathogenic seasonal and pandemic influenza A viruses resulted in rapid and dose-dependent increases in OxyBURST fluorescence in mouse primary AMs (Fig. 1c, d) and converts superoxide to H2O2 (Fig. 1e, f). In contrast the ROS signal was significantly increased in AMs from mice deficient in endosomal sod (SOD3−/− mice), establishing the detection of a superoxide derivative (Supplementary Fig. 2c, d). For confirmation that ROS production occurred in acidified endosomes we demonstrated a co-localization of OxyBURST fluorescence with LysoTracker (50 nM) in the presence of influenza virus (Fig. 1g). Inhibition of the vacuolar V-ATPase pump with bafilomycin A (100 nM), and thus inhibition
Endosomal acidification, abolished the LysoTracker fluorescence and endosomal ROS production in response to influenza A virus infection (Fig. 1g). Endosomal ROS was minimal in NOX2−/y AMs, but was unaffected in NOX4−/− macrophages and in macrophages treated with the NOX1 inhibitor ML171 (100 nM) (Fig. 1e, f, Supplementary Fig. 2h, i). Internalization of influenza A virus into AMs was not impaired in NOX2−/y cells (Supplementary Fig. 2g), indicating that reduced endosomal ROS production was not due to reduced viral entry. In addition, heat- and UV-inactivated forms of influenza (replication-deficient) caused an increase in endosomal ROS production that was similar to the live virus control (Fig. 1i, j). Therefore,
influenza A viruses, irrespective of subtype, strain and pathogenicity, stimulate NOX2, but not NOX4 or NOX1 oxidase-dependent ROS production in endosomes, and this involves endosomal acidification, but does not require viral replication.

Endosome TLR7-NOX2 signaling axis. RNA viruses are recognized by endosomal TLR7 (for ssRNA viruses) and TLR3 (dsRNA viruses), as well as the cytosolic sensors retinoic acid inducible gene I (RIG-I) (which can detect viral RNA bearing 5’ triphosphates) and NOD-like receptors (NLRs)13, 20, 21. We hypothesized that influenza A virus entry into acidified endosomes results in the liberation of viral RNA, activation of TLR7 and stimulation of NOX2 oxidase-dependent ROS production. Consistent with this suggestion, TLR7 co-locates with influenza A virus (Fig. 2a), NOX2 (Fig. 2b) and EEA1 (Fig. 2c, Supplementary Fig. 3a) and primary AMs from TLR7−/− mice, and TLR7−/− and MyD88-deficient BMDM, display minimal endosomal ROS production in response to influenza A virus (Fig. 2d, Supplementary Fig. 3b–e). The lack of endosomal ROS production in response to virus in TLR7−/− and MyD88−/− cells was not due to a reduced capacity of the NOX2 oxidase per se, as NOX2 activation by the PKC activator phorbol dibutyrate (PDB; 10−6 M) was similar in these cells and wild-type (WT) control cells (Supplementary Fig. 3c). As a second measure of NOX2 oxidase activity, we assessed enzyme assembly by examining the degree of association of the NOX2 catalytic subunit with the p47phox regulatory subunit. In unstimulated cells, there was very little co-localization of NOX2 and p47phox (Fig. 2e). However, influenza virus caused strong co-location of NOX2 and p47phox, which was reduced by Dynasore or bafilomycin A pre-treatment, and almost abolished in TLR7−/− cells (Fig. 2e). To provide further evidence that the activation of TLR7 leads to endosomal ROS production, we used the specific TLR7 agonist, imiquimod (10 μg/ml). Imiquimod markedly increased endosomal ROS in AMs from human and WT mice, but not from NOX2−/− mice (Fig. 2f) or macrophages deficient in TLR7 or MyD88 (Supplementary Fig. 3b). Finally, we pulsed AMs or RAW264.7 cells with a guanidine- and uridine-rich ssRNA sequence (ssRNA40; 100 μM). In concentrations capable of increasing IL-1β, IL-6, and TNF-α mRNA via a TLR7-dependent mechanism (Supplementary Fig. 4), ssRNA40 caused elevated endosomal ROS production (Fig. 2g). In contrast, endosomal ROS production in response to influenza A virus was preserved in RIG-I−/−, NLRP3−/−, TLR2−/−, and TLR4−/− macrophages, and in macrophages treated with the TLR3 inhibitor (50 μM) (Supplementary Fig. 3d–h).

We subsequently examined how TLR7 elicits the assembly and activation of endosomal NOX2 oxidase. NOX2 oxidase can be activated by protein kinase C, which triggers robust phosphorylation of key serine residues on p47phox, resulting in a NOX2 oxidase-dependent oxidative burst10. To define the spatiotemporal regulation of PKC signaling and to assess its regulation by TLR7, we expressed the FRET biosensor cytocr1/2, to detect cytosolic PKC22–24 in WT and TLR7−/− macrophages. The treatment of WT macrophages with influenza A virus or imiquimod elevated cytosolic PKC activity within 5 min, but this response was absent in TLR7−/− macrophages and in WT macrophages treated with Dynasore or bafilomycin A (Fig. 2h, i).

A FRET biosensor method for cytosolic pERK1/2 activity21, 24–26 showed that both influenza virus and imiquimod increased cytosolic pERK1/2 in a TLR7-dependent manner. In contrast, blocking pERK1/2 with PD98059 (30 μM) did not influence endosomal ROS production (Supplementary Fig. 5c). These data indicate that influenza A virus increases endosomal NOX2 oxidase activity via TLR7 and the downstream activation of PKC but not via pERK1/2.

We conclude that virus infection triggers a NOX2 oxidase-dependent production of ROS in endosomes using a process that is dependent on low pH. Indeed this conclusion is supported by the following experimental evidence. First it is known that reduced endosome acidification impairs the activation of TLR7 by viral RNA18, 19. Our study is in agreement with this finding, showing that NOX2 dependent ROS production to virus infection and to the TLR7 agonist imiquimod was abolished in TLR7−/− cells and also by pretreatment with bafilomycin A. Second, bafilomycin A suppressed PKC activation due to influenza virus and imiquimod treatment, and PKC is upstream of acute NOX2 activation10, 11. Third, bafilomycin A suppressed the association of p47phox-NOX2, which is a critical step for NOX2 assembly and activation.

