Abstract. This article is devoted to the analysis of a Monte-Carlo method to approximate effective coefficients in stochastic homogenization of discrete elliptic equations. We consider the case of independent and identically distributed coefficients, and adopt the point of view of the random walk in a random environment. Given some final time $t > 0$, a natural approximation of the homogenized coefficients is given by the empirical average of the final squared positions rescaled by $t$ of $n$ independent random walks in $n$ independent environments. Relying on a new quantitative version of Kipnis-Varadhan’s theorem (which is of independent interest), we first give a sharp estimate of the error between the homogenized coefficients and the expectation of the rescaled final position of the random walk in terms of $t$. We then complete the error analysis by quantifying the fluctuations of the empirical average in terms of $n$ and $t$, and prove a large-deviation estimate. Compared to other numerical strategies, this Monte-Carlo approach has the advantage to be dimension-independent in terms of convergence rate and computational cost.

Keywords: random walk, random environment, stochastic homogenization, effective coefficients, Monte-Carlo method, quantitative estimates.

1. Introduction

This article is part of a larger program, which consists in devising and quantitatively analyzing numerical methods to approximate effective coefficients in stochastic homogenization of linear elliptic equations. More precisely, we tackle here the case of a discrete elliptic equation with independent and identically distributed coefficients (see however the end of this introduction for more general statistics), and present and fully analyze an approximation procedure based on a Monte-Carlo method.

A first possibility to approximate effective coefficients is to directly solve the so-called corrector equation. In this approach, a first step towards the derivation of error estimates is a quantification of the qualitative results proved by Kühnemann [Kü83] (and inspired by Papanicolaou and Varadhan’s treatment of the continuous case [PV79]) and Kozlov [Ko87]. In the stochastic case, such an equation is posed on the whole $\mathbb{Z}^d$, and we need to localize it on a bounded domain, say the hypercube $Q_R$ of side $R > 0$. As shown in a series of papers by Otto and the first author [GO10a, GO10b], and the first author [Gl10], there are three contributions to the $L^2$-error in probability between the true homogenized coefficients and its approximation. The dominant error in small dimensions takes the form of a variance: it measures the fact that the approximation of the homogenized coefficients by the average of the energy density of the corrector on a box $Q_R$ fluctuates. This error decays at the rate of the central limit theorem $R^{-d}$ in any dimension (with a logarithmic correction for $d = 2$). The second error is the so-called systematic error: it is due to the
fact that we have modified the corrector equation by adding a zero-order term of strength $T^{-1} > 0$ (as standard in the analysis of the well-posedness of the corrector equation). The scaling of this error depends on the dimension and saturates at dimension 4. It is of higher order than the random error up to dimension 8. The last error is due to the use of boundary conditions on the bounded domain $Q_R$. Provided there is a buffer region, this error is exponentially small in the distance to the buffer zone measured in units of $\sqrt{T}$.

This approach has two main drawbacks. First the numerical method only converges at the central limit theorem scaling in terms of $R$ up to dimension 8, which is somehow disappointing from a conceptual point of view (although this is already fine in practice). Second, although the size of the buffer zone is roughly independent of the dimension, its cost with respect to the central limit theorem scaling dramatically increases with the dimension (recall that in dimension $d$, the CLT scaling is $R^{-d}$, so that in high dimension, we may consider smaller $R$ for a given precision, whereas the use of boundary conditions requires $R \gg \sqrt{T}$ in any dimension). Based on ideas of the second author in [Mo11], we have taken advantage of the spectral representation of the homogenized coefficients (originally introduced by Papanicolaou and Varadhan to prove their qualitative homogenization result) in order to devise and analyze new approximation formulas for the homogenized coefficients in [GM10]. In particular, this has allowed us to get rid of the restriction on dimension, and exhibit refinements of the numerical method of [Gl10] which converge at the central limit theorem scaling in any dimension (thus avoiding the first mentioned drawback). Unfortunately, the second drawback is inherent to the type of method used: if the corrector equation has to be solved on a bounded domain $Q_R$, boundary conditions need to be imposed on the boundary $\partial Q_R$. Since their values are actually also part of the problem, a buffer zone seems mandatory — with the notable exception of the periodization method, whose analysis is yet still unclear to us, especially when spatial correlations are introduced in the coefficients. In order to avoid the issue of boundary conditions, we adopt here another point of view on the problem: the random walk in random environment approach. This other point of view on the same homogenization problem has been analyzed in the celebrated paper [KV86] by Kipnis and Varadhan, and then extended by De Masi, Ferrari, Goldstein, and Wick [DFGW89]. The strategy of the present paper is to obtain an approximation of the homogenized coefficients by the numerical simulation of this random walk up to some large time. As we did in the case of the approach based on the corrector equation, a first step towards the analysis of this numerical method is to quantify the corresponding qualitative result, namely here Kipnis-Varadhan’s convergence theorem. Compared to the deterministic approach based on the approximate corrector equation, the advantage of the present approach is that its convergence rate and computational costs are dimension-independent. As we shall also see, as opposed to the approach based on the corrector equation, the environment only needs to be generated along the trajectory of the random walker, so that much less information has to be stored during the calculation. This may be quite an important feature of the Monte Carlo method in view of the discussion of [Gl10, Section 4.3].

We consider the discrete elliptic operator $-\nabla^* \cdot A \nabla$, where $\nabla^*$ and $\nabla$ are the discrete backward divergence and forward gradient, respectively. For all $x \in \mathbb{Z}^d$, $A(x)$ is the diagonal matrix whose entries are the conductances $\omega_{x,x+e_i}$ of the edges $(x, x + e_i)$ starting at $x$, where $(e_i)_{i \in \{1, \ldots, d\}}$ denotes the canonical basis of $\mathbb{Z}^d$. Let $\mathcal{B}$ denote the set of edges of $\mathbb{Z}^d$. We call the family of conductances $\omega = (\omega_e)_{e \in \mathcal{B}}$
the environment. The environment $\omega$ is random, and we write $P$ for its distribution (with corresponding expectation $E$). We make the following assumptions:

(H1) the measure $P$ is invariant under translations,
(H2) the conductances are i. i. d.$^1$,
(H3) there exists $0 < \alpha < \beta$ such that $\alpha \leq \omega_e \leq \beta$ almost surely.

Under these conditions, standard homogenization results ensure that there exists some deterministic symmetric matrix $A_{\text{hom}}$ such that the solution operator of the deterministic continuous differential operator $-\nabla \cdot A_{\text{hom}} \nabla$ describes the large scale behavior of the solution operator of the random discrete differential operator $-\nabla^* \cdot A \nabla$ almost surely (for this statement, (H2) can in fact be replaced by the weaker assumption that the measure $P$ is ergodic with respect to the group of translations, see [Kü83]).

The operator $-\nabla^* \cdot A \nabla$ is the infinitesimal generator of a stochastic process $(X(t))_{t \in \mathbb{R}_+}$ which can be defined as follows. Given an environment $\omega$, it is the Markov process whose jump rate from a site $x \in \mathbb{Z}^d$ to a neighbouring site $y$ is given by $\omega_{x,y}$. We write $P_x^\omega$ for the law of this process starting from $x \in \mathbb{Z}^d$.

It is proved in [KV86] that under the averaged measure $P \mathbb{P}_0^\omega$, the rescaled process $\sqrt{\varepsilon}X(\varepsilon^{-1}t)$ converges in law, as $\varepsilon$ tends to 0, to a Brownian motion whose infinitesimal generator is $-\nabla \cdot A_{\text{hom}} \nabla$, or in other words, a Brownian motion with covariance matrix $2A_{\text{hom}}$ (see also [AKS82, Kü83, Ko85] for prior results). We will use this fact to construct computable approximations of $A_{\text{hom}}$. As proved in [DFGW89], this invariance principle holds as soon as (H1) is true, (H2) is replaced by the ergodicity of the measure $P$, and (H3) by the integrability of the conductances. Under the assumptions (H1-H3), [SS04] strengthens this result in another direction, showing that for almost every environment, $\sqrt{\varepsilon}X(\varepsilon^{-1}t)$ converges in law under $P_0^\omega$ to a Brownian motion with covariance matrix $2A_{\text{hom}}$. This has been itself extended to environments which do not satisfy the uniform ellipticity condition (H3), see [BB07, MP07, BP07, Ma08, BD10].

Let $(Y(t))_{t \in \mathbb{N}}$ denote the sequence of consecutive sites visited by the random walk $(X(t))_{t \in \mathbb{R}_+}$ (note that the “times” are different in nature for $X(t)$ and $Y(t)$). This sequence is itself a Markov chain that satisfies for any two neighbours $x, y \in \mathbb{Z}^d$:

$$P_x^\omega[Y(1) = y] = \frac{\omega_{x,y}}{p_\omega(x)},$$

where $p_\omega(x) = \sum_{|z|=1} \omega_{x,x+z}$. We simply write $p(\omega)$ for $p_\omega(0)$. Let us introduce a “tilted” version of the law $P$ on the environments, that we write $\tilde{P}$ and define by

$$d\tilde{P}(\omega) = \frac{p(\omega)}{E[p]} \, dP(\omega).$$

The reason why this measure is natural to consider is that it makes the environment seen from the position of the random walk $Y$ a stationary process (see (3.2) for a definition of this process).

Interpolating between two integers by a straight line, we can think of $Y$ as a continuous function on $\mathbb{R}_+$. With this in mind, it is also true that there exists a matrix $A_{\text{hom}}$ such that, as $\varepsilon$ tends to 0, the rescaled process $\sqrt{\varepsilon}Y(\varepsilon^{-1}t)$ converges in law under $\tilde{P}P_0^\omega$ to a Brownian motion with covariance matrix $2A_{\text{disc}}$. Moreover, $A_{\text{hom}}$ and $A_{\text{disc}}$ are related by (see [DFGW89, Theorem 4.5 (ii)]):

$$A_{\text{hom}} = E[p] A_{\text{disc}}.$$  

$^1$(H2) obviously implies (H1) in the present form. Yet for most qualitative (and some quantitative) results (H2) can be weakened and may not imply (H1) any longer.
Given that the numerical simulation of $Y$ saves some operations compared to the simulation of $X$ (there is no waiting time to compute, and the running time is equal to the number of steps), we will focus on approximating $A^\text{disc}_{\text{hom}}$. More precisely, we fix once and for all some $\xi \in \mathbb{R}^d$ with $||\xi|| = 1$, and define
\begin{equation}
\sigma^2 = t^{-1} \mathbb{E}E_0^{\omega}[(\xi \cdot Y(t))^2], \quad \sigma^2 = 2 \xi \cdot A^\text{disc}_{\text{hom}} \xi.
\end{equation}
It follows from results of [KV86] (or [DFGW89, Theorem 2.1]) that $\sigma^2$ tends to $\sigma^2$ as $t$ tends to infinity. Our first contribution is to give a quantitative estimate of this convergence. In particular we shall show that, with i. i. d. coefficients and up to a logarithmic correction in dimension 2, the difference between $\sigma^2$ and $\sigma^2$ is of order $1/t$.

