Light Meson Spectra and Instanton Induced Forces

F. Brau and C. Semay

Groupe de Physique Nucléaire Théorique, Université de Mons-Hainaut, B-7000 Mons, Belgium

(Dated: March 26, 2022)

The spinless Salpeter equation supplemented by an instanton induced force is used to describe the spectra of light mesons, including the pseudoscalar ones. The coupling constants of the instanton induced potential, as well as the quark constituent masses are not treated as simple free parameters but are calculated from the underlying instanton theory. Quite good results are obtained provided the quark are considered as effective degrees of freedom with a finite size. A further test of the model is performed by calculating the electromagnetic mass differences between S-wave mesons.

I. INTRODUCTION

Numerous papers has been devoted to the study of meson spectra in the framework of the potential model. In most of these works, it is assumed that the quark interaction is dominated by a linear confinement potential, and that a supplementary short-range potential stems from the one-gluon exchange mechanism (see for instance Refs. [1, 2]).

The results obtained with these models are generally in good agreement with the experiments but the mesons $\eta$ and $\eta'$ cannot be described without adding an appropriate flavor mixing procedure with supplementary parameters.

On the other hand, Blask et al. [3] have developed a non-relativistic quark model which describes quite well all mesons (including $\eta$ and $\eta'$) and baryons composed of $u, d$ or $s$ quarks. The long-range part of their interaction is the usual linear confinement potential, but their short-range part is a pairing force stemming from instanton effects.

This force presents the peculiarities to act only on quark-antiquark states with zero spin and zero angular momentum, and to generate constituent masses for the light quarks. The main problem of this model, and more generally of all non-relativistic models, is that the velocity of a light quark inside a meson is not small compared with the speed of light. This makes the interpretation of the parameters of such models questionable [2, p. 164].

At present, several works have been devoted to the study of mesons with the instanton induced forces in the framework of relativistic or semi-relativistic models [4, 5, 6], but in all the cases constituent masses and coupling constants of the instanton induced forces have been considered has free parameters fitted to reproduce at best meson spectra. Actually, these quantities can be calculated from instanton theory. In this work, our purpose is to develop a semi-relativistic model for meson spectra including the instanton induced forces, but with parameters calculated, as far as possible, with the underlying theory. We will show that such a procedure is possible and gives very good results provided the quarks are considered as effective degrees of freedom with a finite size.

Our paper is organized as follows. In Sec. II the model is constructed and the various parameters are presented, including the quark size parameters. The numerical techniques and the fitting procedure for the parameters are described in Sec. III, where the results are analyzed and a further test of the model is achieved with the calculation of the electromagnetic mass differences. Concluding remarks are given in Sec. IV.

II. MODEL

A. Spinless Salpeter equation

Our models rely on the spinless Salpeter equation. This equation is not a covariant one, but it takes into account the relativistic kinematics. It can be deduced from the Bethe-Salpeter equation by neglecting the retardation effects, the mixing with negative energy states and the spinor structure of the eigenstates. The spinless Salpeter equation has been often used to describe meson spectra (see for instance Refs. [1, 2, 3]). This equation has the following form

$$H = \sqrt{\vec{p}^2 + m_1^2} + \sqrt{\vec{p}^2 + m_2^2} + V(\vec{r}),$$

where $V$ is the potential between the particles and where $\vec{p}$ is their relative momentum. The vector $\vec{p}$ is the conjugate variable of the inter-distance $\vec{r}$.

As usual, we assume that the isospin symmetry is not broken, that is to say that the $u$ and $d$ quarks have the same mass. In the following, these two quarks will be named by the symbol $n$ (for normal or non-strange quark).
B. Funnel potential

It is now well accepted that the long range part of the interquark interaction is dominated by the confinement. The best way to simulate this phenomenon in a semi-relativistic equation is to use a potential increasing linearly with the distance. With such an interaction, the Regge trajectories of light mesons are well reproduced \[2, \text{p. 137}\]. Moreover, lattice calculations also find that the confinement is roughly proportional to \( r = |\vec{r}| \). The short range part is very often a Coulomb-like interaction stemming from the one-gluon exchange process. The idea is that, once the confinement is taken into account, other contributions to the potential energy can be treated as residual interactions. It is worth noting that the contribution of a constant potential is always necessary to obtain good spectra. Finally, the central potential considered in our models is the so-called funnel potential \[2\]

\[
V(r) = -\frac{n}{r} + a r + C. \tag{2}
\]

Despite its simple form, this potential was the first one which is able to reproduce the charmonium spectrum quite well \[2\]. Moreover, it gives very good results even in the light meson sector (see for instance Ref. \[7\]).

