Distributed Symmetry Breaking in Sampling
(Optimal Distributed Randomly Coloring with Fewer Colors)

Weiming Feng ∗§ Thomas P. Hayes † Yitong Yin ‡§

Abstract

We examine the problem of almost-uniform sampling proper $q$-colorings of a graph whose maximum degree is $\Delta$. A famous result, discovered independently by Jerrum [31] and Salas and Sokal [39], is that, assuming $q > (2 + \delta)\Delta$, the Glauber dynamics (a.k.a. single-site dynamics) for this problem has mixing time $O(n \log n)$, where $n$ is the number of vertices, and thus provides a nearly linear time sampling algorithm for this problem. A natural question is the extent to which this algorithm can be parallelized. Previous work [15] has shown that a $O(\Delta \log n)$ time parallelized algorithm is possible, and that $\Omega(\log n)$ time is necessary.

We give a distributed sampling algorithm, which we call the Lazy Local Metropolis Algorithm, that achieves an optimal parallelization of this classic algorithm. It improves its predecessor, the Local Metropolis algorithm of Feng, Sun and Yin [PODC’17], by introducing a step of distributed symmetry breaking that helps the mixing of the distributed sampling algorithm.

For sampling almost-uniform proper $q$-colorings of graphs $G$ on $n$ vertices, we show that the Lazy Local Metropolis algorithm achieves an optimal $O(\log n)$ mixing time if either of the following conditions is true for an arbitrary constant $\delta > 0$:

- $q \geq (2 + \delta)\Delta$, on general graphs with maximum degree $\Delta$;
- $q \geq (\alpha^* + \delta)\Delta$, where $\alpha^* \approx 1.763$ satisfies $\alpha^* = e^{1/\alpha^*}$, on graphs with sufficiently large maximum degree $\Delta \geq \Delta_0(\delta)$ and girth at least 9.

1 Introduction

Sampling almost-uniform graph colorings is one of the most extensively studied problems in Markov chain Monte Carlo (MCMC) sampling. Let $G = (V, E)$ be a graph and $q$ a positive integer. A proper $q$-coloring $\sigma \in [q]^V$ of $G$ assigns each vertex a color from $[q] = \{1, 2, \ldots, q\}$ such that no adjacent vertices receive the same color. A classic sequential algorithm for sampling almost-uniform proper $q$-colorings is the Markov chain known as the heat bath Glauber dynamics (a.k.a. single-site dynamics) on proper $q$-colorings. For this Markov chain $(X_t)_{t \geq 0}$, each $X_t \in [q]^V$ is a $q$-coloring, and in a transition $X_t \to X_{t+1}$, a vertex $v \in V$ is chosen uniformly at random and its color $X_t(v)$ is updated to a color chosen uniformly at random from the available colors in $[q]$ that are not currently assigned by $X_t$ to $v$’s neighbors.

A famous result, discovered independently by Jerrum [31] and Salas and Sokal [39], is that, assuming $q > (2 + \delta)\Delta$, where $\Delta$ is the maximum degree and $\delta > 0$ is an arbitrary constant, the Glauber dynamics defined above has mixing time $O(n \log n)$, where $n$ is the number of vertices, and thus provides a nearly linear time sequential algorithm for sampling almost-uniform proper $q$-colorings. For graphs with large maximum degree and large girth, Dyer and Frieze [11] developed an approach, known as the burn-in method, to obtain $O(n \log n)$ mixing time of the Glauber dynamics with an improved condition $q \geq (\alpha^* + \delta)\Delta$, where $\alpha^* \approx 1.763$ satisfies $\alpha^* = e^{1/\alpha^*}$. Subsequently, the condition for the rapid mixing was improved in a series of works [42, 11, 29, 26, 37, 30, 19, 8]. See a survey of Frieze and Vigoda [20] for more detail.

In distributed computing, the problem of constructing a proper $q$-coloring by local distributed graph algorithms has been extensively studied [35, 23, 1, 36, 41, 38, 32, 33, 40, 3, 6, 2, 4, 18], and is a main application for distributed symmetry breaking [4]. These distributed algorithms assume the synchronous message-passing model of communications. The graph $G = (V, E)$ represents a communication network. Communications are synchronized and take place in rounds. In each round, each vertex receives messages from all neighbors, then performs the local computation, and finally sends messages to all neighbors. The time complexity is given by the number of rounds. Ideally, the sizes of messages are bounded in polylogarithmic of $|V|$ and the local computations are tractable.

On the other hand, the problem of sampling an almost-uniform proper $q$-coloring by local distributed algorithms received much less studies. A natural question is the extent to which the sequential sampling algorithms can be parallelized.