We now describe a Monte-Carlo method to approximate $\sigma^2$. Using the definition of the tilted measure (1.1), one can see that
\begin{equation}
\sigma^2 = t^{-1} \mathbb{E}E_0^{\omega}[(\xi \cdot Y(t))^2] = \mathbb{E}E_0^\omega[p(\omega)(\xi \cdot Y(t))^2].
\end{equation}
Assuming that we have easier access to the measure $\mathbb{P}$ than to the tilted $\tilde{\mathbb{P}}$, we prefer to base our Monte-Carlo procedure on the r. h. s. of the second identity in (1.4). Let $Y^{(1)}, Y^{(2)}, \ldots$ be independent random walks evolving in the environments $\omega^{(1)}, \omega^{(2)}, \ldots$, respectively. We write $P^\omega_0$ for their joint distribution, all random walks starting from 0, where $\omega$ stands for $($ $\omega^{(1)}, \omega^{(2)}, \ldots$ $)$. The family of environments $\omega$ is itself random, and we let $\mathbb{P}^\omega$ be the product distribution with marginal $\mathbb{P}$. In other words, under $\mathbb{P}^\omega$, the environments $\omega^{(1)}, \omega^{(2)}, \ldots$ are independent and distributed according to $\mathbb{P}$. Our computable approximation of $\sigma^2$ is defined by
\begin{equation}
\hat{\sigma}_n^2 = \frac{p(\omega^{(1)})(\xi \cdot Y^{(1)}(t))^2 + \cdots + p(\omega^{(n)})(\xi \cdot Y^{(n)}(t))^2}{t[p(\omega^{(1)}) + \cdots + p(\omega^{(n)})]}.
\end{equation}
The following step in the analysis is to quantify the random fluctuations of $\hat{\sigma}_n(t)$ in terms of $n$ — the number of random walks considered in the empirical average to approximate $\sigma^2$ — and $t$. We shall prove a large deviation result which ensures that the $\mathbb{P}^\omega P^\omega_0$-probability that the difference between $\hat{\sigma}_n(t)$ and $\sigma^2$ exceeds $1/t$ is exponentially small in the ratio $n/t^2$.

The rest of this article is organized as follows. In Section 2, which can be read independently of the rest of the paper, we consider a general discrete or continuous-time reversible Markov process. Kipnis-Varadhan’s theorem (and its subsequent development due to [DFGW89]) gives conditions for additive functionals of this process to satisfy an invariance principle. We show that, under additional conditions written in terms of a spectral measure, the statement can be made quantitative. More precisely, Kipnis-Varadhan’s theorem relies on writing the additive functional under consideration as the sum of a martingale plus a remainder. This remainder, after suitable normalization, is shown to converge to 0 in $L^2$. Under our additional assumptions, we give explicit bounds on the rate of decay. In Section 3, we make use of this result, in the context of the approximation of homogenized coefficients, to estimate the systematic error $|\sigma^2 - \sigma^2|$. The central achievement of this section is to prove that the relevant spectral measure satisfies the conditions of our quantitative version of Kipnis-Varadhan’s theorem. Section 4 is dedicated to the estimate of the random fluctuations. These are controlled through large deviations estimates. Relying on these results, we give in Section 5 a complete error analysis of the Monte-Carlo method to approximate the homogenized matrix $A^\text{disc}_{\text{hom}}$, which we illustrate by numerical tests.

Let us quickly discuss the sharpness of these results. If $A$ was a periodic matrix (or even a constant matrix) the systematic error would also be of order $1/t$ (without
logarithmic correction for $d = 2$), and the fluctuations would decay exponentially fast in the ratio $n/t^2$ as well. This shows that our analysis is optimal (the additional logarithm seems unavoidable for $d = 2$, as discussed in the introduction of [GO10a]).

Let us also point out that although the results of this paper are proved under assumptions (H1)-(H3), the assumption (H2) on the statistics of $\omega$ is only used to obtain the variance estimate of [GO10a, Lemma 2.3]. In particular, (H2) can be weakened as follows:

- the distribution of $\omega(z,z+\epsilon_1)$ may in addition depend on $\epsilon_1$,
- independence can be replaced by finite correlation length $C_L > 0$, that is for all $\epsilon, \epsilon' \in \mathbb{R}$, $\omega_{\epsilon}$ and $\omega_{\epsilon'}$ are independent if $|\epsilon - \epsilon'| \geq C_L$,
- independence can be replaced by mixing in the sense of Dobrushin and Shlosman — we refer the reader to work in progress by Otto and the first author for this issue [GO11].

**Notation.** So far we have already introduced the probability measures $P^\omega_0$ (distribution of $Y$), $P^{\omega_0}_0$ (distribution of $Y^{(1)}, Y^{(2)}, \ldots$), $P$ (i.i.d. distribution for $\omega = (\omega_e)_{e \in \mathbb{R}}$), $\tilde{P}$ (tilted measure defined in (1.1)) and $P^\omega$ (product distribution of $\omega$ with marginal $P$). It will be convenient to define $P^\omega_0$ the product distribution of $\omega$ with marginal $P$. For convenience, we write $P_0$ as a short-hand notation for $P_P^{\omega_0}, P_0$ for $PP^{\omega}_0$, $P^\omega_0$ for $P^{\omega}_0 P^\omega_0$, and $P^\omega$ for $P^\omega_0 P^\omega_0$. The corresponding expectations are written accordingly, replacing “$P$” by “$E$” with the appropriate typography. Finally, we write $| \cdot |$ for the Euclidian norm of $\mathbb{R}^d$.

2. **Quantitative version of Kipnis-Varadhan’s theorem**

Kipnis-Varadhan’s theorem [KV86] concerns additive functionals of reversible Markov processes. It gives conditions for such additive functionals to satisfy an invariance principle. The proof of the result relies on a decomposition of the additive functional as the sum of a martingale term plus a remainder term, the latter being shown to be negligible. In this section, which can be read independently of the rest of the paper, we give conditions that enable to obtain some quantitative bounds on this remainder term.

We consider discrete and continuous times simultaneously. Let $(\eta_t)_{t \geq 0}$ be a Markov process defined on some measurable state space $\mathcal{X}$ (here, $t \geq 0$ stands either for $t \in \mathbb{N}$ or for $t \in \mathbb{R}_+$). We denote by $P_x$ the distribution of the process started from $x \in \mathcal{X}$, and by $E_x$ the associated expectation. We assume that this Markov process is reversible and ergodic with respect to some probability measure $\nu$. We write $P_\nu$ for the law of the process started from the distribution $\nu$, and $E_\nu$ for the associated expectation.

To the Markov process is naturally associated a semi-group $(P_t)_{t \geq 0}$ defined, for any $f \in L^2(\nu)$, by

$$P_t f(x) = E_x[f(\eta_t)].$$

Each $P_t$ is a self-adjoint contraction of $L^2(\nu)$. In the continuous-time case, we assume further that the semi-group is strongly continuous, that is to say, that $P_t f$ converges to $f$ in $L^2(\nu)$ as $t$ tends to 0, for any $f \in L^2(\nu)$. We let $L$ be the $L^2(\nu)$-infinitesimal generator of the semi-group. It is self-adjoint in $L^2(\nu)$, and we fix the sign convention so that it is a positive operator (i.e., $P_t = e^{-tL}$).

Note that in general, one can see using spectral analysis that there exists a projection $\mathcal{P}$ such that $P_t f$ converges to $\mathcal{P} f$ as $t$ tends to 0, $t > 0$. Changing $L^2(\nu)$ to the image of the projection $\mathcal{P}$, and $P_0$ for $\mathcal{P}$, one recovers a strongly continuous semigroup of contractions, and one can still carry the analysis below replacing $L^2(\nu)$ by the image of $\mathcal{P}$ when necessary.
In discrete time, we set $L = \text{Id} - P_1$. Again, $L$ is a positive self-adjoint operator on $L^2(\nu)$. Note that we slightly depart from the custom of defining the generator as $P_1$ in order to match more closely the continuous time situation.

We denote by $\langle \cdot, \cdot \rangle$ the scalar product in $L^2(\nu)$. For any function $f \in L^2(\nu)$ we define the spectral measure of $L$ projected on the function $f$ as the measure $\epsilon_f$ on $\mathbb{R}_+$ that satisfies, for any bounded continuous $\Psi : \mathbb{R}_+ \to \mathbb{R}$, the relation

$$\langle f, \Psi(L)f \rangle = \int \Psi(\lambda) \, d\epsilon_f(\lambda). \tag{2.1}$$

The Dirichlet form associated to $L$ is given by

$$\|f\|_1^2 = \int \lambda \, d\epsilon_f(\lambda). \tag{2.2}$$

We denote by $H^1$ the completion of the space $\{ f \in L^2(\nu) : \|f\|_1 < +\infty \}$ with respect to this $\| \cdot \|_1$ norm, taken modulo functions of zero $\| \cdot \|_1$ norm. This turns $(H^1, \langle \cdot, \cdot \rangle_1)$ into a Hilbert space, and we let $H^{-1}$ denote its dual. One can identify $H^{-1}$ with the completion of the space $\{ f \in L^2(\nu) : \|f\|_{-1} < +\infty \}$ with respect to the norm $\| \cdot \|_{-1}$ defined by

$$\|f\|_{-1}^2 = \int \lambda^{-1} \, d\epsilon_f(\lambda).$$

Indeed, for all $f \in L^2(\nu)$, the linear form

$$\begin{cases} (L^2(\nu) \cap H^1, \| \cdot \|_1) & \to \mathbb{R} \\ \phi & \mapsto \langle f, \phi \rangle \end{cases}$$

has norm $\|f\|_{-1}$, and thus defines an element of $H^{-1}$ (with norm $\|f\|_{-1}$) iff $\|f\|_{-1}$ is finite. The notion of spectral measure introduced in (2.1) for functions of $L^2(\nu)$ can be extended to elements of $H^{-1}$. Indeed, let $\Psi : \mathbb{R}_+ \to \mathbb{R}$ be a continuous function such that $\Psi(\lambda) = O(\lambda^{-1})$ as $\lambda \to +\infty$. One can check that the map

$$\begin{cases} (L^2(\nu) \cap H^{-1}, \| \cdot \|_{-1}) & \to H^1 \\ f & \mapsto \Psi(L)f \end{cases}$$

extends to a bounded linear map on $H^{-1}$. One can then define the spectral measure of $L$ projected on the function $f$ as the measure $\epsilon_f$ such that for any continuous $\Psi$ with $\Psi(\lambda) = O(\lambda^{-1})$, (2.1) holds. With a slight abuse of notation, for all $f \in H^{-1}$ and $g \in H^1$, we write $\langle f, g \rangle$ for the $H^{-1} - H^1$ duality product between $f$ and $g$.

