Abstract. Seedlings of tomato (Lycopersicon esculentum Mill.) and cabbage (Brassica oleracea L. var. Capitata) were planted in 240-cell plug trays in the greenhouse and subjected to irrigation with water at different temperatures once a day. Irrigation with cold (5 to 15 °C) water reduced stem length of tomato by 28% to 32% in comparison with irrigation with water at room temperature (27.5 to 30.5 °C). Use of water at 10 °C did not affect total shoot dry weight but increased the shoot dry weight per centimeter of stem. Irrigation with water at 5 °C reduced stem length of cabbage seedlings 40%, but use of water at 10 and 15 °C did not. Both shoot and root dry weights were increased by irrigation with water at 10 °C. These results demonstrate that irrigation with cold water provides an effective method for improving the quality of plug-grown seedlings.

Vegetable plug seedlings are used extensively in automatic transplanting systems (Leskovar and Cantliffe, 1991; Weston and Zandstra, 1986). To facilitate handling of transplant plants by machines, short, sturdy seedlings of plug-grown vegetable crops are required. One major problem in commercial plug production is the control of the plant height when seedlings are grown in small plug cells, especially during the summer. Height of seedlings can be controlled by growth retardants. However, considering the legal restrictions on their use because of human health and environmental concerns, an effective nonchemical method is needed (Erwin and Heins, 1995; Moe et al., 1992).

Nonchemical strategies to control plant height include withholding water (Latimer, 1990), light quality manipulation (Liptay, 1985), shaking or brushing the shoot (Biddington and Dearman, 1985; Heuchert and Mitchell, 1983; Latimer, 1990), and temperature regulation in the greenhouse (Moe et al., 1992). In particular, emphasis has been placed on regulating day/night temperatures (Erwin and Heins, 1990; Moe et al., 1991).

The DIF concept, [difference between day (DT) and night temperature (NT)], was proposed by Erwin et al. (1989). They found that the effect of DT and NT on stem elongation could be described quantitatively using DIF. The stem elongation response to DIF has been reported in many crops, including lily (Visser Co., The Netherlands) containing a peat/sea-sand medium (VBV No. 4; Bas Van Buuren Co., The Netherlands) containing 400 mg·L−1·N (Peter’s 20N–20P–20K; Scotts-Sierra Horticultural Products Co., Maryville, Ohio) by overhead sprinkler once a week. The plug trays were kept on adjacent benches in a plastic-covered greenhouse (90% of light penetration) throughout the experiment. Temperature and light intensity were recorded with a data-logger (CD750; Priva Co., De Lier, The Netherlands). One tray was assigned to each irrigation treatment in a randomized complete-block design with three replications. Treatments were initiated 5 to 7 d after seeding, when the first true leaf was beginning to expand. Cold-water (5, 10, or 15 °C) irrigation treatments were supplied from temperature-controlled tanks. The control (water at room temperature) used water pumped directly from a tank built in the greenhouse. Irrigation water was applied once a day at 0900 hr. No additional irrigation was applied during the day. The seedlings were watered by overhead sprinkler until water dripped from the bottom of the plug tray. About 5 to 6 mL of water was retained in each cell after each irrigation.

The average temperature during the experiment was 28.5 °C and average maximum light intensity was 2025 µmol·m−2·s−1 photosynthetic photon flux (PPF). At the time cold-water treatment started (0900 hr), air temperature ranged from 27.5 to 30.5 °C and light intensity from 1215 to 1485 µmol·m−2·s−1·PPF. The temperature of the growing medium dropped 6 to 9 °C within 3 min of irrigation with cold water, then rose to the original temperature after 1.5 to 2 h.

Fifteen seedlings per block were sampled randomly from each treatment, and stem length and diameter were determined immediately. Stem length was measured from the base of the stem to the top of the shoot. Chlorophyll (Chl) was extracted in absolute methanol and analyzed spectrophotometrically (Holder, 1965). For shoot and root dry-weight determination, samples were dried at 80 °C for 2 d.

The statistical significance of treatment differences was evaluated by the least significant differences (LSD) test.