Continuous-time Glauber dynamics: Perhaps the most natural process to talk about as a starting point is the continuous-time Glauber dynamics. Each vertex gets an i.i.d. Poisson clock with expected delay 1; the vertex updates its color every time the clock rings. The relationship between continuous-time and discrete-time Markov chains is well understood, and there are very close connections between their mixing times; see, for instance, [34] [Theorem 20.3], and [28] [Corollary 2.2]. In our setting, we get that the mixing time for the continuous-time dynamics is very close to being a factor $n$ speedup of the discrete Glauber dynamics.

How fast can we simulate this chain in a distributed setting? Offhand, it looks potentially very tricky, since every now and then, there will be long chains of consecutive updates done in very short time intervals, each of which affects the next one. However, a simple disagreement percolation argument shows that, with high probability, the continuous-time Glauber dynamics can be simulated for time $t$ in a distributed setting, with one processor for each vertex, in the time needed for $O(t \Delta/n + \log(n))$ single-vertex updates, essentially an $n/\Delta$ factor of parallel speedup.
Assuming we are in a setting, such as $q > (2 + \delta)\Delta$, in which the discrete-time Glauber dynamics has mixing time $O(n \log n)$, this implies a local distributed algorithm with running time $O(\Delta \log n)$.

**Chromatic scheduler and systematic scans:** A natural way to parallelize single-site dynamics is to use a chromatic scheduler to parallelize the updates, so that updates in the same round will not affect each other. The idea was implemented in [25] and also by the LubyGlauber algorithm in a previous work [15]. The latter achieves a $O(\Delta \log n)$ mixing time under the condition $q \geq (2 + \delta)\Delta$, which is essentially due to the rapidly mixing of systematic scans [10, 9], in which vertices are updated sequentially according to an arbitrarily fixed order.

A fundamental issue of this type of approaches is: as a price for not allowing adjacent updates in the same round, a factor of chromatic number (or the maximum degree $\Delta$ for local distributed algorithms) is inevitably introduced to the time complexity.

**Local Metropolis filters:** In a previous work [15], a new parallel Markov chain, called the Local Metropolis algorithm is introduced. It falls into the propose-and-filter paradigm of the Metropolis-Hastings algorithm. In each step, every vertex independently proposes a random color and applies a local filtration rule to accept or reject the proposals. Assuming a stronger condition on the number of colors $q \geq (2 + \sqrt{2} + \delta)\Delta$, this new Markov chain achieves a $O(\log n)$ mixing time, beating the barrier of factor-$\Theta(\Delta)$ slowdown in previous approaches and achieving an ideal factor-$\Theta(n)$ speedup of the $O(n \log n)$ mixing time of Glauber dynamics. It was also proved in [15] that this $O(\log n)$ time complexity is optimal for sampling almost-uniform $q$-colorings by message-passing distributed algorithms as long as $q = O(\Delta)$. It seems that the drawback of this approach is its requirement of bigger number of colors.

### 1.1 Main results

We give a distributed MCMC sampling algorithm, called the Lazy Local Metropolis algorithm, for sampling almost-uniform proper $q$-colorings. The algorithm improves the Local Metropolis algorithm in [15] by introducing a step of symmetry breaking, and achieves the optimal $O(\log n)$ mixing time while assuming smaller lower bounds on the number of colors $q$.

For sampling almost-uniform proper $q$-colorings of graphs with maximum degree $\Delta$, assuming $q \geq (2 + \delta)\Delta$, the Lazy Local Metropolis chain is rapidly mixing with rate $\tau(\epsilon) = O(\log(\frac{n}{\epsilon}))$. Note that Fischer and Ghaffari [17] also obtain the same result independently and simultaneously. They prove this result by a different path coupling argument. See [17] for more details.

**Theorem 1.** For any constant $\delta > 0$, for every graph $G$ on $n$ vertices with maximum degree $\Delta = \Delta_G$, if $q \geq (2 + \delta)\Delta$, then given any $\epsilon > 0$, the Lazy Local Metropolis algorithm returns an almost uniform proper $q$-coloring of $G$ within total variation distance $\epsilon$ in $O(\log n + \log \frac{1}{\epsilon})$ rounds, where the constant factor in $O(\cdot)$ depends only on $\delta$.

For graphs with large girth and sufficiently large maximum degree, by an advanced coupling similar to the one developed by Dyer et al. for sequential dynamics [8], the condition on $q$ can be further relaxed.

**Theorem 2.** For any constant $\delta > 0$, there exists a constant $\Delta_0 = \Delta_0(\delta)$, such that for every graph $G$ on $n$ vertices with maximum degree $\Delta = \Delta_G$ and girth $g = g(G)$, if

- $\Delta \geq \Delta_0$ and $g \geq 9$,
• and $q \geq (\alpha^* + \delta)\Delta$, where $\alpha^* \approx 1.763$ satisfies $\alpha^* = e^{1/\alpha^*}$,

then given any $\epsilon > 0$, the Lazy Local Metropolis algorithm returns an almost uniform proper $q$-coloring of $G$ within total variation distance $\epsilon$ in $O(\log n + \log \frac{1}{\epsilon})$ rounds, where the constant factor in $O(\cdot)$ depends only on $\delta$.