For any $f \in H^{-1}$, we define $(Z_f(t))_{t \geq 0}$ as

$$Z_f(t) = \int_0^t f(\eta_s) \, ds \quad \text{or} \quad Z_f(t) = \sum_{s=0}^{t-1} f(\eta_s), \tag{2.3}$$

according to whether we consider the continuous or the discrete time cases. In the continuous case, the meaning of (2.3) is unclear a priori. Yet it is proved in [DFGW89, Lemma 2.4] that for any $t \geq 0$ the map

$$\begin{cases} L^2(\nu) \cap H^{-1} & \to L^2(P_\nu) \\ f & \mapsto Z_f(t) \end{cases}$$

can be extended by continuity to a bounded linear map on $H^{-1}$, and moreover, that (2.3) coincides with the usual integral as soon as $f \in L^1(\nu)$. The following theorem is due to [DFGW89], building on previous work of [KV86].
Theorem 2.1. (i) For all \( f \in H^{-1} \), there exists \((M_t)_{t \geq 0}, (\xi_t)_{t \geq 0}\) such that \( Z_f(t) \) defined in (2.3) satisfies the identity \( Z_f(t) = M_t + \xi_t \), where \((M_t)\) is a square-integrable martingale with stationary increments under \( P_v \) (and the natural filtration), and \((\xi_t)\) is such that:

\[
(2.4) \quad t^{-1} E_v[|\xi_t|^2] \xrightarrow{t \to +\infty} 0.
\]

As a consequence, \( t^{-1/2}Z_f(t) \) converges in law under \( P_v \) to a Gaussian random variable of variance \( \sigma^2(f) < +\infty \) as \( t \) goes to infinity, and

\[
(2.5) \quad t^{-1} E_v[(Z_f(t))^2] \xrightarrow{t \to +\infty} \sigma^2(f).
\]

(ii) If, moreover, \( f \in L^1(\nu) \) and, for some \( T > 0 \), \( \sup_{0 \leq t \leq T}|Z_f(t)| \) is in \( L^2(\nu) \), then the process \( t \mapsto \sqrt{\epsilon} Z_f(e^{-\epsilon}t) \) converges in law under \( P_v \) to a Brownian motion of variance \( \sigma^2(f) \) as \( \epsilon \) goes to 0.

Remarks. The additional conditions appearing in statement (ii) are automatically satisfied in discrete time, due to the fact that \( H^{-1} \subseteq L^2(\nu) \) in this case. In the continuous-time setting and when \( f \in L^1(\nu) \), the process \( t \mapsto Z_f(t) \) is almost surely continuous, and \( \sup_{0 \leq t \leq T}|Z_f(t)| \) is indeed a well-defined random variable.

Under some additional information on the spectral measure of \( f \), we can estimate the rates of convergence in the limits (2.4) and (2.5). For any \( \gamma > 1 \) and \( q \geq 0 \), we say that the spectral exponents of a function \( f \in H^{-1} \) are at least \((\gamma, -q)\) if

\[
(2.6) \quad \int_0^\mu \lambda^{-1} d e_f(\lambda) = O(\mu^{\gamma-1} \ln^q(\mu^{-1})) \quad (\mu \to 0).
\]

Note that the phrasing is consistent, since if \((\gamma', -q') \leq (\gamma, -q)\) for the lexicographical order, and if the spectral exponents of \( f \) are at least \((\gamma, -q)\), then they are at least \((\gamma', -q')\). In [Mo11], it was found more convenient to consider, instead of (2.6), a condition of the following form:

\[
(2.7) \quad \int_0^\mu \lambda^{-1} d e_f(\lambda) = O(\mu^{\gamma-1} \ln^q(\mu^{-1})) \quad (\mu \to 0).
\]

One can easily check that conditions (2.6) and (2.7) are equivalent. Indeed, on the one hand, one has the obvious inequality

\[
\int_0^\mu d e_f(\lambda) \leq \mu \int_0^\mu \lambda^{-1} d e_f(\lambda),
\]

which shows that (2.7) implies (2.6). On the other hand, one may perform a kind of integration by parts, use Fubini’s theorem:

\[
\int_0^\mu \lambda^{-1} d e_f(\lambda) = \int_0^\mu \int_\lambda^{+\infty} \delta^{-2} d \delta d e_f(\lambda)
\]

\[
= \int_0^{+\infty} \delta^{-2} \int_{\lambda=0}^{\delta \wedge \mu} d e_f(\lambda) d \delta,
\]

and obtain the converse implication by examining separately the integration over \( \delta \) in \([0, \mu]\) and in \([\mu, +\infty)\).

For all \( \gamma > 1 \) and \( q \geq 0 \), we set

\[
(2.8) \quad \psi_{\gamma,q}(t) = \begin{cases} t^{1-\gamma} \ln^q(t) & \text{if } \gamma < 2, \\ t^{-1} \ln^{q+1}(t) & \text{if } \gamma = 2, \\ t^{-1} & \text{if } \gamma > 2. \end{cases}
\]

The quantitative version of Theorem 2.1 is as follows.
Theorem 2.2. If the spectral exponents of \( f \in H^{-1} \) are at least \((\gamma, -q)\), then the decomposition \( Z_f(t) = M_t + \xi_t \) of Theorem 2.1 holds with the additional property that
\[
(t^{-1} E_\nu[\xi_t]^2) = O(\psi_{\gamma, q}(t)) \quad (t \to +\infty).
\]
Moreover,
\[
(\sigma^2(f) - E_\nu[Z_f(t)]^2) = O(\psi_{\gamma, q}(t)) \quad (t \to +\infty).
\]

Proof. In the continuous-time setting, the argument for the first estimate is very similar to the one of [Mo11, Proposition 8.2], and we do not repeat the details here. It is based on the observation that
\[
(2.9) \quad \frac{1}{t} E_\nu[\xi_t]^2 = 2 \int \frac{1 - e^{-\lambda t}}{\lambda^2 t} \, d\nu_t(\lambda).
\]

One needs to take into account the possible logarithmic terms that appear in (2.7) and which are not considered in [Mo11]. Some care is also needed because we do not assume that \( f \in L^2(\nu) \). Yet one can easily replace the bound involving the \( L^2(\nu) \) norm of \( f \) by its \( H^{-1} \) norm. The second part of the statement is given by [Mo11, Proposition 8.3].

We now turn to the discrete time setting. In this context, identity (2.9) should be replaced by
\[
\frac{1}{t} E_\nu[\xi_t]^2 = 2 \int \frac{1 - (1 - \lambda)^t}{\lambda^2 t} \, d\nu_t(\lambda).
\]

By definition, \( L = \text{Id} - P_1 \), where \( P_1 \) is the semi-group at time 1. Hence the spectrum of \( L \) is contained in \([0, 2]\). One can then follow the same computations as before to prove the first part of Theorem 2.2.

Somewhat surprisingly, the second part of the statement requires additional attention in the discrete time setting. Indeed, in the continuous case, the argument of [Mo11, Proposition 8.3] (which already appears in [DFGW89]) is that \( Z_f(t) \) and \( \xi(t) \) are orthogonal in \( L^2(P_\nu) \), a fact obtained using the invariance under time symmetry. This orthogonality is only approximately valid in the discrete-time setting. Indeed, let us recall that \( Z_f(t) \) is given by (2.3), while \( \xi_t \) is obtained as the limit in \( L^2(P_\nu) \) of
\[
-u_\varepsilon(\eta) + u_\varepsilon(\eta_0),
\]
where \( u_\varepsilon = (\varepsilon + L)^{-1} f \). Using time symmetry, what we obtain is that \( \xi_t \) is orthogonal to \( (Z_f(t) + f(\eta)) \). As a consequence, the cross-product \( E_\nu[Z_f(t)\xi_t] \), which is equal to 0 in the proof of [Mo11, Proposition 8.3], is in the present case equal to \(-E_\nu[f(\eta)\xi_t]\). Yet spectral analysis ensures that this term is equal to
\[
\int \frac{1 - (1 - \lambda)^t}{\lambda} \, d\nu_t(\lambda) = O(1) \quad (t \to +\infty),
\]
which is what we need to obtain the second claim of the theorem.

\[\square\]

3. The systematic error

We now come back to the analysis of the Monte-Carlo approximation of the homogenized coefficients within assumptions (H1)-(H3). The aim of this section is to estimate the difference between \( \sigma^2 \) and the quantity \( \sigma^2 \) we wish to approximate (both being defined in (1.3)). This difference, that we refer to as the systematic error after [GO10a], is shown to be of order \( 1/t \) as \( t \) tends to infinity, up to a logarithmic correction in dimension 2.
Theorem 3.1. Under assumptions (H1)-(H3), there exists \( q \geq 0 \) such that, as \( t \) tends to infinity,

\[
\sigma_t^2 - \sigma^2 = O\left( t^{-1} \ln^q(t) \right) \quad \text{if} \quad d = 2,
\]

\[
O\left( t^{-1} \right) \quad \text{if} \quad d > 2.
\]

Theorem 3.1 is a discrete-time version of [Mo11, Corollary 2.6]. Its proof makes use of an auxiliary process that we now introduce.

Let \( \{ \theta_x \}_{x \in \mathbb{Z}^d} \) be the translation group that acts on the set of environments as follows: for any pair of neighbours \( y, z \in \mathbb{Z}^d \), \( (\theta_x, \omega)_{y,z} = \omega_{x+y,x+z} \). The environment viewed by the particle is the process defined by

\[
\omega(t) = \theta_{Y(t)} \omega.
\]

One can check that \( (\omega(t))_{t \in \mathbb{N}} \) is a Markov chain, whose generator is given by

\[
-Lf(\omega) = \frac{1}{\rho(\omega)} \sum_{|z|=1} \omega_0, z(f(\theta_z \omega) - f(\omega))
\]

so that \( \mathbb{E}_0^\omega [f(\omega(1))] = (I - L)f(\omega) \). Moreover, the measure \( \mathbb{P}^\omega \) defined in (1.1) is reversible and ergodic for this process [DFGW89, Lemma 4.3 (i)]. As a consequence, the operator \( L \) is (positive and) self-adjoint in \( L^2(\mathbb{P}) \).

The proof of Theorem 3.1 relies on spectral analysis. For any function \( f \in L^2(\mathbb{P}) \), let \( \epsilon_f \) be the spectral measure of \( L \) projected on the function \( f \). This measure is such that, for any positive continuous function \( \Psi : [0, +\infty) \rightarrow \mathbb{R}_+ \), one has

\[
\mathbb{E}[f \Psi(L)f] = \int \Psi(\lambda) \, d\epsilon_f(\lambda).
\]

For any \( \gamma > 1 \) and \( q \geq 0 \), we recall that we say that the spectral exponents of a function \( f \) are at least \( (\gamma, -q) \) if (2.6) holds.