Experiment shows that vibrational and orbital excitations give much more contributions to the meson masses than variations of spin \( S \) or total angular momentum \( J \) in a multiplet. In this case, a spinless Salpeter equation, only supplemented by the funnel potential, can yield very satisfactory results. Nevertheless, the situation is completely different for the \( L = 0 \) mesons for which the mass differences between \( S = 0 \) and \( S = 1 \) states is extremely large. For these mesons, another interaction must be taken into account in the model.

C. Instanton interaction

The instanton induced interaction provides a suitable formalism to reproduce well the pseudoscalar spectrum. Indeed it is possible to explain the masses of the pion and the kaon and to describe states with flavor mixing as \( \eta \) and \( \eta' \)-mesons. The form of the interaction depends on the quantum numbers of the state \[3\].

- For \( L \neq 0 \) or \( S \neq 0 \):

\[ V_{\text{inst}} = 0; \tag{3} \]

- For \( L = S = 0 \) and \( I = 1 \):

\[ V_{\text{inst}} = -8 g \delta(\vec{r}); \tag{4} \]

- For \( L = S = 0 \) and \( I = 1/2 \):

\[ V_{\text{inst}} = -8 g' \delta(\vec{r}); \tag{5} \]

- For \( L = S = 0 \) and \( I = 0 \):

\[ V_{\text{inst}} = 8 \left( \frac{g}{\sqrt{2} g'}, \frac{\sqrt{2} g'}{0} \right) \delta(\vec{r}), \tag{6} \]

in the flavor space \((1/\sqrt{2}(|u\bar{u}| + |d\bar{d}|), |s\bar{s}|)\). The parameters \( g \) and \( g' \) are two dimensioned coupling constants \[4\] defined as

\[
g = \frac{3}{8} g_{\text{eff}}(s), \tag{7}
\]

\[
g' = \frac{3}{8} g_{\text{eff}}(n), \tag{8}
\]

\[
g_{\text{eff}}(i) = \left( \frac{4}{3} \pi^2 \right)^2 \int_0^{\rho_0} d\rho \, d_0(\rho) \, \rho^2 \, (m_i^0 - \rho^2 c_i), \tag{9}
\]

where \( m_i^0 \) is the current mass of the flavor \( i \) and \( c_i = (2/3)\pi^2 \langle \bar{q}_i q_i \rangle, \langle \bar{q}_i q_i \rangle \) being the quark condensate for this flavor. The function \( d_0(\rho) \) is the instanton density as a function of the instanton size \( \rho \). For three colors and three flavors this quantity is given by \[4\],

\[
d_0(\rho) = 3.63 \times 10^{-3} \left( \frac{8\pi^2}{g^2(\rho)} \right)^6 \exp \left( -\frac{8\pi^2}{g^2(\rho)} \right) \tag{10}
\]
where
\[
\left( \frac{8\pi^2}{g^2(\rho)} \right) = 9 \ln \left( \frac{1}{\Lambda\rho} \right) + \frac{32}{9} \ln \left( \ln \left( \frac{1}{\Lambda\rho} \right) \right),
\]
within two-loop accuracy \[4\]. The quantity \( \Lambda \) is the QCD scale parameter and \( \rho_c \) is the maximum size of the instanton. This is a cutoff value for which the \( \ln\ln \)-term in Eq. (11) is still reasonably small compared with the \( \ln \)-term.