The condition $q \geq (\alpha^* + \delta)\Delta$ matches the one achieved by Dyer et al. in [8] for the $O(n \log n)$-rapidly mixing of the Glauber dynamics on proper $q$-colorings of graphs with girth at least 5 and sufficiently large maximum degree. The threshold $q \geq (\alpha^* + \delta)\Delta$ has also appeared elsewhere variously, including: the strong spatial mixing of proper $q$-colorings of triangle-free graphs [24, 21], and rapid mixing of sequential Markov chains on proper $q$-colorings of graphs with large girth and sufficiently large maximum degree [12, 26, 30], neighborhood-amenable graphs [24], or Erdős-Rényi random graphs $G(n, \Delta/n)$ [13].

The Lazy Local Metropolis algorithm in above two theorems is communication- and computation-efficient: each message consists of at most $O(\log n)$ bits and all local computations are fairly cheap. In a concurrent work [16], through network decomposition [22, 38], a $O(\log^3 n)$-round algorithm is given for sampling proper $q$-colorings of triangle-free graphs with maximum degree $\Delta$ assuming $q \geq (\alpha^* + \delta)\Delta$, however, with messages of unbounded sizes and unbounded local computations.

Theorem 2 is proved by establishing a so-called local uniformity property for the Markov chain of the Lazy Local Metropolis algorithm. Similar properties have been analyzed by Hayes [27] for Glauber dynamics. This is perhaps the first time this property is proved on a chain other than Glauber dynamics, not to mention a chain as a distributed algorithm.

Due to a lower bound proved in [15], approximately sampling within total variation distance $\epsilon > 0$ from a joint distribution with exponential decay of correlations (which is the case for uniform proper $q$-colorings as long as $q = O(\Delta)$) requires $\Omega(\log n + \log \frac{1}{\epsilon})$ rounds of communications. Therefore, the time complexity $O(\log n + \log \frac{1}{\epsilon})$ in Theorem 1 and 2 is optimal.

Organization of the paper. Preliminaries are given in Section 2. The Lazy Local Metropolis algorithm is given in Section 3. Theorem 1 is proved in Section 4. The local uniformity property is proved in Section 5, with which Theorem 2 is proved in Section 6.

2 Preliminaries

2.1 Graph colorings

Let $G = (V, E)$ be an undirected graph. For any vertex $v \in V$, we use $\Gamma(v) = \{u \mid \{u, v\} \in E\}$ to denote the set of neighbors of $v$, and $\Gamma^+(v) = \Gamma(v) \cup \{v\}$ the inclusive neighborhood of $v$. Let $\deg(v) = |\Gamma(v)|$ denote the degree of $v$, and $\Delta = \Delta_G = \max_{v \in V} \deg(v)$ the maximum degree of $G$. For vertices $u, v \in V$, let $\text{dist}(u, v) = \text{dist}_G(u, v)$ denote the distance between $u$ and $v$ in $G$, which equals the length of the shortest path between $u$ and $v$ in graph $G$. For any integer $r \geq 0$ and vertex $v \in V$, the $r$-ball and $r$-sphere centered at $v$ are defined as $B_r(v) \triangleq \{u \in V \mid \text{dist}(u, v) \leq r\}$ and $S_r(v) \triangleq \{u \in V \mid \text{dist}(u, v) = r\}$, respectively.

Let $q$ be a positive integer. A $q$-coloring, or just coloring, is a vector $X \in [q]^V$. A coloring $X \in [q]^V$ is proper if for all edges $\{u, w\} \in E$, $X(u) \neq X(v)$. For any coloring $X \in [q]^V$ and subset $S \subseteq V$, we denote by $X(S)$ the set of colors used by $X$ on subset $S$, i.e. $X(S) \triangleq \{X(v) \mid v \in S\}$. 

For any two colorings $X, Y \in [q]^V$, we denote by $X \oplus Y$ the set of vertices on which $X, Y$ disagree:

$$X \oplus Y \triangleq \{v \in V \mid X(v) \neq Y(v)\}.$$  

The Hamming distance between two colorings $X, Y$ is $|X \oplus Y|$.

Let $\Omega = [q]^V$ be the set of all colorings of graph $G$. A uniform distribution over proper colorings of $G$ is a distribution $\mu$ over $\Omega$ such that for any coloring $X \in [q]^V$, $\mu(X) > 0$ if and only if $X$ is proper; and $\mu(X) = \mu(Y)$ for any two proper colorings $X, Y$.