Viral strain independence of endosomal ROS. Exposure of macrophages to rhinovirus (picornaviridae, Group IV), respiratory syncytial virus (paramyxoviridae, Group V), human parainfluenza virus (paramyxoviridae, Group V), human metapneumovirus (paramyxoviridae, Group V), Sendai virus (paramyxoviridae, Group V), Dengue virus (flaviviridae Group IV) or HIV (retroviridae, Group VI, ssRNA-RT virus) resulted in a significant elevation of endosomal ROS that was markedly suppressed in TLR7−/− macrophages, but unaffected in TLR9−/− cells (Fig. 3a, b). Both mumps virus (paramyxoviridae Group V) and Newcastle disease virus (NDV, paramyxoviridae Group V) failed to generate significant endosomal ROS (Fig. 3a, b), and it is noteworthy that these viruses primarily enter cells by a cell membrane fusion process and not via endocytosis. Rotavirus (rhoeus monkey strain or bovine UK strain,
(reoviridae Group III) exposure of macrophages also failed to generate endosomal ROS (Fig. 3a, b). The DNA viruses Herpes simplex virus 2 (herpesviridae, Group I) and vaccinia virus (poxviridae, Group I) each caused an elevation in endosomal ROS in WT macrophages and TLR7−/− macrophages, but not in TLR9−/− macrophages (Fig. 3a, b). We conclude that the specific recognition of either ssRNA viruses by TLR7, or DNA viruses by TLR9, leads to a NOX2 oxidase-dependent burst of endosomal ROS.

**Bacteria and viruses activate distinct ROS pathways.** Plasma membrane TLRs, especially TLR1, TLR2, and TLR4, and not those present within endosomes (such as TLR7), sense bacteria resulting in the recruitment of mitochondria to macrophage phagosomes and mitochondrial dependent ROS production. However, the stimulation of endosomal TLRs failed to augment mitochondrial ROS. We confirmed that TLR7 activation with imiquimod, which caused a significant elevation in endosomal ROS (Fig. 2f), failed to increase macrophage mitochondrial ROS.

superoxide production (Supplementary Fig. 3i). We examined the production of phagosomal ROS in response to the Gram-positive bacteria *Streptococcus pneumoniae* (SP) or gram-negative non-typeable *Haemophilus influenzae* (NTHI). Both SP and NTHI caused ROS production in WT mouse macrophages (Fig. 4), which was enhanced in SOD3−/− cells (Supplementary Fig. 2i), but unaffected in TLR7−/- macrophages (Fig. 4). Thus, endosomal ROS production is not a characteristic of endocytosis per se, but a “pathogen (cargo)-specific” response. ROS produced for antibacterial purposes involves an obligatory role of mitochondria, which serves as a central hub to promote innate immune signaling. By contrast, ssRNA viruses do not employ these antibacterial ROS generating pathways.

**Endosomal H$_2$O$_2$ suppresses TLR7 immunity.** To establish the functional importance of endosomal ROS, we assessed the impact of NOX2 inhibition on the production of cytokines that are endosome TLR7-dependent and thus relevant to virus pathogenicity. We first confirmed an endosome- and TLR7-dependent signal by showing that imiquimod caused a significant elevation in IFN-β, IL-1β, TNF-α, and IL-6 expression in WT macrophages, but not in TLR7−/- macrophages (Fig. 5a) or in macrophages treated with bafilomycin A (100 nM) (Fig. 5b). Second, pre-treatment with the NOX2 oxidase inhibitor and H$_2$O$_2$ scavenger, apocynin (300 μM) significantly enhanced IFN-β, IL-1β, TNF-α, and IL-6 expression in response to imiquimod, in WT macrophages but not in TLR7−/- macrophages, indicating that the suppressive effect of NOX2 oxidase-derived ROS on cytokine expression is dependent on TLR7 (Fig. 5a). In contrast, IFN-β, IL-1β, TNF-α, and IL-6 expression in response to the TLR3 agonist, poly I:C (25 μg/ml), was suppressed by apocynin pre-treatment (Supplementary Fig. 6a) whereas increases in these same cytokines triggered by the TLR9 agonist CpG (10 μg/ml), were unaffected by apocynin (Supplementary Fig. 6b). We further tested whether NOX2 oxidase influences TLR7 immunity in vivo. WT and NOX2−/- mice were treated with a single dose of imiquimod (50 μg per mouse, intranasally) for measurements of lung IFN-β, IL-1β, IL-6, and TNF-α after 24 h. This time point was chosen to reflect early phases of RNA infection. There were no discernible alterations in airway inflammation in response to imiquimod (Fig. 5c), however, imiquimod treatment resulted in elevated levels of IFN-β, IL-1β, IL-6, and TNF-α in NOX2−/- mice (Fig. 5d).

We sought to establish how endosomal NOX2 oxidase activity results in the suppression of TLR7-dependent responses and hypothesized that the parent species superoxide and its immediate downstream product, H$_2$O$_2$ are culprit mediators. Inactivation of superoxide by adding exogenous SOD (300 U/ml) failed to influence either basal or imiquimod-stimulated expression of IFN-β, IL-1β, TNF-α, and IL-6, suggesting little role for superoxide itself in modulating TLR7 responses (Supplementary Fig. 7). To examine H$_2$O$_2$, we utilized catalase to inactivate the H$_2$O$_2$ generated within endosomes. We found that within 30 min, exposure to a FITC-labeled catalase resulted in co-localization with LysoTracker, confirming internalization into acidified endosomal compartments (Fig. 6a). A 1 h “pulse” exposure to catalase (1000 U/ml) resulted in significant elevations in IFN-β and IL-1β expression after 24 h in WT macrophages, but not in TLR7−/- macrophages (Fig. 6b). Moreover, imiquimod-dependent responses were significantly increased in the presence of catalase (Fig. 6c). The catalase-dependent increase in cytokines was significantly suppressed in WT macrophages treated with Dynasore (Fig. 6d) but unaffected in TLR7−/- macrophages (Fig. 6e, Supplementary Fig. 8a). The translocation of TLR7 to endosomes is governed by the actions of the chaperone protein, UNCB93. Indeed in the absence of UNCB93 there are substantial signaling defects due to the failure of the nucleotide-sensing TLRs to reach the endolysosomes, where they initiate MyD88/TRIF-dependent signaling pathways. In UNCB93−/− cells, the increase in cytokines to catalase treatment was significantly smaller than that observed in WT cells (Fig. 6f, Supplementary Fig. 8b). Thus, the suppressive actions of H$_2$O$_2$ are most likely occurring when TLR7 is located within the endosomal compartment. Catalase had no effect on TLR7, TREML4 or NLRP3 expression indicating that H$_2$O$_2$ does not modulate the expression of TLR7, a positive regulator of TLR7 activity (i.e., TREML4) or NLRP3 that drives similar anti-viral cytokines to TLR7 (Fig. 6g–j). Therefore the effect of H$_2$O$_2$ is likely to be post-translational. We then examined whether endosomal NOX2 oxidase-derived H$_2$O$_2$ influences TLR7 responses in vivo. We administered catalase (1000 U per mouse) intranasally to WT mice and showed a three to four fold increase in lung IFN-β, IL-1β, TNF-α, and IL-6 after 24 h and this occurred prior to overt airway inflammation (Fig. 6k, l).