An interesting property of the instanton induced interaction is the renormalization of quark masses, as it gives contributions to the constituent masses. The expression of these contributions are given by \[4\]
\[
\Delta m_n = \frac{4}{3} \pi^2 \int_0^{\rho_c} d\rho \, d_0(\rho) (m_n^0 - \rho^2 c_n) (m_n^0 - \rho^2 c_s),
\]
and
\[
\Delta m_s = \frac{4}{3} \pi^2 \int_0^{\rho_c} d\rho \, d_0(\rho) (m_n^0 - \rho^2 c_s)^2.
\]
The instanton interaction is not necessarily the only source for the constituent masses \[3\]. Actually we introduce two supplementary terms \( \delta_n \) and \( \delta_s \) which can be added to the running masses. These terms are free parameters and are not dependent on the instanton parameters. Results with vanishing and non-vanishing \( \delta_n \) and/or \( \delta_s \) are given in Table \[11\]. Finally the constituent masses in our models are given by
\[
\begin{align*}
m_n &= m_n^0 + \Delta m_n + \delta_n \\
m_s &= m_s^0 + \Delta m_s + \delta_s
\end{align*}
\]
and defining another dimensionless quantity
\[
x = \Lambda\rho,
\]
where \( x = \Lambda\rho_c \). So we obtain
\[
\begin{align*}
g &= \frac{\delta \pi^2}{2} \frac{1}{\Lambda^3} \left[ m_n^0 \alpha_{11}(x_c) - \frac{c_s}{\Lambda^2} \alpha_{13}(x_c) \right], \\
g' &= \frac{\delta \pi^2}{2} \frac{1}{\Lambda^3} \left[ m_n^0 \alpha_{11}(x_c) - \frac{c_n}{\Lambda^2} \alpha_{13}(x_c) \right], \\
\Delta m_n &= \delta \frac{1}{\Lambda} \left[ m_n m_n^0 \alpha_9(x_c) - \frac{(c_n m_n^0 + c_s m_s^0)}{\Lambda^2} \alpha_{11}(x_c) + \frac{c_n c_s}{\Lambda^4} \alpha_{13}(x_c) \right], \\
\Delta m_s &= \delta \frac{1}{\Lambda} \left[ (m_n^0)^2 \alpha_9(x_c) - 2 \frac{c_n m_n^0}{\Lambda^2} \alpha_{11}(x_c) + \frac{(c_n)^2}{\Lambda^4} \alpha_{13}(x_c) \right],
\end{align*}
\]
with \( \delta = 3.63 \times 10^{-3} \times 4\pi^2/3 \). Except the quantity \( x_c \), all parameters involved in Eqs. \[15\] - \[24\] have expected values from theoretical and/or experimental considerations. The integration in Eq. \[17\] must be carried out until the ratio of the \( \ln\)-term on the \( \ln\ln\)-term in Eq. \[11\] stays small. This ratio, called \( R \) here, increases with \( x \) from zero at \( x = x_1 = 1/e \) to very large values (see Fig. \[1\]). At \( x = x_2 \approx 0.683105 \), the value of this ration is 1. This last value corresponds to the minimum of the instanton density (see Fig. \[1\]). Thus we define the parameter \( \epsilon \) by
\[
x_c = x_1 + \epsilon (x_2 - x_1) \quad \text{with} \quad \epsilon \in [0, 1].
\]
In this work \( \epsilon \) is a pure phenomenological parameter whose value must be contained between 0 and 1. To save calculation times, we have calculated some values of \( \alpha_9(x_c) \) functions for some given values of \( \epsilon \), and we use a spline algorithm to find others values. A good accuracy can be obtained since these functions and their derivatives are known. We have verified that the spline procedure allows an accuracy better than \( 10^{-3} \) on values of quark masses and instanton coupling constants. So, no numerical integration is necessary. The functions \( \alpha_9(x), \alpha_{11}(x) \) and \( \alpha_{13}(x) \) between \( x_1 \) and \( x_2 \) are given in Fig. \[2\].
D. Effective quarks

The quark masses used in our model are the constituent masses and not the current ones. It is then natural to suppose that a quark is not a pure point-like particle, but an effective degree of freedom which is dressed by the gluon and quark-antiquark pair cloud. As a correct description of this effect is far from being obvious, we use a phenomenological Ansätze, as it is the case in many other works (see for instance Refs. [1, 6]). It seems natural to consider that the probability density of a quark in the configuration space is a peaked function around its average position. The form that we retain is a Gaussian function

\[ \rho_i(\vec{r}) = \frac{1}{(\gamma_i \sqrt{\pi})^{3/2}} \exp\left(-r^2/\gamma_i^2\right). \]  

(23)

It is generally assumed that the quark size \( \gamma_i \) depends on the flavor. So, we consider two size parameters \( \gamma_n \) and \( \gamma_s \) for quarks \( n \) and \( s \) respectively. Any operator which depends on the quark positions \( \vec{r}_i \) and \( \vec{r}_j \) must be replaced by an effective one which is obtained by a double convolution of the original bare operator with the density functions \( \rho_i \) and \( \rho_j \). As a double convolution is a heavy procedure which generates very complicated form for the convoluted potentials, we assume that the dressed expression \( \tilde{O}_{ij}(\vec{r}) \) of a bare operator \( O_{ij}(\vec{r}) \), which depends only on the relative distance \( \vec{r} = \vec{r}_i - \vec{r}_j \) between the quarks \( q_i \) and \( q_j \), is given by

\[ \tilde{O}_{ij}(\vec{r}) = \int d\vec{r}' O_{ij}(\vec{r}') \rho_{ij}(\vec{r} - \vec{r}'), \]  