### 2.2 Mixing rate and coupling

Let $\mu$ and $\nu$ be two distributions over $\Omega$, the total variation distance between $\mu$ and $\nu$ is defined as

$$d_{TV}(\mu, \nu) = \frac{1}{2} \sum_{\sigma \in \Omega} |\mu(\sigma) - \nu(\sigma)| = \max_{A \subseteq \Omega} |\mu(A) - \nu(A)|.$$  

Let $(X_t)_{t \geq 0}$ denote a Markov chain on a finite state space $\Omega$. Assume that the chain is irreducible and aperiodic, and is reversible with respect to the stationary distribution $\pi$. Then by the Markov chain Convergence Theorem [34], the chain $(X_t)_{t \geq 0}$ converges to the stationary distribution $\pi$. For the formal definitions of these concepts, we refer to the textbook [34].

Let $\pi^t_\sigma$ denote the distribution of $X_t$ when $X_0 = \sigma$. The mixing rate $\tau(\cdot)$ is defined as

$$\forall \epsilon > 0 : \quad \tau(\epsilon) \triangleq \max_{\sigma \in \Omega} \min \{t \mid d_{TV}(\pi^t_\sigma, \pi) \leq \epsilon\}.$$  

Let $(X_t)_{t \geq 0}, (Y_t)_{t \geq 0}$ be two Markov chains with the same transition rule. A coupling of the Markov chains is a joint process $(X_t, Y_t)_{t \geq 0}$ satisfying that $(X_t)$ and $(Y_t)$ individually follow the same transition rule as the original chain and $X_{t+1} = Y_{t+1}$ if $X_t = Y_t$. For any coupling $(X_t, Y_t)_{t \geq 0}$ of the Markov chains, the total variation distance between $\pi^t_\sigma$ and $\pi$ is bounded as

$$\max_{\sigma \in \Omega} d_{TV}(\pi^t_\sigma, \pi) \leq \max_{X_0, Y_0 \in \Omega} \Pr[X_t \neq Y_t].$$

The path coupling is a powerful engineering tool for constructing couplings.

**Lemma 3** (Bubley and Dyer [5]). Given a pre-metric, which is a weighted connected undirected graph on state space $\Omega$ such that all edge weights are at least 1 and every edge is a shortest path. Let $\Phi(X, Y)$ be the length of shortest path between states $X$ and $Y$ in pre-metric. Suppose that there is a coupling $(X, Y) \rightarrow (X', Y')$ of the Markov chain defined only for adjacent states $X, Y$ in pre-metric, which satisfies that

$$\mathbb{E} [\Phi(X', Y') \mid X, Y] \leq (1 - \delta) \Phi(X, Y),$$

for some $0 < \delta < 1$. Then the mixing rate of the Markov chain is bounded by

$$\tau(\epsilon) \leq \frac{1}{\delta} \log \left( \frac{\text{diam}(\Omega)}{\epsilon} \right),$$

where $\text{diam}(\Omega) = \max_{X, Y \in \Omega} \Phi(X, Y)$ stands for the diameter of $\Omega$ in the pre-metric.
3 The Lazy Local Metropolis Algorithm

In this section, we give the lazy local metropolis algorithm *ll-Metropolis* for uniform sampling random proper graph coloring.

The algorithm is a Markov chain. Let $G = (V, E)$ be a graph, $q$ a positive integer and $0 < p < 1$. The *ll-Metropolis chain with activeness $p$* on $q$-colorings of graph $G$, denoted as $(X_t)_{t \geq 0}$, is defined as follows. Initially $X_0 \in [q]^V$ is arbitrary (not necessarily a proper coloring). At time $t$, given the current coloring $X_t \in [q]^V$, the $X_{t+1}$ is constructed as follows:

- Each vertex $v \in V$ becomes active independently with probability $p$, otherwise it becomes lazy. Let $\mathcal{A} \subseteq V$ denote the set of active vertices.
- Each active vertex $v \in \mathcal{A}$ independently proposes a color $c(v) \in [q]$ uniformly at random.
- For each active edge $\{u, v\} \in E(\mathcal{A})$, where $E(\mathcal{A}) \triangleq \{\{u, v\} \in E \mid u \in \mathcal{A} \land v \in \mathcal{A}\}$, we say that the edge $\{u, v\}$ passes its check if and only if $c(u) \neq c(v) \land c(u) \neq X_t(v) \land X_t(u) \neq c(v)$. For each boundary edge $\{u, v\} \in \delta \mathcal{A}$, where $\delta \mathcal{A} \triangleq \{\{u, v\} \in E \mid u \notin \mathcal{A} \land v \in \mathcal{A}\}$ and $v \in \mathcal{A}$ is active, we say that the edge $\{u, v\}$ passes its check if and only if $c(v) \neq X_t(u)$.
- For each vertex $v \in V$, if $v$ is active and all edges incident to $v$ passed their checks, then $v$ accepts its proposed color and updates its color as $X_{t+1}(v) \leftarrow c(v)$; otherwise $X_{t+1}(v) \leftarrow X_t(v)$.