We questioned whether H$_2$O$_2$ released by endosomal NOX2 oxidase targets cysteine residues on protein domains of TLR7 that regulate receptor activity and are exposed upon activation within endosomal compartments. We then performed site-directed mutagenesis to create a series of TLR7 mutants including (1) a mutant with all six of these cysteine residues replaced with alanine, (2) mutants with a dual mutation of Cys98 and Cys445 (TLR7C98A/C445A), and (3) single mutations of Cys98 (TLR7C98A) and Cys445 (TLR7C445A). Transfection of WT TLR7 or TLR7C445A into TLR7−/- macrophages restored the ability of imiquimod to stimulate cytokine expression.
in these cells; however, transfection with the TLR7 containing the 6 mutations, the TLR7C98A/C445A or the TLR7C98A did not (Fig. 7a). Catalase (1000 U/ml) treatment had little or no effect on cytokine expression in cells expressing the mutated TLR7, TLR7C98A/C445A or TLR7C98A whereas it markedly increased cytokine expression in cells with WT TLR7 or TLR7-C445A (Fig. 7a).

We performed sequence analysis using both multiple sequence analysis algorithms (i.e., CLUSTAL OMEGA) and pair-wise sequence analysis (NCBI, Blast) with human TLR7 as a reference
NOX2 oxidase dampens antibody production. We examined if the suppressive effect of endosomal NOX2 oxidase activity on Type I IFN and IL-1β expression also occurs following influenza A virus infection. Firstly, virus triggered translocation of the transcription factor, IRF-7, to the nucleus of WT BMDMs, but not TLR7−/− BMDMs, indicating that influenza A virus activates TLR7-dependent antiviral signaling in macrophages (Supplementary Fig. 11). Second, virus elevated IFN-β, IL-1β, IL-6, and TNF-α expression to a greater extent in NOX2−/− AMs (Fig. 8a). Third, influenza A virus (Hkx31; 105 PFU per mouse) infection in mice in vivo for 24 h resulted in greater increases in lung IFN-β, IL-1β, IL-6, and TNF-α mRNA (Fig. 8b), as well as serum (Fig. 8c) and lung IFN-β protein (Fig. 8d) in NOX2−/− mice. Thus a fully functional NOX2 oxidase suppresses anti-viral cytokine production triggered by influenza A virus.

TLR7 is essential for the activation of B-cells and for antibody production. To test whether NOX2 oxidase suppresses TLR7-dependent immunity to influenza A virus in vivo, we used heat-inactivated, replication-deficient influenza A virus as a stimulus, and hence a form of virus expected to mainly trigger engagement of the TLR7 PRR with very little contribution of RIG-I and NLRP320. Intranasal inoculation with inactivated virus had no effect on weight loss over 7-days (Fig. 8e) or airways BALF inflammation (Fig. 8f). NOX2 deletion resulted in a significant elevation in lung levels of IFN-β and IL-1β (Fig. 8g), and in both serum and BALF levels of IgA, total IgG, IgG1, IgG2b, and IgG3 (Fig. 8h, i). Therefore, activation of endosomal NOX2 oxidase following influenza A virus infection results in the suppression of antiviral cytokines and humoral immunity via the suppression of antibody production—processes that are required for optimal clearance of the virus and resistance to re-infection.

Endosomal targeted NOX2 inhibitor. We synthesized an innovative molecular targeting system, to deliver a specific NOX2 oxidase inhibitor (i.e., gp91ds-TAT) directly to endosomes, so as to disrupt the viral signaling platform by abrogating ROS production. To do this we generated a tripartite structure comprising gp91ds-tat conjugated to the membrane anchor cholestanol via a PEG-linker at the N-terminal region of the peptide. Similar constructs have been shown previously to enhance endosome localization for inhibitors of the enzyme beta secretase28. A Cy5 fluorophore conjugated to cholestanol using the same PEG linker resulted in cytosolic fluorescence in the peri-nuclear region and co-localization with EEA1, NOX2 and influenza virus NP following viral infection in a dynasore (100 μM)-sensitive manner providing evidence for endocytosis as its primary mode of cell entry (Fig. 9a–e). Superoxide generation in macrophages in vitro was suppressed with at least a 10-fold greater potency by cholestanol-conjugated gp91ds-TAT (Cgp91ds-TAT) when compared to the unconjugated drug (Ugp91ds-TAT; Fig. 9f), which is not attributed to enhanced ROS scavenging properties of the compound (Fig. 9g).

We examined whether Cgp91ds-TAT suppresses disease severity following influenza A virus infection in vivo. Daily intranasal administration of Cgp91ds-TAT (0.02 mg/kg/day) from 1 day prior, until day 3 post-infection A virus A virus infection resulted in a ~40% reduction in airways inflammation (Fig. 9h), whereas Ugp91ds-TAT had no significant effect (Fig. 9h). Cgp91ds-TAT significantly increased lung Type I IFN-β mRNA levels compared to the control virus group, whereas Ugp91ds-TAT failed to do so (Fig. 9i). To eliminate the possibility that this improvement in NOX2 inhibition by cholestanol conjugation of gp91ds-TAT was attributed to cholestanol-PEG linker per se, we conjugated the cholestanol PEG-linker to a scrambled gp91ds-TAT (Sgp91ds-TAT) and examined its effect against influenza A virus infection in vivo. Sgp91ds-TAT had no effect on airway inflammation, lung IFN-β mRNA levels and superoxide production (Supplementary Fig. 12). Increasing the dose of the Ugp91ds-TAT by 10-fold to 0.2 mg/kg/day significantly reduced the weight loss caused by influenza A virus at day 3 and almost abolished airway inflammation, as well superoxide production in BALF inflammatory cells, similar to Cgp91ds-TAT at the same dose (Fig. 9j–l). Strikingly, both Cgp91ds-TAT (0.2 mg/kg/day) and Ugp91ds-TAT (0.2 mg/kg/day) caused an almost 10,000-fold, decrease in lung influenza A viral burden (Fig. 9m). Thus, suppression of endosome NOX2 oxidase via nasal administration of gp91ds-TAT results in a substantial reduction in influenza A virus pathogenicity. This is an innovative approach for suppressing NOX2 oxidase activity that occurs within the endosome compartment. We would like to emphasize that our custom-made NOX2 inhibitor is unlikely to solely suppress endosome NOX2. However, our inhibitor is specifically and preferentially delivered via the endocytic compartment owing to the cholestanol conjugation. In support of this, our findings of Fig. 9a and b show that cholestanol conjugation results in a drug delivery system that promotes endosome delivery i.e our drug displayed a strong degree of co-location with EEA1+ endosomes that was abolished by dynasore pretreatment. This delivery system brings a NOX2 inhibitor to the predominant site of action that relates to virus infection (see Fig. 9d showing strong co-location of viral nucleoprotein and our NOX2 inhibitor).

