Enterobacter sakazakii kills 40%–80% of infected infants and has been associated with powdered formula. We analyzed 46 cases of invasive infant E. sakazakii infection to define risk factors and guide prevention and treatment. Twelve infants had bacteremia, 33 had meningitis, and 1 had a urinary tract infection. Compared with infants with isolated bacteremia, infants with meningitis had greater birthweight (2,454 g vs. 850 g, p = 0.002) and gestational age (37 weeks vs. 27.8 weeks, p = 0.02), and infection developed at a younger age (6 days vs. 35 days, p<0.001). Among meningitis patients, 11 (33%) had seizures, 7 (21%) had brain abscess, and 14 (42%) died. Twenty-four (92%) of 26 infants with feeding patterns specified were fed powdered formula. Formula samples associated with 15 (68%) of 22 cases yielded E. sakazakii; in 13 cases, clinical and formula strains were indistinguishable. Further clarification of clinical risk factors and improved powdered formula safety is needed.

Enterobacter sakazakii, a gram-negative bacillus, is a rare cause of bloodstream and central nervous system infections (1–8). The organism has also been associated with necrotizing enterocolitis; however, it has not been firmly established as a causative agent (8–10). Reported outcomes are often severe: seizures; brain abscess; hydrocephalus; developmental delay; and death in as many as 40%–80% of cases (11). Premature infants are thought to be at greater risk than more mature infants, other children, or adults, and outbreaks of disease have occurred in hospital units for newborns (1,2,4,6,8–10,12). Infant infections with E. sakazakii have been associated with contaminated powdered formula products, but other environmental sources of contamination are possible (1,3,9,10,13). In this analysis, we attempt to more clearly define the host risk factors and disease course to refine prevention and treatment efforts.
Cases were reported in 7 countries in North America, Europe, and the Middle East. Thirty-three (72%) infants had meningitis, 12 (26%) had bacteremia, and 1 (2%) had a urinary tract infection.

Clinical characteristics were available for a subset of cases (Table 2). Eight (40%) of 20 infants for whom data were available were delivered by cesarean section. Twenty-nine (69%) of 42 infants experienced disease onset within a hospital. Gestational duration was available for 38 infants; 21 (55%) were born prematurely, and the median gestational age overall was 36 weeks (range 23.5–40 weeks). The median birthweight was 2,063 g (range 540–3,401); 18 (56%) of 32 infants had LBW; 9 (28%) of these met the definition for VLBW, and 7 (22%) met the definition for ELBW. Median age at the time of infection onset was 8.5 days (range 2–300).

Although the proportion of infants who experienced nosocomial disease onset was not significantly different between the meningitis and bacteremia groups, other infant characteristics differed by site of infection (Figure). The median gestational ages of infants with meningitis and bacteremia were 37 and 27.8 weeks, respectively (p = 0.02). Median birthweights were 2,063 g (range 540–3,401); 18 (56%) of 32 infants had LBW; 9 (28%) of these met the definition for VLBW, and 7 (22%) met the definition for ELBW. Median age at the time of infection onset was 8.5 days (range 2–300).

Although numerous reports include infants with *E. sakazakii* isolated from nonsterile sites, such as respiratory secretions or stool, 46 infants identified from the literature and CDC sources met the case definition for this analysis (1,9,10,12). Of the infants with sterile-site infection, 72% had meningitis. Contrary to previous characterizations of *E. sakazakii* disease, we found that infants with meningitis and bacteremia alone fell into 2 distinct groups. Those in whom meningitis developed tended to be of greater gestational age and birthweight than those with bacteremia alone. In fact, infants in whom meningitis developed tended to attain near-term gestational age and birthweight. In contrast, infants in whom bacteremia alone developed tended to be born very prematurely and have ELBW. A second major difference between the group with meningitis and the group with bacteremia was the infants’ chronological ages. Infants with meningitis were generally <1 week of age at the onset of infection with *E. sakazakii*, whereas infants with bacteremia had generally surpassed the neonatal period at the onset of their disease. Rates of adverse outcome also differed between the 2 groups, although this was not unexpected. Most infants with...
E. sakazakii bacteremia fared better than those with meningitis. Among those in whom meningitis developed, rates of adverse outcome were similar to those reported in the literature: In this case series, 74% of meningitis survivors experienced an adverse neurologic outcome, while other studies cite adverse outcome in 20%–78% of neonatal or infant meningitis survivors (21–23).