(24)

where \( \rho_{ij} \) is also a Gaussian function of type (23) with the size parameter \( \gamma_{ij} \) given by

\[ \gamma_{ij} = \sqrt{\gamma_i^2 + \gamma_j^2}. \]  

(25)

This formula is chosen because the convolution of two Gaussian functions, with size parameters \( \gamma_i \) and \( \gamma_j \) respectively, is also a Gaussian function with a size parameter given by Eq. (25).

After convolution with the quark density, the funnel dressed potential has the following form

\[ \tilde{V}(r) = -\kappa \frac{\text{erf}(r/\gamma_{ij})}{r} + ar \left[ \frac{\gamma_{ij} \exp(-r^2/\gamma_{ij}^2)}{\sqrt{\pi} r} + \left(1 + \frac{\gamma_{ij}^2}{2r^2}\right) \text{erf}(r/\gamma_{ij})\right] + C, \]  

(26)

while the Dirac-distribution is transformed into a Gaussian function

\[ \tilde{\delta}(\vec{r}) = \frac{1}{(\gamma_{ij} \sqrt{\pi})^{3/2}} \exp(-r^2/\gamma_{ij}^2). \]  

(27)

Despite this convolution, we will consider, for simplicity, that the instanton induced forces act only on \( L = 0 \) states.

The modification of the confinement potential seems very important but, actually, only its short range part is modified. It has little effect for a potential whose essential role is to govern the long range dynamics. It has been verified [4] that the convolution of the linear potential could be neglected without changing sensibly the results, but we have nevertheless used the form (26) to be consistent.

The Coulomb part of the interaction is transformed into a potential with a finite value at origin. This can be seen as a mean to simulate asymptotic freedom. It has also been noticed that the use of an error function remove the singularity of the spin-spin interaction, when this correction is taken into account [2, p. 162].

The introduction of a quark size is only necessary, from a mathematical point of view, to avoid collapse of the eigenvalues due to the presence of a Dirac-distribution in the instanton induced interaction. The definition of the size parameter \( \gamma_{ij} \) is not obvious in the case of the non-diagonal term of the instanton induced interaction [8]. This matrix element mixes \( |\bar{n}\bar{n}\rangle \) and \( |s\bar{s}\rangle \) flavor states. So, what definition choose for \( \gamma_{ij} \), that we will note \( \gamma_{mf} \) in this case? A first possibility is to take

\[ \gamma_{mf} = \sqrt{\gamma_n^2 + \gamma_s^2}, \]  

(28)

as in the case of \( |\bar{n}\bar{n}\rangle \) mesons. But we can also choose

\[ \gamma_{mf} = \sqrt{2\gamma_n\gamma_s}, \]  

(29)

for instance. Other choices are possible, but we only take into account these two definitions in the following.
III. NUMERICAL RESULTS

A. Numerical techniques

The eigenvalues and the eigenvectors of our Hamiltonian are obtained in expanding trial states in a harmonic oscillator basis \(|nlm\). In such a basis, matrix elements of the potential are given by

\[
\langle n'l'm'|V(r)|nlm\rangle = \sum_{p=l}^{l+n'\pm n} B(n', l, n, l, p) I_p,
\]

with

\[
I_p = \frac{2}{\Gamma(p+3/2)} \int_0^\infty dx x^{2p+2} \exp(-x^2)V(bx).
\]

The quantities \(I_p\) are the Talmi integrals, while the coefficients \(B(n', l, n, l, p)\) are geometric factors \[^8\] which can be calculated once for all. The parameter \(b\) is the oscillator length which fixes the scale of the basis states. With this parameter a dimensionless length \(x = b/r\) can be defined. In our model all the Talmi integrals for the potential part of the Hamiltonian are given by analytical expressions \[^6\]. The matrix elements of the kinetics part can be calculated with numerical integrations, but we prefer to use another technique, much accurate and less time consuming. This method is described in Ref. \[^7\]. We just give here the main hits of the procedure. We calculate the matrix elements of the operator \(\vec{p}^2 + m^2\) in the oscillator basis (this is an analytical calculation). Let us assume that \(P\) is the corresponding matrix, \(D\) the diagonal matrix of the eigenvalues of \(P\), and \(U\) the transformation matrix \((D = U^{-1}PU)\). Then the matrix elements of the operator \(\sqrt{\vec{p}^2 + m^2}\), are contained in the matrix \(UD^{1/2}U^{-1}\). This procedure is about six times faster than a numerical integration and gives a better accuracy. The utilisation of this procedure and the analiticity of the Talmi integrals lead to very short time of calculation. A minimization with thirteen parameters lasts about 10–20 minutes on a Pentium 200 workstation.