Fig. 3 Endosomal ROS production to ssRNA and DNA viruses are via TLR7 and TLR9-dependent mechanisms, respectively. a Endosomal ROS production in WT and TLR7−/− bone marrow-derived macrophages as assessed by OxyBURST (100 μM) fluorescence microscopy in the absence or presence of influenza A virus (Hkx31 virus), rhinovirus (rhino), respiratory syncytial virus (RSV), human parainfluenza virus (PIV), human metapneumovirus (HMV), sendai virus, dengue virus, human immunodeficiency virus (HIV), mumps virus (MuV), Newcastle disease virus (NDV), rotavirus (UK and bovine strains), herpes simplex virus 2 (HSV-2), and vaccinia virus and labeled with 4',6-diamidino-2-phenylindole (DAPI). Also shown is the quantification of the results (n = 5). b Endosomal ROS production in WT and TLR9−/− mouse primary alveolar macrophages as assessed by OxyBURST fluorescence microscopy in the absence or presence of Hkx31 virus, rhinovirus, sendai virus, dengue virus, and herpes simplex virus 2 (HSV-2) and labeled with DAPI (n = 5). a and b Images are representative of >150 cells analyzed over each experiment. Original magnification ×100. All data are represented as mean ± S.E.M. One-way ANOVA followed by Dunnett’s post hoc test for multiple comparisons. #P < 0.05 compared to WT control. *P < 0.05 comparisons indicated by horizontal bars. Scale bars: 10 μm.
We speculate that following internalization into the endosome the drug is most likely on the luminal face of the endosome membrane and due to the TAT portion can penetrate the membrane and suppress NOX2 activity. The drug might still be able to diffuse towards other sites or locations of NOX2, however, we believe the immediate and primary site of action will be NOX2 activity at the endosome, given that the drug appears to be selectively delivered via the endocytic pathway.

Discussion

We have accumulated evidence that virus entry into endosomal compartments triggers a NOX oxidase-dependent production of ROS in endosomes. However, some ROS may have possibly been generated in sites outside of the endosome, which may have then diffused into the endosomes. As such the site of ROS generation and site of detection in some instances might be distinct. We suggest that the major contributor to endosomal concentrations of superoxide will be superoxide generated directly in this compartment. Superoxide is the primary product of NOX2 and it will only be generated within the endosome compartment owing to the topology of the NOX2 and the unidirectional transfer of electrons through this catalytic subunit. In keeping with this, it is well regarded that superoxide does not travel far from its site of generation due to its negative charge. By contrast to superoxide, H$_2$O$_2$ has some capacity to permeate membranes and diffuse, and as such, it can be envisaged that some endosome H$_2$O$_2$ might have been generated elsewhere by NOX2 expressed in other sites of the cell such as the plasma membrane. However for several lines of evidence we suggest that it is very likely that little remotely generated H$_2$O$_2$ is finding its way into the endosome compartment. First we demonstrate that PKC activation following virus infection, which is critical for NOX2 activation, is significantly impaired if: (1) the virus is prevented from entering cells (Fig. 2h, i); (2) endosome acidification is blocked by Bafilomycin A (Fig. 2h, i) or (3) if TLR7 is absent (i.e., TLR7$^{-/-}$ macrophages are used). Therefore, endosomal NOX2 derived ROS generation occurs only after virus has entered endosomes and activates endosome-specific pathways, lending further credence to endosome NOX2 as the predominant site of H$_2$O$_2$ generation. Second, elegant studies addressing spatialtemporal aspects of H$_2$O$_2$ diffusion clearly demonstrate that H$_2$O$_2$ diffusion in the cytoplasm is strongly limited, but is instead localized to near the sites of its generation$, providing evidence that endosome H$_2$O$_2$ is unlikely to have been generated at a remote site.

Here we demonstrate that endosomal ROS are essential negative regulators of a fundamental molecular mechanism of viral pathogenicity that impacts on antiviral immunity and the capacity of the host to fight and clear viral infections. Importantly, this effect is conserved, regardless of viral classification, for all viruses that enter cells via the endocytic pathway, and is TLR7 dependent. This provides a potential target for antiviral therapy for a range of viruses that cause significant morbidity and mortality worldwide. Previous work has demonstrated that a deficiency in the phagocyte NADPH oxidase can result in exacerbated inflammation and necrosis in response to fungal components including β-glucans that activate TLR2 and dectin-1$. Our study is not a universal mechanism that defines how NOX2 oxidase might be regulating inflammation to fungi and other pathogens but certainly provides strong mechanistic insight into ROS-dependent regulation of antiviral immunity.

Intriguingly, our study raises a broader paradox: Why does a mammalian cell generate ROS that may ultimately cause harm (i.e., by promoting viral pathogenicity)? We hypothesize that suppression of TLR7 activation by endosomal NOX2 is a hitherto unrecognized mechanism that has evolved to inhibit an inflammatory response against self-RNA/antigens and the development of autoimmunity, but which in a very similar manner results in a host response to viral RNA that inadvertently exacerbates viral pathogenicity. Realizing the delicate balance between viral clearance and the induction of an autoimmune response, the current data suggest the potential to employ short term suppression of endosomal ROS as a means of reducing viral pathogenicity without causing long term problems with autoimmunity.

Methods

Viruses. The influenza A virus vaccine strains HKx31 (H3N2) and BJx109 (H3N2) were kindly provided by A/Prof John Stambas (School of Medicine, Deakin University, Geelong, Australia).
Fig. 5 Endosomal NOX2 oxidase suppresses cytokine expression in response to TLR7 activation in vitro and in vivo. a, b WT and TLR7\(^{-/-}\) immortalized bone marrow-derived macrophages (BMDMs) were untreated or treated with imiquimod (Imiq; 10 \(\mu\)g/ml) in the absence or presence of a apocynin (Apo; 300 \(\mu\)M) or b baflomycin A1 (Bal-A1; 100 nM), and IFN-\(\beta\), IL-1\(\beta\), TNF-\(\alpha\) and IL-6 mRNA expression determined by QPCR after 24 h (\(n = 6\)). c, d WT and NOX2\(^{-/-}\) mice were administered with imiquimod (50 \(\mu\)g per mouse, intranasal) and \(\delta\) total airway inflammation quantified by bronchoalveolar lavage fluid analysis and d cytokine expression assessed 24h later (\(n = 5\)). a, b, d Responses are relative to GAPDH and then expressed as a fold-change above WT controls. a-d Data are represented as mean ± S.E.M. a, b and d Kruskal–Wallis test with Dunn’s post hoc test for multiple comparisons. c One-way ANOVA followed by Dunnett’s post hoc test for multiple comparisons. Statistical significance was accepted when \(P < 0.05\). *\(P < 0.05\), **\(P < 0.01\).

Bacteria. S. pneumoniae EF3030 (capsular type 19 F) was used as the parent S. pneumoniae strain in all experiments (provided by Dr. Odilia Wijburg, University of Melbourne, Australia). S. pneumoniae EF3030 is a clinical isolate that is frequently used as a model of human carriage as it typically colonizes the nasopharynx in the absence of bacteremia. For infection experiments, pneumococci were grown statically at 37 °C in Todd–Hewitt broth, supplemented with 0.5% yeast extract, to an optical density (600 nm) of 0.4–0.45. Cultures were on wet ice for 5 min and frozen in 8% (v/v) glycerol at -80 °C. Live bacterial counts were confirmed prior to each experiment. A defined strain of non-typeable H. influenzae (NTHi; MU/MMC-1) was previously typed and sequenced and demonstrated to be NTHi, as we have previously shown\(^1\).