The division of the infant population into 2 distinct groups occurred for unclear reasons. That infants <1 week of age comprised the meningitis group was not surprising; the disparities in other infant characteristics, however, are not intuitive. Since infants in the 2 groups experienced similar rates of nosocomial disease onset, the infants with bacteremia were unlikely to have simply received treatment earlier in the disease course than the infants with meningitis. Other risk factors are probable.

One likely set of risk factors is infant formula-feeding practices. Powdered infant formula is a demonstrated source of E. sakazakii infection. A microbiologic survey of powdered infant formulas published in 1988 found E. sakazakii in 20 (14%) of 141 samples tested (24). However, a survey of 82 powdered infant formula samples in 2003 yielded E. sakazakii in 2 (2.4%), which suggests that recent rates of powdered formula contamination may be lower (25). Powdered formula has also been implicated both epidemiologically and microbiologically as a vehicle in several cases of E. sakazakii disease in infants (1,3,9,10,13). Although we could not explore feeding exposures fully with the data available in this series, infant feeding practices may relate to the differences we describe in chronological age of infants at onset of meningitis and bacteremia. Infants with nearly normal gestational ages and birthweights are likely to be tended in normal newborn nurseries during the first 24–72 hours of life. In such nurseries, powdered formula is frequently given to babies who are not breast-fed, and it may also be used as a supplement by mothers who have chosen to breast-feed. Since infants are at highest risk for meningitis during the first several weeks of life, possibly because of immaturity of the blood-brain barrier, exposures to E. sakazakii in powdered

| Characteristic                  | Published cases, n/N | Unpublished cases, n/N | Overall % |
|--------------------------------|----------------------|------------------------|-----------|
| Male                           | 15/30                | 6/9                    | 54        |
| Cesarean delivery              | 6/13                 | 2/7                    | 40        |
| Nosocomial onset               | 24/31                | 5/11                   | 69        |
| Premature birth                | 17/29                | 4/9                    | 55        |
| Birthweight*                   |                      |                        |           |
| LBW                            | 16/27                | 2/5                    | 56        |
| VLBW                           | 8/27                 | 1/5                    | 28        |
| ELBW                           | 6/27                 | 1/5                    | 22        |

*LBW, low birth weight; VLBW, very low birth weight; ELBW, extremely low birth weight.

Conversely, in the intensive care settings where immature and low birthweight infants are tended, babies are not often fed powdered formula in the first few weeks of life. They may be given parenteral nutrition initially and may be fed breast milk from their own mothers or from a banked source when they do begin enteral feeds. If breast milk is not available, they are more likely to be given sterile, premixed infant formula than powdered formula, since standard preterm infant formula is only available in this form (28). Powdered breast milk fortifiers are not introduced until premature infants tolerate full-volume feeds,

\[ \text{Figure. Box plot with each box indicating range (vertical lines), first and third quartiles (lower and upper boundaries of box, respectively), and median value (horizontal solid line) for gestational age in weeks, birth weight in grams, and age of onset in days for infants with bacteremia only or meningitis. The dotted lines indicate median values for all cases. *Significantly different values (α=0.05) between groups.} \]
which may not occur for days or weeks after birth. Thus, infants in intensive care settings may not be exposed to nonsterile formula until they are more mature, which would lead to a greater proportion of E. sakazakii bacteremia than meningitis in this group if powdered formula is a source of infection. In this series, we were unable to explore the roles of indwelling enteric tubes, prior gastrointestinal surgery, and antecedent antacid or antimicrobial drug use as risk factors for infection.