The algorithm terminates after $T$ iterations and outputs $X = (X_T(v))_{v \in V}$. The parameters $p$ and $T$ will be specified later. The pseudocode for the *ll-Metropolis* algorithm is given in Algorithm 1.

```
Algorithm 1: Pseudocode for the ll-Metropolis algorithm

Input: Each vertex $v \in V$ receives the set of colors $[q]$ and $0 < p < 1$ as input.

1 each $v \in V$ initializes $X(v)$ to an arbitrary color in $[q]$;

2 for $t = 1$ through $T$ do

3   foreach $v \in V$ do

4       become active independently with probability $p$, otherwise become lazy;

5   foreach active $v \in V$ do

6       propose a color $c(v) \in [q]$ uniformly at random;

7   foreach $\{u, v\} \in E$ where both $u$ and $v$ are active do

8       pass the check if $c(u) \neq c(v) \land c(u) \neq X(v) \land X(u) \neq c(v)$;

9   foreach $\{u, v\} \in E$ where $u$ is lazy and $v$ is active do

10      pass the check if $c(v) \neq X(u)$;

11   foreach $v \in V$ and $v$ is active do

12      if all edges incident to $v$ passed their checks then

13         $X(v) \leftarrow c(v)$;

14 return each $v \in V$;
```

Compared to the Local Metropolis chain proposed in [15], the *ll-Metropolis* chain allows each vertex to be lazy independently. It turns out this step is operation of symmetry breaking and is essential to the mixing of the parallel chain. We will see this in details in later sections.
Let $\mu$ denote the uniform distribution over proper colorings of graph $G = (V, E)$, and $\Delta$ the maximum degree of $G$. The following theorem guarantees that the ll-Metropolis chain converges to the correct stationary distribution $\mu$.

**Theorem 4.** For any $0 < p < 1$, the ll-Metropolis chain with activeness $p$ is reversible with stationary distribution $\mu$, and converges to the stationary distribution $\mu$ as long as $q \geq \Delta + 2$.

**Proof.** First, when $q \geq \Delta + 2$, in each iteration, each vertex $v$ with positive probability becomes the only active vertex in its neighborhood and successfully updates its color. Once a vertex $v$ being successfully updated, its color will not conflict with its neighbors and will keep in that way. Therefore, when $q \geq \Delta + 2$, the ll-Metropolis chain is absorbing to proper colorings.

Let $\Omega = [q]^V$ denote the state space and $P \in \mathbb{R}^{[q]^V \times [q]^V}$ the transition matrix for the ll-Metropolis chain. We will then verify the chain’s irreducibility among proper colorings and aperiodicity. For any two proper colorings $X, Y$, since $q \geq \Delta + 2$, we can construct a finite sequence of proper colorings $X = Z_0 \rightarrow Z_1 \rightarrow \ldots \rightarrow Z_\ell = Y$, such that $Z_i$ and $Z_{i+1}$ differ at a single vertex $v_i$. When the current coloring is $Z_i$, with positive probability, all vertices except $v_i$ are lazy, and $v_i$ proposes the color of $v_i$ in $Z_{i+1}(v_i)$, in which case the chain will move from coloring $Z_i$ to coloring $Z_{i+1}$. The chain is irreducible among proper colorings. On the other hand, due to the laziness, $P(X, X) > 0$ for all $X \in \Omega$, so the chain is aperiodic.

In the rest of the proof, we show that the following detailed balance equation is satisfied:

$$\forall X, Y \in \Omega : \quad \mu(X)P(X, Y) = \mu(Y)P(Y, X). \quad (1)$$

This will prove the reversibility of the chain with respect to the stationary distribution $\mu$. Together with the absorption to the proper colorings, the irreducibility among proper colorings, and the aperiodicity proved above, the theorem follows according to the Markov chain convergence theorem.

If both $X, Y$ are improper colorings, then $\mu(X) = \mu(Y) = 0$, the equation holds trivially. If precisely one of $X, Y$ is proper, say $X$ is a proper coloring and $Y$ is an improper coloring, then $X$ cannot move to $Y$ since at least one edge cannot pass its check, which implies $P(X, Y) = 0$. In both cases, the detailed balance equation holds.

Assume that $X, Y$ are both proper colorings. Consider a single move in the ll-Metropolis chain. Let $\mathcal{A}$ be the set of active vertices and $c \in [q]^\mathcal{A}$ be the colors proposed by active vertices. Given the current coloring, the next coloring of ll-Metropolis chain is fully determined by the pair $(\mathcal{A}, c)$.