Let us define the local drift \( \mathfrak{d} \) in direction \( \xi \) as

\[
\mathfrak{d}(\omega) = \mathbb{E}_0^\omega [\xi \cdot Y(1)] = \frac{1}{\rho(\omega)} \sum_{|z|=1} \omega_{0,z} \xi \cdot z.
\]

As we shall prove at the end of this section, we have the following bounds on the spectral exponents of \( \mathfrak{d} \).

Proposition 3.2. Under assumptions (H1)-(H3), there exists \( q \geq 0 \) such that the spectral exponents of the function \( \mathfrak{d} \) are at least

\[
(2, -q) \quad \text{if} \quad d = 2,
\]

\[
(d/2 + 1, 0) \quad \text{if} \quad 3 \leq d \leq 5,
\]

\[
(4, -1) \quad \text{if} \quad d = 6,
\]

\[
(4, 0) \quad \text{if} \quad d \geq 7.
\]

Let us see how this result implies Theorem 3.1. In order to do so, we also need the following information, that is a consequence of Proposition 3.2.

Corollary 3.3. Let

\[
\mathfrak{d}_t(\omega) = \mathbb{E}_0^\omega [\mathfrak{d}(\omega(t))]
\]

be the image of \( \mathfrak{d} \) by the semi-group at time \( t \) associated with the Markov chain \( (\omega(t))_{t \in \mathbb{N}} \). There exists \( q \geq 0 \) such that

\[
\mathbb{E}[(\mathfrak{d}_t)^2] = O\left( t^{-2} \ln^q(t) \right) \quad \text{if} \quad d = 2,
\]

\[
O\left( t^{-(d/2+1)} \right) \quad \text{if} \quad 3 \leq d \leq 5,
\]

\[
O\left( t^{-4} \ln(t) \right) \quad \text{if} \quad d = 6,
\]

\[
O\left( t^{-4} \right) \quad \text{if} \quad d \geq 7.
\]
Proof. This result is the discrete-time analog of [GM10, Corollary 1]. It is obtained the same way, noting that

$$\tilde{E}[(\xi t)^2] = \int (1 - \lambda)^{2t} \, d\mu_f(\lambda),$$

and that the support of the measure $e_f$ is contained in $[0, 2]$. □

We are now in position to prove Theorem 3.1.

Proof of Theorem 3.1. The proof has the same structure as for the continuous-time case of [Mo11, Proposition 8.4]. Note that [DFGW89, Theorem 2.1] ensures that

$$\lim_{t \to \infty} \sigma_t^2 \overset{(\text{def})}{=} \lim_{t \to \infty} t^{-1}E_0[(\xi \cdot Y(t))^2] = \sigma^2.$$  

The starting point is the observation that, under $\tilde{E}_0$, the process defined by

$$N_t = \xi \cdot Y(t) - \sum_{s=0}^{t-1} \mathcal{D}(\omega(s))$$

is a square-integrable martingale with stationary increments. On the one hand, following (2.3), we denote by $Z_0(t)$ the sum appearing in the r. h. s. of (3.7). From Proposition 3.2 and Theorem 2.2, we learn that there exist $\overline{\sigma}$ and $q \geq 0$ such that

$$\overline{\sigma}^2 - \tilde{E}_0[(Z_0(t))^2] = \begin{cases} O(\ln^q(t)) & \text{if } d = 2, \\ O(1) & \text{if } d > 2. \end{cases}$$

On the other hand, since $N_t$ is a martingale with stationary increments,

$$\tilde{E}_0[(N_t)^2] = t\tilde{E}_0[(N_1)^2].$$

As in the proof of Theorem 2.2 in the discrete time case, we then use that $\xi \cdot Y(t)$ is orthogonal to $(Z_0(t) + \mathcal{D}(\omega(t)))$ to turn (3.7) into

$$t^{-1}\tilde{E}_0[(N_t)^2] = t^{-1}\tilde{E}_0[(\xi \cdot Y(t))^2] + t^{-1}\tilde{E}_0[(Z_0(t))^2] + 2t^{-1}\tilde{E}_0[\mathcal{D}(\omega(t))(\xi \cdot Y(t))].$$

We already control the l. h. s. and the second term of the r. h. s. of (3.10). In order to quantify the convergence of $t^{-1}\tilde{E}_0[(\xi \cdot Y(t))^2]$ it remains to control the last term. In particular, provided we show that

$$\tilde{E}_0[\mathcal{D}(\omega(t))(\xi \cdot Y(t))] = \begin{cases} O(\ln^q(t)) & \text{if } d = 2, \\ O(1) & \text{if } d > 2, \end{cases}$$

(3.10), (3.8), (3.9), and (3.6) imply first that $\sigma^2 = \tilde{E}_0[(N_1)^2] - \overline{\sigma}^2$, and then the desired quantitative estimate (3.1). We now turn to (3.11) and write

$$\tilde{E}_0[\mathcal{D}(\omega(t))(\xi \cdot Y(t))] = \sum_{s=0}^{t-1} \tilde{E}_0[\mathcal{D}(\omega(t))(\xi \cdot (Y(s+1) - Y(s)))]$$

$$= \sum_{s=0}^{t-1} \tilde{E}_0[\mathcal{D}(\omega(t-s-1))(\xi \cdot (Y(s+1) - Y(s))],$$

where we have used the Markov property at time $s + 1$, together with the definition (3.5) of $\mathcal{D}_t(s-1)$. Using Cauchy-Schwarz inequality and the stationarity of the process $(\omega(t))_{t \in \mathbb{N}}$ under $\tilde{E}_0$, this sum is bounded by

$$|\xi|^2 \sum_{s=0}^{t-1} \tilde{E}[(\mathcal{D}_t(s-1))^2]^{1/2}.$$

Estimation (3.11) then follows from Corollary 3.3. This concludes the proof of the theorem. □
We finally turn to the proof of Proposition 3.2, which is a discrete-time counterpart of [GM10, Theorem 5]. In [GM10, Theorem 5] however, we had proved in addition that the spectral exponents are at least \((d/2 - 2, 0)\), which is sharper than the exponents of Proposition 3.2 for \(d > 10\). In particular for \(d > 10\) the bounds of [GM10, Theorem 5] follow from results of [Mo11], whose adaptation to the discrete time setting is not straightforward. As shown above, the present statement is sufficient to prove the optimal scaling of the systematic error, and we do not investigate further this issue. The proof of Proposition 3.2 is rather involved and one may wonder whether this is worth the effort in terms of the application we have in mind — namely Theorem 3.1. In order to obtain the optimal convergence rate in Theorem 3.1 we need the spectral exponents to be larger than \((2, 0)\). Proving that the exponents are at least \((2, 0)\) is rather direct using results of [GO10a] (see the first three steps of the proof of Proposition 3.2). Yet proving that they are larger than \((2, 0)\) for \(d > 2\) is as involved as proving Proposition 3.2 itself. This is the reason why we display the complete proof of Proposition 3.2 — although the precise values of the spectral exponents are not that important in the context of this paper.

**Proof of Proposition 3.2.** The present proof is a direct version of the proof of [GM10, Theorem 5]. In particular, the proof of [GM10, Theorem 5] relies on a nontrivial (weaker) estimate of the spectral exponents obtained in [GO10b] using a covariance estimate. Yet if one wants to extend these results to more general statistics of the conductivity function — for instance to mixing coefficients in the sense of Dobrushin and Shlosman — one has to give up the covariance estimate (which we are not able to prove any longer, see [GO11]). With this in mind we only rely on the variance estimate of [GO10a, Lemma 2.3]. Our strategy is similar to the strategy used for (continuous) elliptic equations in [GO11] to prove the estimate of the systematic error. In particular we directly focus on the spectral exponents rather than on some other quantity like the systematic error itself. Yet we will go slightly further. Starting point is the inequality:

\[
\int_0^{T^{-1}} d\lambda \leq T^{-4} \int_0^\infty \frac{1}{(T^{-1} + \lambda)^4} d\lambda,
\]

which follows from the fact that for \(\lambda \leq T^{-1}, \frac{T^{-4}}{(T^{-1} + \lambda)^4} \geq 1\) (here and below \(\lesssim\) and \(\gtrsim\) stand respectively for \(\leq\) and \(\geq\) up to multiplicative constants). The variable \(T^{-1}\) for \(T\) large plays the role of \(\mu\) in (2.6). In what follows we make the standard identification between stationary functions \((z, \omega) \mapsto f(z, \omega)\) of both the space variable \(z \in \mathbb{Z}^d\) and the environment \(\omega\) and their translated versions at \(0\) \(\omega \mapsto f(0, \theta z, \omega)\) depending on the environment only. We define \(\phi_T\) as the unique stationary solution to

\[
T^{-1} \phi_T(x) - \frac{1}{p_\omega(x)} \nabla^* A(x) \nabla \phi_T = \frac{1}{p_\omega(x)} \nabla^* A(x) \xi,
\]

whose existence and uniqueness follow from Lax-Milgram’s theorem in \(L^2(\mathbb{P})\) using the identification between the stationary function \(\phi_T\) and its version defined on the environment only (see a similar argument of [Kü83]). In particular, with the notation \(\bar{\omega} = \frac{1}{p_\omega(x)} \nabla^* A(x) \xi\),

\[
\phi_T = (T^{-1} + \mathcal{L})^{-1} \bar{\omega},
\]

where \(\mathcal{L}\) is the operator defined in (3.3), and the spectral theorem ensures that

\[
\mathbb{E}(\phi_T^2) = \mathbb{E}(\bar{\omega}(T^{-1} + \mathcal{L})^{-2} \bar{\omega}) = \int_0^\infty \frac{1}{(T^{-1} + \lambda)^2} d\lambda.
\]
where $e_\delta$ is the spectral measure of $\mathcal{L}$ projected on the drift $\delta$. We also let $\psi_T$ be the unique stationary solution to

$$T^{-1}\psi_T(x) - \frac{1}{p_\omega(x)} \nabla^* \cdot A(x) \nabla \psi_T(x) = \phi_T(x), \tag{3.14}$$

whose existence and uniqueness also follows from Lax-Milgram’s theorem in the probability space as well. This time,

$$\psi_T = (T^{-1} + \mathcal{L})^{-2} \delta,$$

and the spectral theorem yields

$$\hat{E}(\psi_T^2) = \hat{E}(\delta(T^{-1} + \mathcal{L})^{-4} \delta) = \int_0^\infty \frac{1}{(T^{-1} + \lambda)^4} \, d e_\delta(\lambda) \tag{3.15}$$

From now on, we shall use the shorthand notation $\langle u \rangle := \hat{E}(u)$ and $\text{var}[u] = \langle (u - \langle u \rangle)^2 \rangle$ for all $u \in \mathbb{L}^2(\hat{P})$. In particular the identity above turns into

$$\int_0^\infty \frac{1}{(T^{-1} + \lambda)^4} \, d e_\delta(\lambda) = \text{var}[\psi_T],$$

since $\langle \psi_T \rangle = \frac{1}{\hat{P}[\psi_T]} \int \psi_T \, d\hat{P} = \frac{T}{\hat{P}[\psi_T]} \int \phi_T \, d\hat{P} = 0$ using equations (3.14) and (3.13).