Conjugation of NOX2 oxidase inhibitors. Preparation of gp91 ds-tat (YGRKK-RQRR-RGTR-RQRL-NH\(_2\)) was carried out by standard Fmoc solid-phase peptide synthesis (SPPS) on Fmoc-PAL-PEG-PS resin (Life Technologies, USA, loading 0.17 mmol/g). Fmoc deprotection reactions were carried out using 95% (v/v) piperidine in N,N-dimethylformamide (DMF). Coupling reactions were carried out using Fmoc-protected amino acids with O-(6-chlorobenzotriazol-1-yl)-N,N,N',N',-tetramethyluronium hexafluorophosphate (HCTU) as coupling agent and N,N-diisopropylethylamine (DIPEA) as activating agent. Reactions were monitored using the 2,4,6-trinitrobenzenesulfonic acid test to indicate the absence or presence of free amino groups. The alternating

University, CSIRO) and A/Prof. Patrick Reading (Department of Immunology and Microbiology, University of Melbourne, The Peter Doherty Institute for Infection and Immunity). Human strains of influenza A virus, including seasonal H3N2 (A/New York/55/2004, A/Brisbane/9/2007), seasonal H1N1 (A/Brazil/11/1978, A/New Caledonia/20/1999, A/Solomon Islands/3/2006), A/H1N1pdm09 strains (A/California/7/2009, A/Auckland/1/2009), rhinovirus (RV16 strain), respiratory syncytial virus (strain A2), human parainfluenza virus type-3 (C243), human metapneumovirus (strain CAN97-83), mumps virus (strain Enders), and Newcastle disease virus (strain V4) were provided by A/Prof David Tscharke. Additional viruses were provided by the following people: dengue virus serotype 2 (Vietnam strain A/Prof. Patrick Reading. Additional viruses were provided by the following people: dengue virus serotype 2 (Vietnam 2005 isolate, Associate Prof Elizabeth McGraw; Monash University); rotavirus (Rheuss and UK strains, A/Prof Barbara Coulson, Department of Microbiology and Immunology, The Peter Doherty Institute for Infection and Immunity); sendai virus (Cantell strain, Dr. Ashley Mansell from Hudson Institute of Medical Research, Monash University); herpes simplex virus type-2 (strain Ks 186; Dr. Niamh Mangan, Hudson Institute of Medical Research, Monash University); vaccinia virus (Western Reserve strain, WR NIH-TG; A/Prof. David Tschäke, Australia National University), and HIV (NL4-3 (A68)-EGFP strain, Prof. Sharon Lewin, The Peter Doherty Institute for Infection and Immunity, The University of Melbourne). The viruses were provided in phosphate buffered saline (PBS, Cat # D8537, Sigma, USA) and stored at −80 °C until used. On the day of use, virus was thawed quickly and incubated at 37 °C prior to infection. Where indicated, HK331 virus was inactivated by heat (56 °C) for 30 min or UV light (30 min).
sequence of deprotection and coupling reactions was carried out manually for all 20 amino acid residues using the appropriate Fmoc- and side-chain protected amino acids. After a final de-protection step, a small portion of the peptide was cleaved from resin using TFA/TIPS/EDT/water (92.5:2.5:2.5:2.5). The crude peptide was purified as described previously to give cgp91 ds-tat: calcd. for C172H320N56O43S [M + 6H+] m/z 780.6, obs. m/z 780.3; calcd. for C172H278N56O43S [M + 7H+] m/z 650.4, obs. m/z 650.7; calcd. for C172H320N56O43S [M + 8H+] m/z 557.6, obs. m/z 558.0.

Preparation of ethyl ester-conjugated cgp91 ds-tat (cgp91 ds-tat; Ac-Asp(OEt)-PEG4-PEG3-PEG4 cgp91-NH2) was carried out in the same way as for cgp91 ds-tat, except for replacement of Fmoc-Asp(OChol)-OH with Fmoc-Asp(OEt)-OH in the final coupling step: calcd. for C172H320N56O43S [M + 6H+] m/z 711.8, obs. m/z 712.1; calcd. for C172H278N56O43S [M + 7H+] m/z 593.3, obs. m/z 593.7; calcd. for C172H320N56O43S [M + 8H+] m/z 508.7, obs. m/z 509.0.

Preparation of the 18 amino acid scrambled cgp91 ds-tat (Scramble cgp91 ds-tat; Ac-Asp(OChol)-PEG4-PEG3-PEG4-RKQK-RQRK-RCLR-RTQSR-NH2) peptide was carried out by manual SPPS as described above for unscrambled cgp91 ds-tat. The resi-bound sgp91 ds-tat was then conjugated to cholesterol via a PEG linker using the same method described above for unscrambled cgp91 ds-tat. The crude peptide was purified in the same way to give cgp91 ds-tat: calcd. for C172H320N56O43S [M + 6H+] m/z 736.3, obs. m/z 736.5; calcd. for C172H320N56O43S [M + 7H+] m/z 613.7, obs. m/z 614.0; calcd. for C172H320N56O43S [M + 8H+] m/z 526.2, obs. m/z 526.3

Animal ethics statement. The mouse experiments described in this manuscript were approved by the Animal Experimentation Ethics Committee of The University of Tokyo.
**Fig. 7** C98 on TLR7 regulates activity of the receptor and is a target for endosomal H$_2$O$_2$. **a** TLR7$^{-/-}$ BMDMs were transfected with empty vector, WT TLR7 or with either TLR7 with cysteines 98, 260, 263, 270, 273, and 445 mutated to alanine (TLR7 6 mut), TLR7 with cysteines 98 and 445 mutated to alanine (TLR7C98A/445A) or with TLR7 with cysteines 445 (TLR7C445A) or 98 (TLR7C98A) mutated to alanine. After 48 h, cells were left untreated or treated or with either TLR7 with cysteines 98, 260, 263, 270, 273, and 445 mutated to alanine (TLR7 6 mut), TLR7 with cysteines 98 and 445 mutated to alanine (TLR7C98A/445A) or with TLR7 with cysteines 445 (TLR7C445A) or 98 (TLR7C98A) mutated to alanine. After 48 h, cells were left untreated or treated with either catalase (1000 U/ml) or imiquimod (Imiq, 10 μg/ml) or cytokine expression assessed 24 h later (n = 6). Responses are relative to GAPDH and then expressed as a fold-change above TLR7−/− control. Data are represented as mean ± S.E.M. One-way ANOVA followed by Dunnett’s post hoc test for multiple comparisons. Statistical significance was accepted when P < 0.05. *P < 0.05. (NS) Denotes not significant. **b** Multiple sequence alignment with CLUSTAL OMEGA showing across species conservation of Cys 98 on TLR7.