Let $\Omega_{X\rightarrow Y}$ be the set of pairs $(\mathcal{A}, c)$ with which $X$ moves to $Y$. Given the current coloring $X$, the set of active vertices $\mathcal{A}$ and the colors $c$ proposed by active vertices, we say a vertex $v$ is **non-restricted** under the tuple $(\mathcal{A}, c)$ if and only if $v$ is active and all edges incident to $v$ can pass their checks. Let $\mathcal{S}(X, \mathcal{A}, c)$ denote the the set of non-restricted vertices. Note that vertex $v$ accepts its proposed color if and only if $v \in \mathcal{S}(X, \mathcal{A}, c)$. Let $\Delta_{X,Y} = \{v \in V \mid X(v) \neq Y(v)\}$ denote the set of vertices on which $X, Y$ disagree. Hence, each $(\mathcal{A}, c) \in \Omega_{X\rightarrow Y}$ satisfies:

- $\Delta_{X,Y} \subseteq \mathcal{S}(X, \mathcal{A}, c)$.
- $\forall v \in \mathcal{S}(X, \mathcal{A}, c) : c(v) = Y(v)$.

Similar holds for $\Omega_{Y\rightarrow X}$, the set of pairs $(\mathcal{A}, c)$ with which $Y$ moves to $X$. Then we have

$$\frac{P(X, Y)}{P(Y, X)} = \frac{\sum_{(\mathcal{A}, c) \in \Omega_{X\rightarrow Y}} \Pr[\mathcal{A}] \Pr[c | \mathcal{A}]}{\sum_{(\mathcal{A}', c') \in \Omega_{Y\rightarrow X}} \Pr[\mathcal{A}'] \Pr[c' | \mathcal{A}']} \quad (2)$$

6
In order to verify the detailed balance equation, we construct a bijection $\phi_{X,Y} : \Omega_{X\to Y} \to \Omega_{Y\to X}$, and for each pair $(A, c) \in \Omega_{X\to Y}$, denote $(A', c') = \phi_{X,Y}(A, c)$. Then, we show that

$$\Pr[A] \Pr[c \mid A] = \Pr[A'] \Pr[c' \mid A'].$$

Since $\mu(X) = \mu(Y)$, then combining (2) and (3) proves the detailed balance equation (1).

The bijection $\phi_{X,Y} : \Omega_{X\to Y} \to \Omega_{Y\to X}$ is constructed as follows:

- $A' = A$.
- $\forall v \in A \cap S(X, A, c)$: since $(A, c) \in \Omega_{X\to Y}$ it must hold $c(v) = Y(u)$, then set $c'(v) = X(v)$.
- $\forall v \in A \setminus S(X, A, c)$: since $(A, c) \in \Omega_{X\to Y}$ it must hold $X(v) = Y(v)$, then set $c'(v) = c(v)$.

Note that the laziness and random proposed colors are fully independent. Since $A = A'$, then

$$\Pr[A] \Pr[c \mid A] = (1 - p)^{|A| - |A'|} \left(\frac{p}{q}\right)^{|A|} = (1 - p)^{|A|} \left(\frac{p}{q}\right)^{|A'|},$$

which proves equation (3). We finish the proof of reversibility by showing that $\phi_{X,Y}$ is indeed a bijection from $\Omega_{X\to Y}$ to $\Omega_{Y\to X}$.

Consider the move from $X$ to $Y$ with pair $(A, c)$. For each edge $\{u, v\} \in E(A) \cup \delta A$, define the indicator variable $\text{pass}(u, v, X, A, c)$ indicating whether edge $\{u, v\}$ passes its check under the tuple $(X, A, c)$. Note that $X(u) \neq X(v)$ because $X$ is a proper coloring, we have

$$\text{pass}(uv, X, A, c) = \begin{cases} 1 & \text{if } uv \in E(A) \\ 1 - p^{\delta(A)} & \text{if } uv \in \delta A \text{ and } v \in A \\ \prod_{x \in \{c(u), c(v), X(u), X(v)\}} 1(x) & \text{if } uv \in E(A) \\ \prod_{x \in \{c(v), X(v)\}} 1(x) & \text{if } uv \in \delta A \text{ and } v \in A. \end{cases}$$

Similarly, for each edge $\{u, v\} \in E(A') \cup \delta A'$, note that $A' = A$, we have

$$\text{pass}(uv, Y, A', c') = \begin{cases} \prod_{x \in \{c'(u), Y(u)\}} 1(x) & \text{if } uv \in E(A) \\ 1 & \text{if } uv \in \delta A \text{ and } v \in A. \end{cases}$$

According to the definition of $\phi_{X,Y}$, it must hold that $\{c(v), X(v)\} = \{c'(v), Y(v)\}$; $\{c(u), X(u)\} = \{c'(u), Y(u)\}$ if $u$ is active; $X(u) = Y(u)$ if $u$ is lazy, which implies $\text{pass}(uv, X, A, c) = \text{pass}(uv, Y, A', c')$. Hence, it holds that $S(X, A, c) = S(Y, A', c')$, with which we can easily verify that $(A', c') \in \Omega_{Y\to X}$ and $\phi_{X,Y} = \phi^{-1}_{Y,X}$. This proves that $\phi_{X,Y}$ is a bijection from $\Omega_{X\to Y}$ to $\Omega_{Y\to X}$.