The rest of the proof, which is dedicated to the estimate of $\text{var}[\psi_T]$, is divided in six steps. Starting point is the application of the variance estimate of [GO10a, Lemma 2.3] to $\psi_T$, which requires to estimate the susceptibility of $\psi_T$ with respect to the random coefficients. In view of (3.14) it is not surprising that we will have to estimate not only the susceptibility of $\psi_T$ but also of $\phi_T$ and of some Green’s function with respect to the random coefficients. In the first step, we establish the susceptibility estimate for the Green’s function. In Step 2 we turn to the susceptibility estimate for the approximate corrector $\phi_T$. We then show in Step 3 that, relying on [GO10a], this implies that the spectral exponents are at least

$$\langle |\nabla \psi_T|^2 \rangle \lesssim \begin{cases} T \ln^2 T & \text{for } d = 2, \\ T^2 & \text{for } d > 2, \end{cases} \tag{3.16}$$

Following step is to estimate the susceptibility of $\psi_T$. In Step 5 we show that this, combined with the suboptimal estimates

$$\langle |\nabla \psi_T|^2 \rangle \lesssim \begin{cases} (2, -q) & \text{for } d = 2, \\ (2, 0) & \text{for } d > 2, \end{cases} \tag{3.17}$$

obtained using (3.16), allow us to improve the spectral exponents to

$$\langle |\nabla \psi_T|^2 \rangle \lesssim \begin{cases} (2, -q) & \text{for } d = 2, \\ (5/2, 0) & \text{for } d = 3, \\ (3, -1) & \text{for } d = 4, \\ (3, 0) & \text{for } d > 4. \end{cases} \tag{3.18}$$

In the last step, we quickly argue that in turn these spectral exponents yield the optimal and suboptimal estimates

$$\langle |\nabla \psi_T|^2 \rangle \lesssim \begin{cases} T \ln^2 T & \text{for } d = 2, \\ \sqrt{T} & \text{for } d = 3, \\ \ln T & \text{for } d = 4, \\ 1 & \text{for } d > 4, \end{cases} \tag{3.19}$$

and

$$\langle |\psi_T^2| \rangle \lesssim \begin{cases} T \ln^2 T & \text{for } d = 2, \\ T^{3/2} & \text{for } d = 3, \\ T \ln T & \text{for } d = 4, \\ T & \text{for } d > 4. \end{cases}$$
which finally bootstrap (3.18) to the desired estimates of the spectral exponents, and consequently yield the following optimal estimate of \( \text{var} [\psi_T] \):

\[
\text{var} [\psi_T] \lesssim \begin{cases} 
T^2 \ln^d T & \text{for } d = 2, \\
T^{3/2} & \text{for } d = 3, \\
T & \text{for } d = 4, \\
\sqrt{T} & \text{for } d = 5, \\
\ln T & \text{for } d = 6, \\
1 & \text{for } d > 6.
\end{cases}
\]

We do not need Step 6 to prove Theorem 3.1. Yet this step is interesting in itself since it may be the starting point of a subtle “multi-level” induction to obtain the sharp spectral exponents in any dimension.

**Step 1. Susceptibility of the Green’s function.**

For all \( y \in \mathbb{Z}^d \) we define the Green’s function \( G_T(\cdot, y) \) with singularity at \( y \) as the unique solution in \( L^2(\mathbb{Z}^d) \) to the equation

\[
T^{-1} p_\omega(x) G_T(x, y) - \nabla_x^* A(x) \nabla_x G_T(x, y) = \delta(x - y),
\]

using Lax-Milgram’s theorem. We shall prove for all \( y \in \mathbb{Z}^d \), \( z \in \mathbb{Z}^d \), \( z' = z + e_i \),

\[
\frac{\partial G_T}{\partial \omega_e}(x, y) = -T^{-1} \left( G_T(z, y) G_T(x, z) + G_T(z', y) G_T(x, z') \right) - \nabla_z G_T(x, z) \nabla_z G_T(z, y),
\]

and

\[
\sup_{\omega_e} |\nabla_z G_T(z, y)| \lesssim |\nabla_z G_T(z, y)| + T^{-1} g_T(y - z),
\]

\[
\sup_{\omega_e} |\nabla_z G_T(y, z)| \lesssim |\nabla_z G_T(y, z)| + T^{-1} g_T(y - z),
\]

where \( g_T : \mathbb{Z}^d \to \mathbb{R}^+ \) satisfies for some constant \( c > 0 \) (depending on \( \alpha, \beta, d \))

\[
g_T(x) = (1 + |x|)^{2-d} \exp \left( -c \frac{|x|}{\sqrt{T}} \right)
\]

for \( d > 2 \), and

\[
g_T(x) = \left| \ln \left( \frac{\sqrt{T}}{1 + |x|} \right) \right| \exp \left( -c \frac{|x|}{\sqrt{T}} \right)
\]

for \( d = 2 \). We define the elliptic operator \( L_T \) as

\[
(L_T u)(x) = \sum_{z', |x - x'| = 1} \omega_{(x, x')} T^{-1} u(x) + \sum_{z', |x - x'| = 1} \omega_{(x, x')} (u(x) - u(x')),
\]

so that (3.20) takes the form

\[
(L_T G_T(\cdot, y))(x) = \delta(x - y).
\]

Formally differentiating this equation with respect to \( \omega_e \) yields

\[
L_T \left( \frac{\partial G_T}{\partial \omega_e}(\cdot, y) \right)(x) + T^{-1} G_T(x, y) (\delta(x - z) + \delta(x - z'))
+ (G_T(z, y) - G_T(z', y)) \delta(x - z) + (G_T(z', y) - G_T(z', y)) \delta(x - z') = 0.
\]
Using (3.25) this identity turns into
\[
L_T \left( \frac{\partial G_T}{\partial \omega_e}(\cdot, y) + T^{-1}(G_T(z, y)G_T(\cdot, z) + G_T(z', y)G_T(\cdot, z')) + \nabla_z G_T(\cdot, z) \nabla_z G_T(z, y) \right)(x) = 0.
\]
Formally erasing the operator $L_T$ on the l. h. s. then yields the desired identity (3.21). To turn this into a rigorous argument, we may proceed as in [Go10a, Proof of Lemma 2.5], first consider finite differences instead of derivative w. r. t. $\omega_e$, use that $L_T$ is bijective on $L^2(\mathbb{Z}^d)$, and then pass to the limit. We leave the details to the reader and directly turn to (3.22).

From (3.21) we infer that
\[
\frac{\partial \nabla_z G_T(z, y)}{\partial \omega_e} = - \nabla_z \nabla_z G_T(z, z) \nabla_z G_T(z, y) - T^{-1}(G_T(z, y) \nabla_z G_T(z, z) + G_T(z', y) \nabla_z G_T(z, z')).
\]
Using then the uniform pointwise estimate $|\nabla G_T| \lesssim 1$ (see [Go10a, Corollary 2.3], whose proof holds as well in the present case with a non-constant zero order term since $2^d \alpha T^{-1} \leq T^{-1} p_\omega(x) \leq 2^d \beta T^{-1}$), the uniform pointwise estimate of the Green's function from [Gl10, Lemma 3], and considering this identity as an ODE for $\nabla_z G_T(z, y)$ in function of $\omega_e$, we obtain (3.22).

**Step 2. Susceptibility of the approximate corrector $\phi_T$.**

In this step we shall prove that for $e = (z, z') \in \mathbb{B}$, $z \in \mathbb{Z}^d$ and $z' = z + e_i$,

\[
\frac{\partial \phi_T}{\partial \omega_e}(x) = -(\nabla_i \phi_T(z) + \xi_i)\nabla_z G_T(x, z) - T^{-1}\phi_T(z)(G_T(x, z) + G_T(x, z')),
\]

\[
\sup_{\omega_e} |\phi_T(x)| \lesssim |\phi_T(x)| + \left( |\nabla_i \phi_T(z)| + 1 \right) \left( |\nabla_z G_T(x, z)| + T^{-1/2}g_T(x - z) \right),
\]

\[
\sup_{\omega_e} \left| \frac{\partial \phi_T}{\partial \omega_e}(x) \right| \lesssim \left( |\nabla_i \phi_T(z)| + 1 \right) \left( |\nabla_z G_T(x, z)| + T^{-1/2}g_T(x - z) \right),
\]

and for all $n \in \mathbb{N}$,

\[
\sup_{\omega_e} \left| \frac{\partial (\phi_T(x)^{n+1})}{\partial \omega_e} \right| \lesssim \left( |\nabla_i \phi_T(z)| + 1 \right) \left( |\nabla_z G_T(x, z)| + T^{-1/2}g_T(x - z) \right) \times \left( |\phi_T(x)| + \left( |\nabla_i \phi_T(z)| + 1 \right) \left( |\nabla_z G_T(x, z)| + T^{-1/2}g_T(x - z) \right) \right)^n.
\]

As for the Green's function, we rewrite the defining equation for $\phi_T$ as

\[
(L_T G_T(\cdot, y))(x) - \nabla^* \cdot A(x) \xi = 0.
\]

Formally differentiating (3.30) w. r. t. $\omega_e$ yields

\[
L_T \frac{\partial \phi_T}{\partial \omega_e}(x) - (\nabla_i \phi_T(z) + \xi_i)(\delta(x - z) - \delta(x - z')) + T^{-1}\phi_T(z)(\delta(x - z) + \delta(x - z')) = 0,
\]
which using (3.25) turns into
\[
L_T \left( \frac{\partial \phi_T}{\partial \omega_e} - (\nabla_i \phi_T(z) + \xi_i) (G_T(\cdot, z) - G_T(\cdot, z')) + T^{-1} \phi_T(z)(G_T(\cdot, z) + G_T(\cdot, z')) \right)(x) = 0.
\]
This (formally) shows (3.26). To turn this into a rigorous argument, we may use the Green representation formula
\[
\phi_T(x) = \int_{\mathbb{Z}^d} G_T(x, y) \nabla^* \cdot A(y) \xi \, dy,
\]
where \(\int_{\mathbb{Z}^d} \, dy\) denotes the sum over all \(y \in \mathbb{Z}^d\), and proceed as in [GO10a, Proof of Lemma 2.4].