**In vivo infection with influenza A virus and drug treatments.** Aged matched (6–12 weeks) littermate naïve WT control and NOX2$^{-/-}$ mice (also known as gp91phox$^{-/-}$ mice) were originally generated in the laboratory of Prof Mary Dinauer$^{[32]}$ were anaesthetized by penthrane inhalation and infected intranasally with Hk-x31 or catalase (1000 U per mouse, i.n.) or cholestanol conjugated-scrambled gp91ds-TAT (100 U per mouse, i.n.) or catalase (1000 U per mouse, i.n.) and cytokine expression assessed 24 h later (n = 6). Responses are relative to GAPDH and then expressed as a fold-change above TLR7−/− controls. Data are represented as mean ± S.E.M. One-way ANOVA followed by Dunnett’s post hoc test for multiple comparisons. Statistical significance was accepted when P < 0.05. *P < 0.05. (NS) Denotes not significant. **b** Multiple sequence alignment with CLUSTAL OMEGA showing across species conservation of Cys 98 on TLR7.

**In vivo infection with influenza A virus and drug treatments.** Aged matched (6–12 weeks) littermate naïve WT control and NOX2$^{-/-}$ mice (also known as gp91phox$^{-/-}$ mice) were originally generated in the laboratory of Prof Mary Dinauer$^{[32]}$ were anaesthetized by penthrane inhalation and infected intranasally (i.n.) with Hk-x31 or catalase (1000 U per mouse, i.n.) or cholestanol conjugated-scrambled gp91ds-TAT (100 U per mouse, i.n.) or catalase (1000 U per mouse, i.n.) and cytokine expression assessed 24 h later (n = 6). Responses are relative to GAPDH and then expressed as a fold-change above TLR7−/− controls. Data are represented as mean ± S.E.M. One-way ANOVA followed by Dunnett’s post hoc test for multiple comparisons. Statistical significance was accepted when P < 0.05. *P < 0.05. (NS) Denotes not significant. **b** Multiple sequence alignment with CLUSTAL OMEGA showing across species conservation of Cys 98 on TLR7.

**Airways inflammation and differential cell counting.** Mice were killed by an intraperitoneal (i.p.) injection of ketamine/xylazine (100 mg/kg) mixture. An incision was made from the lower jaw to the top of the rib cage, where the salivary glands were separated to expose the surface of the trachea. The layer of smooth muscle on the trachea was removed, allowing a small incision to be made near the top of the trachea. A sheathed 21-Gauge needle was inserted to the lumen and 300–400 μl of PBS was lavaged repeatedly (four times). The total number cells in the BALF were stained with 0.4% trypan blue solution (Thermo Fisher Scientific, 0.2 mg/kg) or cholestanol conjugated-scrambled gp91ds-TAT (0.02 mg/kg) one day prior to infection with Hk-x31 and everyday thereafter for 3 days. In additional experiments, anaesthetized mice were treated with imiquimod (50 μg per mouse, i.n.) or catalase (1000 U per mouse, i.n.) and then euthanised for analysis at Day 1.
Fig. 8 Inhibition of NOX2 oxidase increases expression of Type I IFN and IL-1β, and antibody production to influenza A virus infection. 

a) Alveolar macrophages from WT and Nox2^{-/-} mice were either left untreated (naive) or infected with Hkx31 influenza A virus (MOI of 10) for analysis of IFN-β, IL-1β, TNF-α, and IL-6 mRNA expression by QPCR after 24 h (n = 8). b, c WT and Nox2^{-/-} mice were infected with live Hkx31 influenza A virus (1 x 10^{5} PFU per mouse) and b cytokine mRNA expression and IFN-β protein expression in c BALF or d serum were assessed 3 days later (n = 5). e-f WT and Nox2^{-/-} mice were infected with inactivated Hkx31 influenza A virus (equivalent to 1 x 10^{5} PFU per mouse) for measurements at day 7 of e body weight; f) airway inflammation and differential cell counts (i.e., macrophages, neutrophils, and lymphocytes); g) cytokine expression in whole lung (responses are shown as fold change relative to GAPDH) and h) serum and i) BALF antibody levels (n = 6). Data are shown as mean ± SE. a) Kruskal–Wallis test with Dunn’s post hoc for multiple comparisons. b-i Unpaired t-test; statistical significance taken when the P < 0.05. *P < 0.05. **P < 0.01
Cell culture and primary cell isolation. Human AMs were obtained from subjects undergoing a bronchoscopy at Monash Medical Centre, Monash University to investigate underlying lung disease with approval from the ethics committee of Southern Health/Monash Medical Centre. Written consent was obtained from all subjects. The bronchoscope was wedged in the right middle lobe and 25–50 ml of saline was washed into the airway then aspirated. Cells were washed twice with PBS before being suspended in culture medium (Roswell Park Memorial Institute (RPMI, Life Technologies, Cat # 21870-076) with 10% FCS with 100 U/ml penicillin and 100 μg/ml streptomycin) for ~24 h before use.

AMs were isolated by lung lavage from age-matched (6–12 weeks) male C57Bl/6 J (WT), NOX2−/−, NOX4−/− (provided by Dr Hitesh Peshavariya, Centre for Eye Research, The University of Melbourne, Australia), TLR7−/− (provided by Prof Phil Hansbro, School of Biomedical Sciences and Pharmacy, Faculty of Health and Medicine, The University of Newcastle, and Hunter Medical Research Institute, New South Wales, Australia), TLR9−/− (provided by Prof. Karlheinz Peter (Baker IDI Heart & Diabetes Institute, Melbourne, Victoria, Australia)) or SOD3−/− mice (provided by A/Prof Steven Bozinovski, School of Health and Biomedical Sciences, RMIT University). A thin shallow midline incision from the lower jaw to the top of
Endosomal ROS production. Human AMs; WT, TLR7+/−, TLR7−/−, TLR3+/−, TLR3−/−, TRIF−/−, MyD88−/−, RIG-1−/− and XBP1R3−/− BMDMs; mouse primary WT, NOX2−/−, NOX4−/−, TRAIL−/−, TRAIL+/− and SOD3−/− AMs and RAW264.7 cells were seeded (1 × 10^5 cells per well) onto glass coverslips in 24-well plates allowing the cells to adhere for 24 h in DMEM or RPMI medium before being preincubated with OxyBURST Green H2HFF (100 μM) and/or LysoTracker Deep Red (50 nM) for 5 min. This was followed by incubation with cells (control groups: 0.01 μM), immature (10 μg/ml), single stranded RNA (ssRNA; 100 μM), or infected with either H3N2 influenza viruses (A/New York/55/2004, A/Brisbane/9/2007), seasonal H1N1 influenza A viruses (A/Brazil/11/1978, A/New Caledonia/20/1999, A/Solomon Islands/3/2006), A(H1N1)pdm influenza A viruses (A/California/7/2009, A/Auckland/1/2009), or mDAV cells pretreated with DOD (300 μM), apocynin (300 μM), gp91dsT (50 μM) or bafilomycin A (100 nM), for 30 min prior to infection. Next, the cells were washed with PBS (0.01 M) and fixed with 4% paraformaldehyde (PFA) for 15 min. In some cases, cells were pretreated with SOD (300 μM), apocynin (300 μM), gp91dsT (50 μM) or bafilomycin A (100 nM), for 30 min prior to virus infection. After exposing samples with 10% goat serum-containing PBS for 2 h, the rabbit anti-p47phox antibody (1:1000) and the mouse anti-NOX2 antibody (1:500) were added followed by addition of appropriate secondary antibodies, and as specified above.