At last, it is worth noting that all the results obtained with the technique described above have been verified with the three-dimensional Fourier grid Hamiltonian method \[^9\].

B. Fitting procedure

The purpose of this work is to try to reproduce the spectrum of light mesons with a quite simple model. Indeed we use only a central potential supplemented by an instanton induced interaction to describe the pseudoscalar sector. We need thirteen parameters to obtain a satisfactory theoretical spectrum. The instanton interaction is defined by six parameters: The current quark masses, the quark condensates for the flavors \(n\) and \(s\), the QCD scale parameter \(\Lambda\), and the maximum size \(\rho_c\) of the instanton. Three parameters are used for the spin-independent part of the potential: The slope of the confinement \(a\), the strength \(\kappa\) for the Coulomb-like part, and the constant \(C\) which renormalize the energy. Four supplementary parameters are introduced: The effective size of the quarks \(n\) and \(s\), and two terms \(\delta_n\) and \(\delta_s\), which contribute to the constituent quarks masses.

In our model, the quantum numbers \(L, S\) and \(I\) are good quantum numbers. For \(L = 0\) states, the instanton induced interaction raises the degeneracy between \(S = 0\) (pseudoscalar) and \(S = 1\) (vector) mesons, but \(S = 1\) \(n\bar{n}\)-mesons, which differ only by isospin, have the same mass. This is in quite good agreement with the data. In the sector \(L \neq 0\), instanton induced interaction vanishes and the potential is spin independent. Consequently, states which differ only by \(S, J\) and \(I\) are degenerate. In first approximation, this corresponds also quite well to the experimental situation.

To find the value of the parameters, we minimize a \(\chi^2\) function based on the masses of 18 centers of gravity (c.o.g.) of multiplets containing well-known mesons (see Table 1):

\[
\chi^2 = \sum_i \left[ \frac{M_i^{\text{th}} - M_i^{\text{exp}}}{\Delta M_i^{\text{exp}}} \right]^2,
\]

where the quantity \(\Delta M_i^{\text{exp}}\) is the error on the experimental masses (it is fixed at the minimum value of 10 MeV). The quantum number \(v\) (vibrational or radial quantum number), \(L\), and \(S\) of these mesons are determined on an assignment made in the Particle Data Group tables \[^10\]. It is worth noting that all members of several multiplets considered here are not known. So we calculate the center of gravity with only the known mesons; no attempt is made
to estimate the masses of the missing states. The usual procedure to define a center of gravity is

\[
M_{\text{c.o.g.}} = \frac{\sum_{I,J}(2J+1)(2J+1) M_{J,I}}{\sum_{I,J}(2J+1)(2J+1)}.
\] (33)

In the following, a center of gravity will be indicated by the name of the state of the multiplet with the higher quantum numbers \( J \) and \( I \). At last, note that we do not include the mesons \( a_0(980) \) and \( f_0(980) \) in the \( L = 1 \) multiplet since experimental considerations and some theoretical works \[10\] p. 99, 557 suggest that they are not \( q\bar{q} \)-mesons.

To perform the minimization, we use the most recent version of the MINUIT code from the CERN library \[11\].

### C. Meson spectra

A great number of parameter sets have been found for our model Hamiltonian. We present here only five among the most interesting ones, denoted from I to V. Parameters for these models are presented in Table II. All these models have common features. For instance, it is always possible to obtain a quite good fit with a low current quark mass \( m_0^q \), in agreement with the bounds expected \[10\]. The strange quark mass \( m_s^0 \) varies more significantly following the model, but its value is always reasonable \[10\]. The QCD scale parameter \( \Lambda \) is a very sensible parameter of our model since a small change can largely modify the quantities deduced from the instanton theory (see Eq. (15) to (21)). Nevertheless, the values found are always in agreement with usual estimations \[10\]. Values for the quark condensates are also reasonable \[12\]. There is no direct measurement of the string tension parameter \( a \), but lattice calculations favor the value 0.20 GeV\(^2\) with about 30\% error \[13\]. Our values are in good agreement with this prediction.