We now turn to (3.28). This estimate follows from (3.26), (3.22), and the following two facts:
\[
\|\phi_T\| \lesssim \sqrt{T}
\]
and
\[
\sup_{\omega_e} |\nabla_i \phi_T(z)| \lesssim |\nabla_i \phi_T(z)| + 1.
\]
Starting point to prove (3.31) is the Green representation formula in the form of
\[
\|\phi_T(x)\| = \left| \int_{\mathbb{Z}^d} G_T(x, y) \nabla^* \cdot A(y) \xi \, dy \right|
\]
\[
= \left| \int_{\mathbb{Z}^d} \nabla_y G_T(x, y) \cdot A(y) \xi \, dy \right|
\]
\[
\lesssim \int_{\mathbb{Z}^d} |\nabla_y G_T(0, y)| \, dy,
\]
from which we deduce the claim by a dyadic decomposition of space combined with Cauchy-Schwarz’ inequality and [GO10a, Lemma 2.9] (a similar calculation is detailed in [Gl10, Proof of Lemma 4]). For (3.32), we first note that (3.26) implies
\[
\frac{\partial \nabla_i \phi_T(z)}{\partial \omega_e} = -(\nabla_i \phi_T(z) + \xi_i)(\nabla_{z'} G_T(z', z) - \nabla_{z'} G_T(z, z)) + T^{-1} \phi_T(z)(\nabla_{z'} G_T(z, z) + \nabla_{z'} G_T(z, z'))
\]
which — seen as an ODE w. r. t. \(\omega_e\) — yields the claim using the uniform bound \(|\nabla G_T| \lesssim 1\) of [GO10a, Corollary 2.3] and (3.31).

Estimate (3.27) is a direct consequence of (3.28), whereas (3.29) follows from the Leibniz’ rule combined with (3.26), (3.27), and (3.28).

**Step 3. Proof of (3.16).**
The estimates (3.16) of the spectral exponents follow from the more general estimates: for all \(q > 0\) there exists \(\gamma(q) > 0\) such that
\[
\langle |\phi_T|^q \rangle \lesssim \begin{cases} 
\ln\gamma(q) T & \text{for } d = 2, \\
1 & \text{for } d > 2,
\end{cases}
\]
combined with the fact that
\[
\int_0^{T^{-1}} d\omega_0(\lambda) \lesssim T^{-2} \int_0^\infty \frac{1}{(T^{-1} + \lambda)^2} d\omega_0(\lambda) = T^{-2} \langle \phi_T^2 \rangle.
\]
The proof of (3.33) is an adaptation of [GO10a, Proof of Proposition 2.1] which already covers the case of a constant coefficient in the zero order term of \( L_T \), that is for \( T^{-1}\phi_T \) instead of \( T^{-1}\rho_w\phi_T \) (no randomness in the zero order term).

The first step to apply the variance estimate of [GO10a, Lemma 2.3] is to show that \( \phi_T \) is measurable with respect to cylindrical topology associated with the random variables. This can be proved exactly as in [GO10a, Lemma 2.6]. The estimates (3.22), (3.27), (3.28), and (3.29) of Steps 1 and 2 are like in the auxiliary lemmas of [GO10a] provided we replace the terms \( |\nabla_x G_T(x, z)| \) in [GO10a, Lemmas 2.4 \& 2.5] by \( |\nabla_x G_T(x, z)| + T^{-1/2}g_T(x-z) \). A close look at the proof of [GO10a, Proposition 2.1] shows that these terms \( |\nabla_x G_T(x, z)| \) are either estimated by the Green’s function itself (in which case the additional term \( T^{-1/2}g_T(x-z) \) is of higher order), or they are controlled on dyadic annuli by the Meyers’ estimate [GO10a, Lemma 2.9]. This lemma shows in particular that there exists \( p > 2 \) such that for all \( q \geq 2 \), \( k > 0 \) and \( R \gg 1 \),

\[
\int_{R \leq |x-z| < 2R} |\nabla_x G_T(x, z)|^q dz \lesssim R^d(R^{1-d})^q \min\{1, \sqrt{T}R^{-1}\}^k.
\]

By the properties (3.23) for \( d > 2 \) and (3.24) for \( d = 2 \) of the function \( g_T \), it is easy to see that for \( d > 2 \)

\[
\int_{R \leq |x-z| < 2R} (T^{-1/2}g_T(x-z))^q dz \lesssim R^d(R^{1-d})^q \min\{1, \sqrt{T}R^{-1}\}^k
\]
as well, whereas for \( d = 2 \)

\[
\int_{R \leq |x-z| < 2R} (T^{-1/2}g_T(x-z))^q dz \lesssim R^2(R^{-1})^q \ln^q T \min\{1, \sqrt{T}R^{-1}\}^k.
\]

Hence the proof of [GO10a, Proposition 2.1] adapts mutatis mutandis to the present case (with possibly an additional logarithmic correction for \( d = 2 \)), and we have (3.33).

**Step 4. Susceptibility of \( \psi_T \).**

In this step we shall prove that for \( e = (z, z') \), \( z \in \mathbb{Z}^d \) and \( z' = z + e_i \),

\[
(3.34) \quad \frac{\partial \psi_T}{\partial e_i}(x) = -\nabla_z G_T(x, z)\nabla_i \psi_T(z) - T^{-1}G_T(x, z)\psi_T(z)
\]

\[
-\nabla_T G_T(x, z')\psi_T(z')
\]

\[
- (\nabla_i \phi_T(z) + \xi_i) \int_{\mathbb{Z}^d} G_T(x, y)\rho_w(y)\nabla_x G_T(y, z) \, dy
\]

\[
- T^{-1} \phi_T(z) \int_{\mathbb{Z}^d} G_T(x, y)\rho_w(y)(G_T(y, z) + G_T(y, z')) \, dy
\]

\[
+ G_T(x, z)\phi_T(z) + G_T(x, z')\phi_T(z'),
\]

and

\[
(3.35) \quad \sup_{x \in B_R} \left| \frac{\partial \psi_T}{\partial e_i}(0) \right| \lesssim g_T(z)(|\nabla_i \psi_T(z)| + T^{-1}(|\psi_T(z)| + \nu_T(1 + |\phi_T(z)| + |\phi_T(z')|))
\]

\[
+ (1 + |\phi_T(z)| + |\phi_T(z')|) \int_{\mathbb{Z}^d} g_T(y)(|\nabla_x G_T(y, z)| + T^{-1}g_T(y-z)) \, dy,
\]

where

\[
(3.36) \quad \nu_T = \begin{cases} 
T & \text{for } d = 2, \\
\sqrt{T} & \text{for } d = 3, \\
\ln T & \text{for } d = 4, \\
1 & \text{for } d > 4.
\end{cases}
\]
Starting point is again the Green representation formula
\[ \psi_T(x) = \int_{\mathbb{R}^d} G_T(x, y)p_\omega(y)\phi_T(y) \, dy, \]
associated with (3.14) in the form
\[ T^{-1}p\psi_T - \nabla^* \cdot A\nabla \psi_T = \rho_T. \]
Differentiated w. r. t. \( \omega_e \) it turns into
\[ \frac{\partial \psi_T(x)}{\partial \omega_e} = \int_{\mathbb{R}^d} \frac{\partial G_T(x, y)}{\partial \omega_e} p_\omega(y)\phi_T(y) \, dy + \int_{\mathbb{R}^d} G_T(x, y) \frac{\partial p_\omega(y)}{\partial \omega_e} \phi_T(y) \, dy + \int_{\mathbb{R}^d} G_T(x, y) p_\omega(y) \frac{\partial \phi_T(y)}{\partial \omega_e} \, dy. \]
Combined with (3.21), (3.26), and the Green representation formula itself, this shows (3.34).

We now turn to (3.35) and treat each term of the r. h. s. of (3.34) separately. We begin with the third line of (3.34), appeal to (3.32), then bound the gradient of the approximate corrector \( |\nabla \phi_T(z)| \) by the approximate corrector \( |\phi_T(z)| + |\phi_T(z')| \) itself, control the Green’s function \( G_T \) by \( g_T \), and use (3.22) to estimate the supremum in \( \omega_e \) of the gradient of the Green’s function \( |\nabla, G_T(y, x)| \). This term is thus controlled by the second term of the r. h. s. of (3.35). The term in the fourth line of (3.34) is also estimated by the second term of the r. h. s. of (3.35) using (3.27) (and the uniform bounds \( |\nabla G_T|, T^{-1/2}G_T \leq 1 \)), whereas the last two terms of (3.34) are bounded by the first term of the r. h. s. of (3.35) using (3.27). The subtle terms are the first three ones, for which we have to estimate the suprema of \( |\nabla \psi_T(z)|, |\psi_T(z)|, \) and \( |\psi_T(z')| \) w. r. t. \( \omega_e \).

We begin with the following two estimates
\[
\begin{align*}
(3.37) \quad \sup_{\omega_e} |\psi_T(z)| & \lesssim |\psi_T(z)| + (|\phi_T(z)| + |\phi_T(z')| + 1)\nu_d(T) \\
& \quad + \sup_{\omega_e} |\nabla, \psi_T(z)|, \\
(3.38) \quad \sup_{\omega_e} |\nabla, \psi_T(z)| & \lesssim |\nabla, \psi_T(z)| + (|\phi_T(z)| + |\phi_T(z')| + 1)\nu_d(T) \\
& \quad + T^{-1} \sup_{\omega_e} |\psi_T(z)|,
\end{align*}
\]
which — considered as a system of two coupled ODEs — show that there exists some \( T_0 > 0 \) such that for all \( T \geq T_0 \),
\[
\begin{align*}
(3.39) \quad \sup_{\omega_e} |\psi_T(z)| & \lesssim |\psi_T(z)| + (|\phi_T(z)| + |\phi_T(z')| + 1)\nu_d(T) \\
& \quad + |\nabla, \psi_T(z)|, \\
(3.40) \quad \sup_{\omega_e} |\nabla, \psi_T(z)| & \lesssim |\nabla, \psi_T(z)| + (|\phi_T(z)| + |\phi_T(z')| + 1)\nu_d(T) \\
& \quad + T^{-1} |\psi_T(z)|.
\end{align*}
\]
To prove (3.37) we consider (3.34) as an ODE on \( \psi_T(z) \), bound \( \psi_T(z') \) by \( \psi_T(z) + |\nabla, \psi_T(z)|, \) and use that the four last terms of the r. h. s. of (3.34) are bounded by the second term of the r. h. s. of (3.35), as discussed above. Hence (3.34) turns
into
\[
\left| \frac{\partial \psi_T}{\partial \omega_e}(z) \right| \lesssim \sup_{\omega_e} \left\{ |\nabla_z G_T(x,z)||\nabla_1 \psi_T(z)| + T^{-1}G_T(z,z)|\psi_T(z)| \right. \\
+ T^{-1}G_T(z,z')(|\psi_T(z)| + \sup_{\omega_e} |\nabla_1 \psi_T(z)|) \\
+ (1 + |\phi_T(z)| + |\phi_T(z')|) \\
\left. \times \int_{\mathbb{Z}^d} g_T(y)(|\nabla_z G_T(y,z)| + T^{-1}g_T(y-z)) \, dy \right\}
\]