L-012-enhanced chemiluminescence. ROS production was quantified using L-012-enhanced chemiluminescence. RAW264.7 cells and primary mouse AMs were seeded onto a 96-well OptiView plate (5 × 10^4 cells per well). Raw264.7 cells were either treated with DMSO (control, appropriate concentration), unconjugated gp91dsT (100 μM–30 μM), cholesterol-conjugated gp91dsT (100 nM–30 μM) or ethyl-conjugated gp91dsT (100 nM–30 μM) for 1 h. BALF was collected from mice treated with DMSO (control), unconjugated gp91dsT (0.02 mg/kg), ethyl-conjugated gp91dsT (0.02 mg/kg, 0.2 mg/kg), cholesterol-conjugated gp91dsT (0.02 mg/kg, 0.2 mg/kg) and/or infected with Hx−x31 influenza A virus (1 × 10^5 PFUs). Cells were then washed with media with 37 °C Krebs-HEPES buffer, then exposed to a Krebs-HEPES buffer containing L-012 (10 μmol/l) in the absence (i.e., basal ROS production) or presence (stimulated ROS production) of the PKC and NADPH oxidase activator PDB (10 μM). This was followed by the addition of the appropriate controls, performed in the dark for 2 h. Finally, the cells were washed three times over 30 min with PBS (0.01 M) and fixed with 4% PFA for 15 min. Cells were then washed with PBS for 2 h and/or mouse on mouse IgG blocking reagent (Cat # MAB009, R&D Systems). This was followed by the addition of a primary antibody for nucleoprotein (1:1000) to localize influenza A virus, purified mouse anti-NOX2 (1:500) to localize NOX2, rabbit anti-TLR7 (1:1000) to localize TLR7, or mouse anti-early endosome antigen 1 (1:1000) to localize early endosomes (both from Abcam). This was followed by the addition of secondary antibodies for nucleoprotein (1:1000) to localize in the dark for 2 h. Finally, the cells were washed three times over 30 min with PBS (0.01 M) and fixed with 4% paraformaldehyde (PFA) for 15 min. In some cases, cells were pretreated with SOD (300 μM), apocynin (300 μM), gp91dsT (50 μM) or bafilomycin A (100 nM), for 30 min prior to virus infection. After exposing samples with 10% goat serum-containing PBS for 2 h, the rabbit anti-p47phox antibody (1:1000) and the mouse anti-NOX2 antibody (1:500) were added followed by addition of appropriate secondary antibodies, and as specified above.

NOX2 oxidasase assay. To measure NOX2 oxidasase activity we assessed p47phox and NOX2 assay using confocal fluorescence microscopy. Control and Hx31 virus-infected WT and TLR7+/− AMs were processed as indicated above under “confocal fluorescence microscopy”. In additional experiments, WT cells were treated with Dynasore (100 μM) or bafilomycin A (100 nM) for 30 min prior to virus infection. After exposing samples with 10% goat serum-containing PBS for 2 h, the rabbit anti-p47phox antibody (1:1000) and the mouse anti-NOX2 antibody (1:500) were added followed by addition of appropriate secondary antibodies, and as specified above.

Fig. 9 Endosome targeted delivery of a NOX2 oxidase inhibitor protects mice following influenza A virus infection in vivo. a-e Alveolar macrophages from WT mice were treated with the Cy5 cholesterol-PEG linker fluorophore (Cy5-chole; 100 nM) for 30 min and infected with Hx31 influenza A virus (MOI of 10). Cells were then counter labeled with antibodies to either: a and b EEA1, c NOX2 or d influenza A nucleoprotein (NP). All cells were then stained with 4′,6′-diamidino-2-phenylindole (DAPI) and imaged with confocal microscopy. b Cells were pretreated with Dynasore (100 μM) for 30 min prior to exposure to Cy5-cholesterol. e Quantification of data from a-d (n = 5). f RAW 264.7 macrophages were either untreated or treated with various concentrations of cholesterol-conjugated gp91dsT (Cgp91), ethyl conjugated gp91ds-TAT (Egp91) or unconjugated gp91ds-TAT (Ugp91) for 30 min prior to quantifying ROS production by L-012 (100 μM)-enhanced chemiluminescence (n = 7). g Superoxide production via the xanthine/xanthine oxidase cell-free assay in the absence or presence of Ugp91ds-TAT, (1 μM) or Cgp91ds-TAT (1 μM) (n = 6). h, i Ugp91ds-TAT (0.02 mg/kg/day) or Cgp91ds-TAT (0.02 mg/kg/day) and/or gp91ds-TAT (0.02 mg/kg/day) were delivered intranasally to WT mice once daily for 4 days. At 24 h after the first dose of inhibitor, mice were either treated with saline or infected with Hx31 influenza A virus (1 × 10^5 PFU per mouse). Mice were culled at day 3 post-infection and h airway inflammation was assessed by BALF cell counts and l lung IFN-β mRNA was determined by qPCR (n = 7). (NS) denotes not significant. j-m Mice were subjected to the NOX2 inhibitor treatment regime and virus infection protocol as in h except NOX2 inhibitors were delivered at a dose of 0.2 mg/kg/day (n = 7). Analysis of airway inflammation by BALF counts, k body weight (% weight change from the value measured at Day−1), l ROS production by BALF inflammatory cells with L-012 enhanced chemiluminescence and m viral mRNA by qPCR. Data are represented as mean ± S.E.M. e Unpaired t-test; statistical significance taken when the P < 0.05. f, g, h, j, k, l One-way ANOVA followed by Dunnett’s post hoc test for multiple comparisons. i and m Kruskal-Wallis test with Dunn’s post hoc test for multiple comparisons. Statistical significance was accepted when P < 0.05. *P < 0.05; **P < 0.01. Scale bars: 10 μm.
To test whether the unconjugated or cholesterol-conjugated gp91dsTat exhibited ROS scavenging properties, the xanthine oxidase cell free assay was used. Briefly, Krebs-HEPES buffer containing L-012 (100 μM) was added into a well of a 96-well Optiplate. Following this, 0.1% DMSO, unconjugated gp91dsTat (Ugp91ds-TAT, 1 μM) or cholesterol-conjugated gp91ds-TAT (1 μM) were added in combination with Xanthine (100 μM). Immediately after xanthine addition, a photon emission (relative light units (RLU)/s) was detected using the Chameleon luminometer (Hidex, model 425105, Finland) and recorded from each well for 1 s over 60 cycles. Individual data points for each group were derived from the average values of the three replicates minus the respective blank controls. Data are represented as raw values.