While the reservoir for E. sakazakii is unknown, several environmental sources have been reported. E. sakazakii has been isolated from factories used to produce milk powder, chocolate, cereal, potato flour, spices, and pasta (29). It also has been isolated from household vacuum cleaner bags and from the guts of the stable fly, Stomoxys calcitrans, and the Mexican fruit fly, Anastrapha ludens (29–31). The relationship between these potential environmental sources and infant disease remains unclear. Although a human vaginal tract culture yielding E. sakazakii has been reported, vertical transmission is unlikely because nearly half of infants with E. sakazakii disease in this review were delivered by cesarean section, and symptoms developed in only 1 infant earlier than 3 days of age (32).

Our analyses were constrained by the use of retrospective and often incomplete data. Although cases with more severe outcomes might have been investigated and published more frequently than uncomplicated cases, this possible bias would not likely affect the representativeness of baseline infant characteristics. Assigning a gestational age of 40 weeks to term infants without a reported gestational age may have falsely elevated the median gestational ages we report, since most term infants are born at <40 weeks’ gestation (33). However, a greater proportion of bacteremic infants than meningitic infants received this assignment, and therefore the significance of the differences in gestational age between the groups may be even greater than we report. We were unable to explore the effects of concomitant medical problems, treatments, and other environmental factors, and we relied on existing reports of feeding practices and formula testing. Clearly, additional study is needed to elucidate the lingering questions about E. sakazakii reservoirs, disease risk factors, and disease course.

Other gram-negative organisms, including Escherichia coli, Enterobacter agglomerans, E. cloacae, Klebsiella pneumoniae, K. oxytoca, and Citrobacter freundii, can be found in powdered infant formula (24,25). Powdered infant formula also has been associated with outbreaks of illness due to Citrobacter and multiple Salmonella serotypes (13,34–38). The degree to which E. sakazakii is a marker for a range of neonatal infections possibly related to powdered infant formula remains to be defined.

Certain steps can be taken immediately, however, to prevent or mitigate E. sakazakii disease. In a joint conference on infant formula safety in February, 2004, the World Health Organization and Food and Agriculture Organization of the United Nations made the following recommendations: 1) encourage industry partners to develop a range of affordable sterile formula options; 2) consider setting an industry standard for Enterobacteriaceae and E. sakazakii in infant formula; 3) inform infant caregivers of the risks associated with nonsterile, powdered formula; and 4) consider feeding high-risk infants sterile formula if they cannot breast-feed (39). The findings of our case review suggest that all neonates as well as premature infants should be included in this high-risk infant category. The American Dietetic Association has issued guidelines for infant formula preparation, storage, and administration; these should be followed by infant caregivers in hospitals and private homes (40). Rapid reporting of cases by clinicians could streamline data collection by local health departments and more rapidly resolve remaining questions about this illness. Manufacturer warning labels on powdered infant formula packages should stress that powdered infant formula is nonsterile and requires proper preparation, handling, and storage, and that sterile, liquid formula alternatives are available. These actions, adopted in whole or in part, may decrease the infectious risks associated with powdered formula and prevent this rare but potentially devastating disease.

Acknowledgments

Thanks to L. Clifford McDonald, Matthew Kuehnert, and R. Mike Hoekstra for their unflagging technical support and to Matthew Arduino, Terri Forster, and Bette Jensen for sharing their laboratory expertise.

Dr Bowen is a medical epidemiologist in the Foodborne and Diarrheal Diseases Branch at CDC. Her primary research interests include global infant feeding safety, hygiene, sanitation, and diarrheal diseases in the developing world.

Dr Braden is a medical epidemiologist in the Foodborne and Diarrheal Diseases Branch at CDC. His main areas of interest are the surveillance and epidemiology of foodborne diseases.