Using the uniform bounds $|\nabla G_T|, T^{-1}G_T \lesssim 1$, and replacing the gradient of the Green’s function by the Green’s function itself in the integral — which we then control by $\nu_d(T)$ —, this estimate yields (3.37) by integrating the ODE. We now turn to (3.38) and infer from (3.34) that

\[
\frac{\partial \nabla_1 \psi_T(z)}{\partial \omega_e} = -\nabla_z \nabla_z G_T(z,z) \nabla_1 \psi_T(z) - T^{-1}\nabla_z G_T(z,z) \psi_T(z) \\
- T^{-1}\nabla_z G_T(z,z') \psi_T(z') \\
- (\nabla_1 \phi_T(z) + \xi) \int_{\mathbb{Z}^d} \nabla_z G_T(z,y)p_\omega(y)|\nabla_z G_T(y,z)| \, dy \\
- T^{-1}\phi_T(z) \int_{\mathbb{Z}^d} \nabla_z G_T(z,y)p_\omega(y)(G_T(y,z) + G_T(y,z')) \, dy \\
+ \nabla_z G_T(z,z') \phi(z) + \nabla_z G_T(z,z') \phi(z').
\]

Proceeding as from (3.34) to (3.37), this implies (3.38), and therefore (3.39) and (3.40). Combining the inequality $|\psi_T(z')| \lesssim |\psi_T(z)| + |\nabla_1 \psi_T(z)|$ with (3.39) and (3.40) yields the last estimate we need:

\[
(3.41) \quad \sup_{\omega_e} |\psi_T(z')| \lesssim |\psi_T(z)| + (|\phi_T(z)| + |\phi_T(z')| + 1)\nu_d(T) + |\nabla_1 \psi_T(z)|.
\]

We are finally in position to conclude the proof of (3.35): the first three terms of the r.h.s. of (3.34) are estimated by (3.40), (3.39), and (3.41). Replacing then the gradient of the Green’s function by the Green’s function itself, and the Green’s function by $g_T$, we obtain (3.35), as desired.

**Step 5. Proof of (3.18).**

This is an application of the variance estimate [GO10a, Lemma 2.3] on $\psi_T$ based on (3.35). In particular,

\[
(3.42) \quad \text{var} [\psi_T] \lesssim \sum_{x \in \mathbb{Z}^d} \sup_{\omega_e} \left\{ \left| \frac{\partial \psi_T(0)}{\partial \omega_e} \right|^2 \right\}.
\]

We distinguish the contributions of the two terms of the r.h.s. of (3.35) in this sum and use the notation

\[
A_c \quad := \quad g_T(z)(|\nabla_1 \psi_T(z)| + T^{-1}|\psi_T(z)| + \nu_d(T)(1 + |\phi_T(z)| + |\phi_T(z')|)) \\
B_c \quad := \quad (1 + |\phi_T(z)| + |\phi_T(z')|) \int_{\mathbb{Z}^d} g_T(y)(|\nabla_z G_T(y,z)| + T^{-1}g_T(y-z)) \, dy.
\]
The contribution of the first term is estimated as follows:

\[
\sum_{e \in B} \langle A_e^2 \rangle \lesssim \sum_{e \in B} \langle g_T(z)^2 \rangle \lesssim \left( \sum_{z \in \mathbb{Z}^d} g_T(z)^2 \right) \left( \langle |\nabla \psi_T|^2 \rangle + T^{-2} \langle \psi_T^2 \rangle + \nu_d(T)^2(1 + \langle \psi_T^2 \rangle) \right)
\]

\[
\lesssim \nu_d(T) \left( \langle |\nabla \psi_T|^2 \rangle + T^{-2} \langle \psi_T^2 \rangle + \nu_d(T)^2(1 + \langle \psi_T^2 \rangle) \right),
\]

by stationarity of \( \phi_T \), \( \psi_T \), and \( \nabla \psi_T \). Combined with (3.33) for \( q = 2 \), and (3.17) (which is proved below), this turns into

\[
(3.43) \quad \sum_{e \in B} \langle A_e^2 \rangle \lesssim \begin{cases} T^3 \ln^3 T & \text{for } d = 2, \\ T^{3/2} & \text{for } d = 3, \\ T \ln T & \text{for } d = 4, \\ T & \text{for } d > 4. \end{cases}
\]

Estimate (3.17) is a consequence of the estimate (3.16) of the spectral exponents and of the spectral representations

\[
\langle \psi_T^2 \rangle = \int_0^\infty \frac{1}{(T^{-1} + \lambda)^t} \, \text{d} \varepsilon(\lambda)
\]

\[
\lesssim T^2 \int_0^1 \frac{1}{\lambda^t} \, \text{d} \varepsilon(\lambda) + \int_0^\infty \frac{1}{\lambda} \, \text{d} \varepsilon(\lambda)
\]

\[
\alpha \langle |\nabla \psi_T|^2 \rangle \lesssim \langle \nabla \psi_T \cdot A \nabla \psi_T \rangle
\]

\[
= \int_0^\infty \frac{\lambda}{(T^{-1} + \lambda)^t} \, \text{d} \varepsilon(\lambda)
\]

\[
\lesssim T \int_0^1 \frac{1}{\lambda^t} \, \text{d} \varepsilon(\lambda) + \int_0^\infty \frac{1}{\lambda} \, \text{d} \varepsilon(\lambda),
\]

since \( \int_0^\infty \frac{1}{\lambda} \, \text{d} \varepsilon(\lambda) \lesssim 1 \), and by definition (2.6) of the spectral exponents.

We now turn to the second term of the r. h. s. of (3.35), and note that it coincides with the term treated in [GM10, Step 3, Proof of Lemma 5] so that we have

\[
\sum_{e \in B} \langle B_e^2 \rangle \lesssim \begin{cases} T^2 \ln^2 T & \text{for } d = 2, \\ T^{3/2} & \text{for } d = 3, \\ T & \text{for } d = 4, \\ \sqrt{T} & \text{for } d = 5, \\ \ln T & \text{for } d = 6, \\ 1 & \text{for } d > 6. \end{cases}
\]

Hence, (3.42), (3.35), (3.43) and (3.44) yield (3.18) for \( d > 2 \) using (3.12) and (3.15). Note that (3.43) is not optimal for \( d = 2 \) in view of the estimate of \( \langle \psi_T^2 \rangle \) in (3.17) (which is sharper). This comes from our estimate of \( \sup_{\omega} \psi_T(z) \) where we have replaced a gradient of the Green’s function by the Green’s function itself and therefore given up some potential better decay (at least integrated on dyadic annuli). In high dimensions however, there is no loss because \( g_T \) is then square-integrable itself. Anyway, the optimal spectral exponents for \( d = 2 \) have been already obtained in (3.16).

**Step 6.** Proof of (3.4).

We quickly show how (3.18) allows to get the sharper spectral exponents (3.4). This is the same argument as in Step 5, except that (3.17) can now be bootstrapped.
to (3.19) using (3.18) and
\[
\langle \psi^2_T \rangle = \int_0^\infty \frac{1}{(T^{-1} + \lambda)^4} \, d\sigma(\lambda) \\
\leq T \int_0^{T_*} \frac{1}{\lambda^4} \, d\sigma(\lambda) + T_*^3 \int_0^\infty \frac{1}{\lambda} \, d\sigma(\lambda)
\]
where \( T_* < \infty \) has been defined in Step 4. Proceeding as in the end of Step 5 this yields the spectral exponents (3.4), and concludes the proof of the proposition. \( \square \)

4. The random fluctuations

In this section, we show that the computable quantity \( \hat{A}_n(t) \) defined in (1.5) is a good approximation of \( \sigma_t^2 \), in the sense that its random fluctuations are small as soon as \( n/t^2 \) is large. We write \( \mathbb{N}^* \) for \( \mathbb{N} \setminus \{0\} \).

**Theorem 4.1.** There exists \( c > 0 \) such that, for any \( n \in \mathbb{N}^* \), \( \varepsilon > 0 \) and \( t \) large enough,

\[
\mathbb{P}^\circ \left[ |\hat{A}_n(t) - \sigma_t^2| \geq \varepsilon/t \right] \leq \exp \left( -\frac{n\varepsilon^2}{ct^2} \right).
\]

In order to prove this result, we rewrite \( \hat{A}_n(t) \) as \( A_n(t)/\hat{p}_n \), where

\[
A_n(t) = \frac{p(\omega^{(1)})(\xi \cdot Y^{(1)}(t))^2 + \cdots + p(\omega^{(n)})(\xi \cdot Y^{(n)}(t))^2}{n\mathbb{E}[p]},
\]

and

\[
\hat{p}_n = \frac{p(\omega^{(1)}) + \cdots + p(\omega^{(n)})}{n\mathbb{E}[p]}.
\]

Both are sums of independent and identically distributed random variables under \( \mathbb{P}^\circ \), thus enabling us to use standard tools from large deviations theory. We start with the following classical but instructing fact.

**Proposition 4.2.** There exists \( c_0 > 0 \) such that, for any \( n \in \mathbb{N} \) and any small enough \( \varepsilon > 0 \):

\[
\mathbb{P}^\circ \left[ |\hat{p}_n - 1| \geq \varepsilon \right] \leq \exp \left( -\frac{n\varepsilon^2}{c_0} \right).
\]

**Proof.** Let \( \overline{\mathbb{P}}(\omega) = p(\omega) - \mathbb{E}[p] \). It suffices to show that, for some \( C > 0 \),

\[
\mathbb{P}^\circ \left[ |\overline{\mathbb{P}}(\omega^{(1)}) + \cdots + \overline{\mathbb{P}}(\omega^{(n)})| \geq n\varepsilon \right] \leq \exp(-n\varepsilon^2/C).
\]

Chebyshev’s inequality implies that, for any \( \lambda \geq 0 \),

\[
\mathbb{P}^\circ \left[ \overline{\mathbb{P}}(\omega^{(1)}) + \cdots + \overline{\mathbb{P}}(\omega^{(n)}) \geq n\varepsilon \right] \leq e^{-n\varepsilon^2/C} \mathbb{E}^{\circ} \left[ \exp(\lambda(\overline{\mathbb{P}}(\omega^{(1)}) + \cdots + \overline{\mathbb{P}}(\omega^{(n)}))) \right]
\]

Using a series expansion of the exponential, one can check that there exists \( C > 0 \) such that, for any \( \lambda \) small enough,

\[
\ln \mathbb{E}^{\circ} [\exp(\lambda(\overline{\mathbb{P}}(\omega)))] \leq C\lambda^2.
\]

As a consequence, for any \( \lambda \) small enough,

\[
\mathbb{P}^\circ \left[ \overline{\mathbb{P}}(\omega^{(1)}) + \cdots + \overline{\mathbb{P}}(\omega^{(n)}) \geq \varepsilon \right] \leq \exp \left( -n(\varepsilon - C\lambda^2) \right),
\]
and for \( \lambda = \varepsilon/(2C) \), the latter term becomes \( \exp(-n\varepsilon^2/(4C)) \). The event \( \overline{p}(\omega^{(1)}) + \cdots + \overline{p}(\omega^{(n)}) \leq -n\varepsilon \) can be handled the same way, and we thus obtain (4.1).