Site directed mutagenesis, sequencing and transfections. HA-TLR7 cDNA was purchased from Sino Biological (mouse TLR7; Cat # MG50962-NY with Gene Bank Ref Seq number NM_133211.3). Mutation of the key cysteine residues in TLR7 (Cys260, Cys263, Cys270, Cys273, Cys98, and Cys445) to alanine was performed using the QuikChange Multi Site-Directed Mutagenesis kit (Cat # 205651, Agilent Technologies). Sequences of WT and mutant HA-TLR7 were confirmed by the Australian Genome Research Facility. Cells were transfected using linear polyethyleneimine (PEI)24.

High-content ratiometric FRET imaging. Cells were plated and transfected in suspension with 200 ng well per well FRET biosensor DNA using PEI in black, optically clear 96-well plates for 48 hr. Prior to the experiment, cells were partially serum-starved overnight in 0.5% FBS media. Fluorescence imaging was performed using a Zeiss Axiovert 200M inverted microscope with a Nikon Eclipse Ti-E motorized Upright Microscope (for ELWD 40×(NA 0.6) objective and FRET module as described22. For CFP/YFP (CFAR) emission ratio analysis, cells were sequentially excited using a CFP filter (430/24) with emission measured using YFP (535/30) and CFP (470/24) filters, and a polychroic optimized for the CFP/YFP filter pair (Quad3). For GFP/RFP (EMKAR) emission analysis, cells were sequentially excited using a FITC filter (490/20) with emission measured using dRd (605/52) and FITC (525/36) filters, and a polychroic optimized for the FITC/dsRed filter pair (Quad4). Cells were imaged every 100 s for 20 min (image capture of two fields of view in 12 wells per 100 s). Data were analyzed using in-house scripts written for the FIJI distribution of ImageJ as described24.

Quantification of mRNA by QPCR. Cells were treated with imiquimod (10 μg/ml), poly I:C (100 ng/ml), CpG (10 μM) or catalase (1000 U/ml) for 24 h. Where indicated, cells were pre-treated with apocynin (300 μM) for 1 h. Following this, 0.1% DMSO, unconjugated gp91dsTAT (1 μg/ml) or catalase (1000 U/ml) was added into a 96-well Optiview plate. Following this, 0.1% DMSO, catalase (1000 U/ml) was added into a 96-well plate. RNA samples were measured using the Nanodrop 1000 Spectrophotometer. cDNA synthesis was performed using the High-Capacity cDNA RT kit to make a cDNA template for each sample. qPCR analyses were performed using the ABI StepOne Real Time PCR A (Applied Biosystems, Foster City, CA, USA) using 1.0 μl of 1:20 diluted cDNA samples and 0.25 μl of 1:20 diluted TaqMan primers and probes. PCR conditions for each gene are given in Table 2. This was followed by a melting curve analysis, to confirm the absence of primer-dimer and non-specific amplification products. Table 2, Applied Biosystems, Foster City, CA, USA. Additionlly, a custom designed oligonucleotide was used to visualize genomic DNA contamination in each sample. The PCR program run settings: 40 cycles of 94°C for 2 min, followed by 95°C for 1 min, then 95°C for 15 s + 60 s for 60 s plus plate read (40 cycles). Quantitative values were obtained from the threshold cycle (Ct) number. Target gene expression level was normalized against 18 s or GAPDH mRNA expression for each sample and data was expressed relative to the control.

ELISA and multiplex immunassay. Protein levels of INF-β (Bethyl Laboratories Inc, mouse INF-β ELISA kit; Cat # E12012-H1), IL-1β (Quantikine ELISA, R&D Systems, USA), IL-12 (Quantikine ELISA Mouse TNF α, Cat # MTA00B, R&D Systems), and IL-6 (Quantikine ELISA Mouse IL-6, Cat # M6006B, R&D Systems) were secreted into the BALF of HKx31-infected (1 x 10^6 PFU/s) WT and NOX2−/− mice using the ProcartaPlex Multiplex Immunassay (Mouse Isotyping 7plex, Cat # E4EX07-2815-901, eBioscience) according to the manufacturer’s instructions. Briefly, antibody-conjugated magnetic beads were added into each well of a 96-well plate. Antibody standards were serially diluted (1:4) in universal assay buffer to construct a 7-point standard curve. Serum and BALF samples (diluted 1:20,000 in universal assay buffer) and/or standards were allowed to appropriate wells of the 96-well plate containing the antibody-conjugated magnetic beads. Following this, a detection antibody mix was added to each well and the plate was incubated for 30 min at room temperature on a microplate shaker (500 rpm) in the dark. After washing, a reading buffer was added to all wells. The plate was read by a Magpix multiplex reader (Luminex, USA) with xPONENT software (Luminex, USA). ProcartaPlex Analyst 1.0 software (eBioscience, USA) was used to interpolate serum and BALF antibody concentrations in each sample from the standard curve.

Statistical analysis and image analysis. In order to quantify the fluorescence microscopy data, images acquired from confocal systems were analyzed in Image J. Approximately 100–150 cells per treatment group from at least three independent experiments were examined to establish the figure legend to calculate the fluorescence in each cell, which was then averaged and expressed as a percentage of the area fluorescence. All statistical tests were performed using GraphPad Prism (GraphPad Software Version 6.0, San Diego CA, USA). P < 0.05 was taken to indicate significance. For isolated cell culture work, n is representative of a separate experiment where cells were used from a different passage.

Chemicals. Imiquimod (Cat # tlrl-imq, Invivogen), HMW poly IC (Cat # tlrl-pic, Invivogen), and CpG ODN (Cat # tlrl-1668, Invivogen) were dissolved in endotoxin-free water and prepared as stock solutions of 5–10 mg/ml in aliquots of 30 and 100 μl and stored at −20 °C. Serum (Cat # tlrl-Imm40, Invivogen) was dissolved in endotoxin-free water and prepared as a stock solution of 5 mM in aliquots of 50 μl and stored at −20 °C. Dynasore (Cat # D7693, Sigma) (freshly prepared on the day) was dissolved in DMSO (100%) and prepared as 10 mM stock solutions. FBS (Cat # 12003 C, Sigma) was stored in 50 ml aliquots at −20 °C. For preparation of cytokonyt solutions, 1:20,000 in universal assay buffer to construct a 7-point standard curve. Serum and BALF samples (diluted 1:20,000 in universal assay buffer) and/or standards were appropriate wells of the 96-well plate containing the antibody-conjugated magnetic beads. Following this, a detection antibody mix was added to each well and the plate was incubated for 30 min at room temperature on a microplate shaker (500 rpm) in the dark. After washing, a reading buffer was added to all wells. The plate was read by a Magpix multiplex reader (Luminex, USA) with xPONENT software (Luminex, USA). ProcartaPlex Analyst 1.0 software (eBioscience, USA) was used to interpolate serum and BALF antibody concentrations in each sample from the standard curve.

Data availability. The data that support the findings of this study are available from the corresponding author upon request.