The strength \( \kappa \) of the Coulomb-like potential can strongly vary from one model to another (see for instance Ref. \[2\]). The values found in this paper are always less than 0.5, which can be considered as an upper limit for relevant values. In model V, we have fixed \( \kappa = 0 \) as in the model of Ref. \[3\]. But the \( \chi^2 \) obtained is not good; this is essentially due to radial excitations: \( \rho(1450) \), \( \pi(1300) \) and \( \phi(1680) \). We conclude that the Coulomb-like potential must be taken into account and that instanton induced forces cannot explain alone the short range part of the potential. Actually, this remark is already mentioned in the Ref. \[3\]. As we can see from Table II the constant potential is always necessary to obtain good spectra. Its origin is not simple to explain. It can be considered as a mechanism linked to the flux-tube model of mesons \[3\]. It has also been suggested that \( C \approx -2\sqrt{\alpha} \) \[2\] p. 190. Our models are not in very good agreement with this last prediction, as we can note deviation as large as 40\%. But we do not consider that it is as an important drawback of the models.

There is no real estimation of the quark sizes. They are purely phenomenological parameters whose role is to take into account relativistic effects \[1\] as well as sea-quark contributions. In all our models the size of the \( n \)-quarks \( \gamma_n \) is nearly a constant, around 0.7–0.8 GeV\(^{-1}\). The \( n \)-quark size drops down to 0.6 GeV\(^{-1}\) in model V without the Coulomb-like potential. This shows the strong influence of this interaction in determining \( \gamma_n \). It is worth noting that the introduction of quark sizes modifies deeply the structure of the potential. This is illustrated on the Fig. 8 where the dressed and non-dressed potential for the \( \rho \)-meson are presented. The \( s \)-quark size depends on the \( \text{Ansätze} \) chosen to calculate \( \gamma_{mf} \). When \( \gamma_{mf} = \frac{\sqrt{\gamma_n^0} + \gamma_s}{2} \), \( \gamma_s \) can take vanishing values without generating collapse of the eigenenergies. This is no longer true if \( \gamma_{mf} = \sqrt{2\gamma_n\gamma_s} \). The first definition of \( \gamma_{mf} \) is chosen in model II and we can remark that in this case the value of \( \gamma_s \) is significantly smaller than in other models, where the second definition is used.

Table II shows that the contributions of parameters \( \delta_0 \) and \( \delta_s \) can be quite large when they are not fixed in the minimization. The origin of these terms is not clear but their values indicate that the instanton effects cannot generate solely the constituent masses in our model Hamiltonian. We have found sets of parameters which give reasonable \( \chi^2 \) values but, in this case, the constituent quark masses can be very small. Model III has actually the lowest \( \chi^2 \) value that we have found but the constituent quark masses are so small that a generalization of this model to baryon spectra appears very problematic \[12\].

In all sets of parameters that we have determined, the value of \( \epsilon \) is always close to zero. This is consistent with the fact that the cutoff radius for the integration over instanton density must be small enough in order that the lnln-term in Eq. (11) must be reasonably small compared with the ln-term. Actually, we can fix arbitrarily \( \epsilon = 0 \) without spoiling the results, while values close to unity yield bad results.

In Figs. 4 to 6 we present the meson spectra of model I. We consider this model as the best we have obtained. Model III is characterized by a lowest \( \chi^2 \) value but, as mentioned above, the corresponding constituent quark masses are too small to hope to obtain good baryon spectra. The \( \chi^2 \) value of model II is also good but the strange quark size seems very small with respect to usual estimations found in the literature. In order to decide between models I and II, we have tested these two potentials in the heavy meson sector. By fitting the masses and the sizes of the quarks \( c \) and \( b \) on 10 c.o.g. of \( cc, bb, s\bar{n}, c\bar{s} \) and \( bn \) mesons, we have recalculated a \( \chi^2 \) value for the all 28 c.o.g. considered in
this paper (18 for light mesons and 10 for heavy mesons). The results are indicated in Table III. Clearly, model I is preferable. The bad value obtained for model II is due to an interplay between the small strange quark size and the low Coulomb strength.

The partial $\chi^2$ for each meson (actually, each c.o.g. of a meson multiplet) of model I is below 1.6, except for the $\pi(1300)$-, $\rho(1450)$- and $a_0(2040)$-mesons. In Fig. 4 we can see that the $n\bar{n}$ mesons are quite well reproduced. The larger error is obtained for the $\pi(1300)$, but the uncertainty on this meson is very large. We can remark slight deviation from the linear Regge behavior, but it can be very well reproduced within semi-relativistic kinematics when only a linear potential is used.