\[\square\]

4 Mixing When $q \geq (2 + \delta)\Delta$ on General Graphs

In this section, we analyze the mixing time for the ill-Metropolis chain for proper $q$-colorings on general graphs. We show that the chain mixes within $O(\log n)$ rounds under the Dobrushin’s condition $q \geq (2 + \delta)\Delta$, even when the maximum degree $\Delta$ is unbounded.
Theorem 5. For all $\delta > 0$, there exists $C = C(\delta)$, such that for every graph $G$ on $n$ vertices with maximum degree $\Delta$, if $q \geq (2 + \delta)\Delta$, then the mixing rate of the ll-Metropolis chain with activeness $p = \min\{\frac{\delta}{n}, \frac{1}{n}\}$ on $q$-colorings of graph $G$ satisfies
\[
\tau(\epsilon) \leq C \log \frac{n}{\epsilon}.
\]

The mixing rate is proved by a path coupling with respect to the Hamming distance. Compared to the coupling based on disagreement percolation for a non-lazy version of the chain in [15], where the disagreement may percolate to distant vertices within one step, our new coupling is local, as within one step the disagreement can at most contaminate the adjacent vertices. Thanks to the symmetry breaking due to the independent laziness, this local coupling achieves a much better mixing condition than the one achieved in [15] with a much shorter analysis.

The local coupling: Assume $X, Y \in [q]^V$ to be two colorings (not necessarily proper) that differ only at one vertex $v_0$. Without loss of generality, we assume $X(v_0) = \text{Red}$, $Y(v_0) = \text{Blue}$.

We then construct a coupling $(X, Y) \rightarrow (X', Y')$. Given the current coloring $X$, the random coloring of the next step $X'$ is determined by the random choice of $(A_X, c_X)$ where $A_X$ is the set of active vertices and $c_X \in [q]^{A_X}$ is the vector of colors proposed by active vertices. The coupling of the chain $(X, Y) \rightarrow (X', Y')$ is then specified by a coupling of the random choices $(A_X, c_X)$ and $(A_Y, c_Y)$ of the two chains, which is described as follows:

1. First, the laziness is coupled identically. Each vertex $v \in V$ becomes active in both chains, independently with probability $p$. Let $\mathcal{A} = A_X = A_Y$ denote the set of active vertices.

2. Then, the random proposals $(c_X, c_Y)$ for the active vertices in $\mathcal{A}$ are coupled step by step as follows. Recall that $\Gamma(v_0)$ denotes the set of neighbors of $v_0$.

(a) For every active vertex $v \notin \Gamma(v_0)$, the random proposals $(c_X(v), c_Y(v))$ are coupled identically such that $c_X(v) = c_Y(v) = c(v) \in [q]$ is sampled uniformly and independently.

(b) For every active vertex $v \in \Gamma(v_0)$, if at least one of the following conditions is satisfied, the random proposals $(c_X(v), c_Y(v))$ are coupled identically:

- for at least one of $v$'s neighbor $u \neq v_0$, the current color satisfies that $X(u) = Y(u) \in \{\text{Red}, \text{Blue}\}$;
- for at least one of $v$'s active neighbor $u \notin \Gamma(v_0)$, the random proposal already sampled as in Step 2a has $c_X(u) = c_Y(u) \in \{\text{Red}, \text{Blue}\}$.

For all other active vertices $v \in \Gamma(v_0)$, the random proposals $(c_X(v), c_Y(v))$ are coupled identically except with the roles of Red and Blue switched in the two chains.

With the random choices $(A_X, c_X)$ and $(A_Y, c_Y)$ coupled as above, the colorings $(X', Y')$ of the next step are constructed following the rules of the ll-Metropolis chain described in Algorithm 1.

It is easy to verify this is a valid coupling of the ll-Metropolis chain, as in each individual chain $X$ or $Y$, each vertex $v$ becomes active independently with probability $p$ and proposes a random color $c(v) \in [q]$ uniformly and independently.

The following observations for the coupling can be verified by case analysis.

Observation 6. The followings hold for the coupling constructed above:
For each vertex $u \neq v_0$ that $X_u = Y_u \in \{\text{Red}, \text{Blue}\}$, all its active neighbors $w \in \Gamma(u) \cap A$ sample $(c^X_w, c^Y_w)$ consistently.

For each active vertex $u \in \Gamma(v_0)$, $c^X_u = c^Y_u$ if and only if there exists a vertex $w \in \Gamma(u)$, such that $X_w = Y_w \in \{\text{Red}, \text{Blue}\}$ or $c^X_w = c^Y_w \in \{\text{Red}, \text{Blue}\}$.