**Results**

Stem length of tomato seedlings was significantly reduced by irrigation with cold water within 24 d of culturing (Fig. 1A). Thereafter, stem length increased steadily but at a slower rate as compared with the control seedlings. Differences among cold-water treatments was nonsignificant. The average stem lengths at 35 d were 19.8 and 13.7 cm for the control and the cold water–treated seedlings, respectively. For the cabbage seedlings, irrigation with water at 5 °C significantly inhibited stem growth. However, water at 10 and 15 °C did not (Fig. 1B).

To examine whether the growth characteristics other than stem length were affected by cold-water treatment, tomato and cabbage seedlings were irrigated with water at 10 °C or at room temperature. The 10 °C water treatment had no effect on tomato shoot dry weight as of day 35, but reduced root dry weight 8.6% (Table 1). In contrast, the same treatment significantly increased both shoot and root dry weight of cabbage. At day 35 of culture, shoot and root dry weights were 16.5% and 13.3% greater, respectively, than those of control seedlings (Table 1).
The 10 °C water treatment increased tomato shoot dry weight to stem length ratio, a quality characteristic of tomato. However, no such difference was observed in cabbage. Stem diameter was reduced in tomato but not in cabbage. Leaf chlorophyll content was not affected in either species (Table 1).

Discussion

One of the major problems in commercial tomato seedling production is the control of plant height. In this study, irrigation with cold water reduced stem length 28% (Table 1). The stem elongation pattern can be characterized by internode number and internode length, which vary with temperature (Berghage and Heins, 1991). In our study, internode numbers were not affected in tomato (five internodes, data not shown); reduction of seedling height by cold-water treatment was a result of a decrease in internode length. Water at temperatures from 5 to 15 °C had a similar effect. Seedlings were shorter and sturdier than control seedlings (Table 1).

In contrast with tomato, cabbage is a short-stem type crop. This may explain why the cold-water treatment did not reduce stem length. However, shoot and root dry weights were both increased, which should result in improved suitability for transplanting (Biddington and Dearman, 1985).

Mechanical stress generally affects shoot and/or root dry weight and the partitioning of dry weight (Biddington, 1986; Latimer, 1990; Watts et al., 1981). Latimer (1990) found that the ratio of shoot-to-root dry weight of broccoli (Brassica oleracea L. Group Italica) transplants increased during drought. In lily (Lilium longiflorum Thunb.), the stem dry weight increased linearly as DIF increased and the percentage of partitioning of dry weight into stem depended primarily on day temperature (Erwin and Heins, 1995; Erwin et al., 1989). In this study, we found that the cold-water treatment did not affect the ratio of shoot-to-root dry weight significantly for either tomato or cabbage.

Nitrogen is a major factor affecting vegetable seedling growth (Dufault, 1986, 1998). Melton and Dufault (1991) reported that nitrogen accounted for the major portion of variations in height and leaf chlorophyll content of tomato transplants. Generally, shoot and root growth decreased as N rate decreased (Weston and Zandstra, 1989). Many researchers have suggested that the retardation of seedling growth by chilling stress is related to inadequate nutrient uptake, presumably due to root damage (Bolger et al., 1992; Reyes and Jennings, 1994). However, this was not the case in the present study. Even with the large temperature drop induced by irrigation with water at 5 °C, the temperature in the growing medium remained no lower than 18 to 20 °C level. These temperatures should not inhibit growth (Reyes and Jennings, 1994). Also, total plant dry weight and leaf chlorophyll content were either not affected or increased in response to cold-water treatment. This indicates that the effects of cold-water treatments

used on plant height were mediated by a different mechanism in this study, probably by inducing endogenous ethylene production (Biddington, 1986; Lanahan et al., 1994).

The influence of temperature on stem elongation has been studied with an emphasis on the effects of DIF treatment (Erwin and Heins, 1991, 1995). Such treatments require environmental control, and in addition, the degree of response varies with plant species, stage of plant development and the temperature difference (Berghage and Heins, 1991; Erwin and Heins, 1995; Moe et al., 1992). The DIF treatment is usually applied by ventilating the greenhouse with cool outside air at sunrise for 1 or 2 h and is used extensively in U.S. commercial plug production (Moe et al., 1992). In this study, we tested a simple method for controlling seedling growth that could also be used commercially. Tomato seedling height especially was reduced by irrigating with cold water. To our knowledge, this is the first report on controlling the height of greenhouse-grown containerized seedlings using a cold-water irrigation treatment.