In the $\bar{s}n$ sector, vibrational excitations of the $L = 0$ mesons are not satisfactorily reproduced (these states are not taken into account in the minimization procedure). From the experimental point of view, the situation is not clear [10]. For instance, internal quantum numbers of $K^+(1410)$ and of $K^+(1680)$ are not well defined yet. This problem was also revealed in some previous works [2, 16]. But all the ground states are quite well reproduced.

The $s\bar{s}$ sector is poor in experimental data but all the states obtained in our model are in quite good agreement with these data. In the mixed flavor mesons, we reproduce the $\eta$ and $\eta'$ states. The two vibrational excitations of these mesons can be identified quite well with the $\eta(1295)$ and the $\eta(1760)$. Note that a calculated state lies between the $\eta(1295)$ and $\eta(1440)$, which is a non-$q\bar{q}$ meson candidate [10]. At last, we find a supplementary state between the $\eta(1760)$ and the $\eta(2225)$, the last one being a not-well established state.

D. Electromagnetic corrections

The electromagnetic mass differences between mesons are usually ignored in studies of meson spectra. The reason is that these mass differences are very small, of the order of some MeV, compared with the orbital and vibrational excitations due to the strong interaction, which can amount about one GeV. Nevertheless, it is interesting to calculate the electromagnetic splittings as they provide further tests on the model. In particular, the mass differences are very sensitive to the short range part of the wave functions.

The electromagnetic mass differences between mesons are due to two distinct effects. A first contribution is provided by the mass difference between the $u$ and $d$ quarks. In our models we have assumed that these two quarks have the same mass, but it is no longer relevant to calculate electromagnetic phenomena. In the following, we will assume that $m_n = (\bar{m}_d + \bar{m}_u)/2$, where $\bar{m}_i$ is the real constituent quark mass. We define $\epsilon_d = \bar{m}_d - m_n$ and $\epsilon_u = \bar{m}_u - m_n$. For the strange quark, we have $\bar{m}_s = m_s$ and $\epsilon_s = 0$. The second contribution is due to the electromagnetic potential existing between quarks. In first order approximation, this interaction has the following form

$$V_{em}(r) = \alpha \frac{Q_i Q_j}{r}, \quad (34)$$

where $\alpha$ is the electromagnetic fine-structure constant, and $Q_i$ is the quark charge for the flavor $i$ in unit of $e$. This approximation is too crude since the first relativistic corrections of $V_{em}$ and $V_{em}$ have similar contributions to the electromagnetic mass differences [2]. We will consider only S-wave mesons, that is to say that the spin-spin interaction is the only non-vanishing correction. As we work in the framework of semi-relativistic models, we will use a relativized version of the spin-spin potential. A method to obtain such a potential is suggested in Ref. [2] p. 198 and has been used in Ref. [3]. The idea is to replace the factors $1/m_i$ by the operators $1/\sqrt{\vec{p}^2 + m_i^2}$ in the interaction expression.

The contribution of the electromagnetic Hamiltonian $H_{em}$ can be calculated within the first order in perturbation theory [15]. Assuming that this Hamiltonian is the difference between the total Hamiltonian (strong plus electromagnetic) and the Hamiltonian used in our models, the electromagnetic contribution is in first order approximation

$$\langle H_{em} \rangle = m_i \epsilon_i \left\langle \frac{1}{\sqrt{\vec{p}^2 + m_i^2}} \right\rangle + m_j \epsilon_j \left\langle \frac{1}{\sqrt{\vec{p}^2 + m_j^2}} \right\rangle + \alpha \left\langle \frac{Q_i Q_j}{r} \right\rangle - \alpha \frac{8\pi}{3} \left\langle Q_i Q_j \vec{S}_i \cdot \vec{S}_j \left[ \frac{1}{\sqrt{\vec{p}^2 + m_i^2}} \delta(\vec{r}) \right] \frac{1}{\sqrt{\vec{p}^2 + m_j^2}} \right\rangle, \quad (35)$$

where the symbol $\langle O \rangle$ is used to indicate the symmetrization of the operator $O$. The expression (35) reduces to the usual non-relativistic form when quark masses tend toward infinity [2] p. 169). Mean values of operators can be evaluated as well by using the harmonic oscillator development of the wave functions as well directly in configuration space. The isospin breaking between the $u$ and $d$ quarks is a free parameter in our models, so this quantity has been fitted to reproduce the $K^+ - K^0$ mass difference. The results for model I are shown in Table III. Other models give
similar results since in all cases the pseudoscalar states are well described. In magnitude, all results are around two
times the experimental data, but the hierarchy of mass differences is preserved. In particular the quantity $m_d - m_u$
has the good sign. This is not always obvious to obtain in potential models. It is worth noting that our models
are optimized to reproduce meson mass spectra with an accuracy of around 10 MeV, and not to obtain the best
possible wave function. So, we consider that the results found are quite well satisfactory.