What makes the proof of Proposition 4.2 work is the observation (4.2) that the log-Laplace transform of \( \overline{p} = p - \mathbb{E}[p] \) is quadratic close to the origin. In order to prove the corresponding result for \( A_n(t) \), we will need to control the log-Laplace transform of \( \left( \frac{\xi \cdot Y(t)}{t} \right)^2 - \sigma_t^2 \) uniformly in \( t \). To that end, we use a sharp upper bound on the transition probabilities of the random walk recalled in the following theorem. We refer the reader to [HS93] or [Wo, Theorem 14.12] for a proof.

**Theorem 4.3.** There exists a constant \( c_1 > 0 \) such that, for any environment \( \omega \) with conductances in \([\alpha, \beta] \), any \( t \in \mathbb{N}^* \) and \( x \in \mathbb{Z}^d \),

\[
\mathbb{P}_0 \left[ Y(t) = x \right] \leq \frac{c_1}{t^{3/2}} \exp \left( -\frac{|x|^2}{c_1 t} \right).
\]

From Theorem 4.3 we deduce the following result.

**Corollary 4.4.** Let \( c_1 \) be given by Theorem 4.3. For all \( \lambda < 1/c_1 \), one has

\[
\sup_{t \in \mathbb{N}^*} \tilde{\mathbb{E}}_0 \left[ \exp \left( \lambda \left( \frac{|Y(t)|^2}{t} \right) \right) \right] < +\infty.
\]

**Proof.** Let \( \delta = 1/c_1 - \lambda \). By Theorem 4.3,

\[
\tilde{\mathbb{E}}_0 \left[ e^{\lambda |Y(t)|^2/t} \right] \leq c_1 t^{-d/2} \sum_{x \in \mathbb{Z}^d} e^{-\delta |x|^2/t}.
\]

If the sum ranges over all \( x \in (\mathbb{N}^*)^d \), it is easy to bound it by a convergent integral:

\[
t^{-d/2} \sum_{x \in (\mathbb{N}^*)^d} e^{-\delta |x|^2/t} \leq t^{-d/2} \int_{\mathbb{R}^d_+} e^{-\delta |x|^2/t} \, dx = \int_{\mathbb{R}^d_+} e^{-\delta x^2} \, dx.
\]

By symmetry, the estimate carries over to the sum over all \( x \in (\mathbb{Z}^*)^d \). The same argument applies for the sum over all \( x = (x_1, \ldots, x_d) \) having exactly one component equal to 0, and so on.

The following lemma contains the required uniform control on the log-Laplace transform of \( \left( \frac{\xi \cdot Y(t)}{t} \right)^2 - \sigma_t^2 \).

**Lemma 4.5.** There exist \( \lambda_1 > 0 \) and \( c_2 \) such that, for any \( \lambda < \lambda_1 \) and any \( t \in \mathbb{N}^* \),

\[
\ln \tilde{\mathbb{E}}_0 \left[ \exp \left( \lambda \left( \frac{(\xi \cdot Y(t))^2}{t} - \sigma_t^2 \right) \right) \right] \leq c_2 \lambda^2.
\]

**Proof.** It is sufficient to prove that there exists \( c_3 \) such that, for any \( \lambda \) small enough and any \( t \),

\[
\tilde{\mathbb{E}}_0 \left[ \exp \left( \lambda \left( \frac{(\xi \cdot Y(t))^2}{t} - \sigma_t^2 \right) \right) \right] \leq 1 + c_3 \lambda^2.
\]

We use the series expansion of the exponential to rewrite this expectation as

\[
\sum_{k=0}^{\infty} \frac{\lambda^k}{k!} \tilde{\mathbb{E}}_0 \left[ \left( \frac{(\xi \cdot Y(t))^2}{t} - \sigma_t^2 \right)^k \right].
\]

The term corresponding to \( k = 0 \) is equal to 1, whereas the term for \( k = 1 \) vanishes. The remaining sum, for \( k \) ranging from 2 to infinity, can be controlled using Corollary 4.4 combined with the bound

\[
\tilde{\mathbb{E}}_0 \left[ \left( \frac{(\xi \cdot Y(t))^2}{t} - \sigma_t^2 \right)^k \right] \leq 2 \tilde{\mathbb{E}}_0 \left[ \frac{(\xi \cdot Y(t))^{2k}}{t^k} \right],
\]

which follows from the definition of \( \sigma_t^2 \) and Jensen’s inequality. \( \square \)
We are now in position to prove Theorem 4.1.

**Proof of Theorem 4.1.** Starting point is the inequality

\[(4.3) \quad \mathbb{P}^{0}_{\hat{A}_{n}(t)} \left[ \hat{A}_{n}(t) - \sigma_{t}^{2} \geq \frac{2\varepsilon}{t} \right] \]

We treat both terms of the r. h. s. separately. For the first one, the key observation is that (recalling the definition of \( \tilde{\mathbb{P}} \) given in (1.1))

\[
\mathbb{P}^{0}_{\hat{A}_{n}(t)} \left[ \hat{A}_{n}(t) - \sigma_{t}^{2} \geq \frac{\varepsilon}{t} \right] = \tilde{\mathbb{E}}^{0}_{\hat{A}_{n}(t)} \left[ \frac{(\xi \cdot Y^{(1)}(t))^{2} + \cdots + (\xi \cdot Y^{(n)}(t))^{2}}{nt} - \sigma_{t}^{2} \right].
\]

Let \( \lambda > 0 \). As in the proof of Proposition 4.2, we bound this term using Chebyshev’s inequality:

\[(4.4) \quad \mathbb{P}^{0}_{\hat{A}_{n}(t)} \left[ \hat{A}_{n}(t) - \sigma_{t}^{2} \geq \frac{\varepsilon}{t} \right] \leq \tilde{\mathbb{E}}^{0}_{\hat{A}_{n}(t)} \left[ \exp \left( \lambda \left( \frac{(\xi \cdot Y^{(1)}(t))^{2} + \cdots + (\xi \cdot Y^{(n)}(t))^{2}}{nt} - \sigma_{t}^{2} \right) \right) \right] \exp \left( - \frac{n\lambda\varepsilon}{t} \right).
\]

By Lemma 4.5, the r. h. s. of (4.4) is bounded by

\[
\exp \left( n \left( c_{2} \lambda^{2} - \frac{\lambda\varepsilon}{t} \right) \right),
\]

for all \( \lambda \) small enough. Choosing \( \lambda = \varepsilon / 2c_{2}t \) (which is small enough for \( t \) large enough), we obtain

\[(4.5) \quad \mathbb{P}^{0}_{\hat{A}_{n}(t)} \left[ \hat{A}_{n}(t) - \sigma_{t}^{2} \geq \frac{\varepsilon}{t} \right] \leq \exp \left( - \frac{n\varepsilon^{2}}{4c_{2}t^{2}} \right),
\]
as needed.

We now turn to the second term of the r. h. s. of (4.3). From inequality (4.5), we infer that there exists \( M > 0 \) such that

\[
\mathbb{P}^{0}_{\hat{A}_{n}(t)} \left[ M \right] \leq \exp \left( - \frac{n\varepsilon^{2}}{4c_{2}t^{2}} \right).
\]

Since \( \hat{p}_{n} \) is almost surely bounded by a constant, it is enough to evaluate the probability

\[
\mathbb{P}^{0}_{\hat{p}_{n}^{-1}} \left[ \hat{p}_{n}^{-1} \geq \varepsilon / (Mt) \right],
\]

which is controlled by Proposition 4.2.

We have thus obtained the required control of the l. h. s. of (4.3). The probability of the symmetric event

\[
\mathbb{P}^{0}_{\hat{A}_{n}(t)} \left[ \sigma_{t}^{2} - \hat{A}_{n}(t) \geq 2\varepsilon / t \right]
\]
can be handled the same way. \( \square \)

5. Numerical validation

In this section, we illustrate on a simple two-dimensional example the sharpness of the estimates of the systematic error and of the random fluctuations obtained in Theorems 3.1 and 4.1.

In the numerical tests, each conductivity of \( \mathcal{B} \) takes the value \( \alpha = 1 \) or \( \beta = 4 \) with probability \( 1/2 \). In this simple case, the homogenized matrix is given by Dykhné’s formula, namely \( A_{\text{hom}} = \sqrt{\alpha \beta} \text{Id} = 2\text{Id} \) (see for instance [Gl10, Appendix A]). For the simulation of the random walk, we generate — and store — the environment
Table 1. Systematic error in function of the final time $t$ for $K(t)t^2$ realizations.

| $t$ | 10  | 20  | 40  | 80  | 160 | 320 | 640 |
|-----|-----|-----|-----|-----|-----|-----|-----|
| $K(t)$ | $10^5$ | 3000 | 3000 | 1000 | 500 | 100 | 20 |
| Systematic error | 1.27E-01 | 7.43E-02 | 4.17E-02 | 2.46E-02 | 1.26E-02 | 6.96E-03 | 3.72E-03 |

Figure 1. Systematic error in function of the final time $t$ for $n(t) = K(t)t^2$ realizations along the trajectory of the walk. In particular, this requires to store up to a constant times $t$ data. In terms of computational cost, the expansive part of the computations is the generation of the randomness. In particular, to compute one realization of $A_{t^2}(t)$ costs approximately the generation of $t^2 \times 4t = 4t^3$ random variables. A natural advantage of the method is its full scalability: the $t^2$ random walks used to calculate a realization of $A_{t^2}(t)$ are completely independent.

We first test the estimate of the systematic error: up to a logarithmic correction, the convergence is proved to be linear in time. In view of Theorem 4.1, typical fluctuations of $t(A_{n(t)}(t) - \sigma^2)$ are of order no greater than $t/\sqrt{n(t)}$, and thus become negligible when compared with the systematic error as soon as the number $n(t)$ of realizations satisfies $n(t) \gg t^2$. We display in Table 1 an estimate of the systematic error obtained with $n(t) = K(t)t^2$ realizations. The systematic error is plotted on Figure 1 in function of the time in logarithmic scale. The apparent convergence rate (linear fitting) is $-0.85$, which is consistent with Theorem 3.1, which predicts $-1$ and a logarithmic correction.

We now turn to the random fluctuations of $A_{n(t)}(t)$. Theorem 4.1 gives us a large deviation estimate which essentially says that the fluctuations of $t(A_{n(t)}(t) - \sigma^2)$ have a Gaussian tail, measured in units of $t/\sqrt{n(t)}$. The Figures 2-5 display the...
Figure 2. Histogram of the rescaled fluctuations for $t = 10$

Figure 3. Histogram of the rescaled fluctuations for $t = 20$

histograms of $t(\hat{A}_t^2(t) - \sigma_t^2)$ for $t = 10, 20, 40$ and $80$ (with 10000 realizations of $A_t^2(t)$ in each case). As expected, they look Gaussian.