We also tried to calculate the electromagnetic mass differences with the non-relativistic equivalent of Eq. (35), but
the results obtained are very bad. For instance, isospin breaking between $d$ and $u$ quark can be found as large as
50 MeV. We have found that the non-relativistic form of the electromagnetic spin-spin interaction is responsible of
so poor results. This indicates that relativized forms of operators are important to obtain coherent results in semi-
relativistic models. Since the Coulomb-like strong interaction is of pure vector type, a strong spin-spin interaction
must be introduced if one wants to take into account the relativistic corrections of the strong potential. We can guess
that the use of a relativized form will be highly preferable than the usual non-relativistic form.

IV. CONCLUDING REMARKS

It is well known that the spinless Salpeter equation supplemented by the so-called funnel potential can describe
quite well the main features of the meson spectra. The mass differences between members of a $L$-multiplet are
generally small with respect to vibrational and radial excitations. Except in the pseudoscalar meson sector, the
spinless approximation is then generally good. The instanton induced forces provide a satisfactory way to describe
the structure of light $S$-wave mesons, including the annihilation phenomenon.

Several works are devoted to the study of meson spectra within relativistic or semi-relativistic models using instanton
effects. In these works, the instanton parameters are simply considered as free parameters to be fitted on data. In our paper, we try to calculate these parameters from the underlying theory. Our model relies on the
spinless Salpeter equation supplemented by the usual funnel potential and an instanton induced force. Thirteen
parameters are necessary to completely fix the Hamiltonian. This number could appear large, but six parameters
are strongly constrained by experimental or theoretical considerations, namely, the current quark masses, the QCD
scale parameter, the quark condensates and the string tension. The Coulomb strength and the constant potential are
unavoidable parameters of potential models. Actually, the Coulomb-like potential could be replaced by an interaction
taking into account the asymptotic freedom, but it is a complication especially necessary when describing heavy meson
spectra.

The relevance of the remaining five parameters is most questionable. If quarks are considered as effective degrees
degree of freedom, then a size as well as a constituent mass can be associated with a quark. Generally, the quark size is
described with a two parameter function of the constituent mass. As we consider only two different flavors, it is useless
to introduce such a quark size parameterization. Up to our knowledge, there is no reliable estimation of the quark
size, but our values are in good agreement with values found in other works. The radial part of the instanton
induced potential is a Dirac-distribution, so it is necessary to replace this form by a short range potential peaked at
origin. The introduction of quark sizes offers a natural way to realize that, without introducing a new free parameter
which is the instanton range.

The two dimensioned coupling constants of the instanton induced force are calculated from the instanton theory.
This interaction generates also constituent masses for the light quarks. Our work shows that other contributions must
be added to explain the large constituent masses of $n$ and $s$ quarks. These contributions which lay between 100 and
200 MeV are quite large. It is possible to cancel them, but the price to pay is then to obtain unrealistic very small
constituent masses. We consider that it is better to keep the large values of these contributions. Their origin is not
clear but sea-quark or relativistic effects could explain their presence.

The parameter $\epsilon$ reflects the uncertainties about the form of the instanton density, which is known within the
two-loop approximation. The values found in all models are consistent with the fact that the cutoff radius of the
instanton size must be small.

We have shown that the light meson spectra can be described by a semi-relativistic model including an instanton
induced force whose characteristics are calculated from the underlying theory. Moreover, calculation of electromagnetic
mass differences between mesons indicate that the wave function obtained are quite satisfactory. The next steps are
to calculate meson widths and to generalize the model to baryons. Such a work is in progress.
FIG. 1: One-loop and two-loop approximations of the instanton density (see Eq. (10)) as a function of the dimensionless instanton size $x = \Lambda \rho$. The absolute value of the ratio $R$ (see Sec. II C), and the values of $x$ corresponding to $\epsilon = 0$ and $\epsilon = 1$ are indicated.