For each vertex $u \neq v_0$, the event $X'_u \neq Y'_u$ occurs only if $u \in A$ and $(c^X_u, c^Y_u) \subseteq \{\text{Red}, \text{Blue}\}$.

Proof. The first two observations are easy to verify. We prove the last one.

If $u$ is lazy, then $X'_u = X_u = Y_u = Y'_u$ holds trivially. We then assume that vertex $u$ is active. Supposed $\{c^X_u, c^Y_u\} \not\subseteq \{X_{v_0}, Y_{v_0}\}$, then regardless of which distribution $(c^X_u, c^Y_u)$ is sampled from, it must hold that $c^X_u = c^Y_u \not\subseteq \{X_{v_0}, Y_{v_0}\}$. Supposed $c^X_u = c^Y_u \not\subseteq \{X_{v_0}, Y_{v_0}\}$, we prove that each edge $uw \in E$ passes its check in chain $X$ if and only if $uw$ passes its check in chain $Y$. Note that $X_u = Y_u$. This implies the contradictory result $X'_u = Y'_u$.

There are two cases for vertex $u \neq v_0$:

• Case: $X_u = Y_u \in \{X_{v_0}, Y_{v_0}\}$. In this case, by the first observation, for each $w \in \Gamma(u)$, it holds that
  1. either $\{X_w, Y_w\} = \{X_{v_0}, Y_{v_0}\}$ or $X_w = Y_w$;
  2. if $w$ is active, then $c^X_w = c^Y_w$.

Since we assume that $c^X_u = c^Y_u \not\subseteq \{X_{v_0}, Y_{v_0}\}$, then edge $uw$ passes its check in chain $X$ if and only if $uw$ passes its check in chain $Y$.

• Case: $X_u = Y_u \not\subseteq \{X_{v_0}, Y_{v_0}\}$. In this case, since permuted distribution only swaps the roles of $X_{v_0}$ and $Y_{v_0}$, then for each $w \in \Gamma(u)$. It holds that
  1. either $\{X_w, Y_w\} = \{X_{v_0}, Y_{v_0}\}$ or $X_w = Y_w$;
  2. if $w$ is active, then either $(c^X_w, c^Y_w) = \{X_{v_0}, Y_{v_0}\}$ or $c^X_w = c^Y_w$.

Since we assume that $c^X_u = c^Y_u \not\subseteq \{X_{v_0}, Y_{v_0}\}$, then edge $uw$ passes its check in chain $X$ if and only if $uw$ passes its check in chain $Y$.

The following lemma bounds the discrepancy at each vertex in $(X', Y')$.

Lemma 7. For vertex $v_0$ at which the two colorings $X, Y \in [q]^V$ differ, it holds that

$$\Pr[X'(v_0) = Y'(v_0) \mid X, Y] \geq \frac{p(q - \Delta)}{q} \left(1 - \frac{3p}{q}\right)^\Delta.$$  \hspace{1cm} (4)

For any vertex $u \in \Gamma(v_0)$, it holds that

$$\Pr[X'(u) \neq Y'(u) \mid X, Y] \leq \frac{p}{q}. $$ \hspace{1cm} (5)

For any vertex $w \in V \setminus \Gamma^+(v_0)$, it holds that

$$\Pr[X'(w) \neq Y'(w) \mid X, Y] = 0.$$ \hspace{1cm} (6)
Proof. The event $X'(v_0) = Y'(v_0)$ occurs if following events occur simultaneously:

- Vertex $v_0$ is active, which happens with probability $p$.
- $c_X(v_0) \notin \{X(u) \mid u \in \Gamma(v_0)\}$ (hence $c_Y(v_0) \notin \{Y(u) \mid u \in \Gamma(v_0)\}$) due to $c_X(v_0) = c_Y(v_0)$ and $X(u) = Y(u)$ for all $u \in \Gamma(v_0)$. Since $v_0$ has at most $\Delta$ neighbors, this event occurs with probability at least $\frac{2-\Delta}{q}$ conditioning on the occurrence of the previous event.
- For every vertex $u \in \Gamma(v_0)$, either $u$ is lazy in both chains or $c_X(u) \notin \{\text{Red}, \text{Blue}, c_X(v_0)\}$ (hence regardless of whether $(c_X(u), c_Y(u))$ is coupled identically or with Red/Blue switched, it must hold that $c_Y(u) \notin \{\text{Red}, \text{Blue}, c_Y(v_0)\}$ by the coupling). Since each vertex becomes lazy and proposes color independently and $v_0$ has at most $\Delta$ neighbors, this event occurs with probability at least $\left(1 - p + p\frac{2-\Delta}{q}\right)^\Delta = \left(1 - \frac{3p}{q}\right)^\Delta$ conditioning on the occurrences of previous events.

Inequality (4) then follows by the chain rule.

For each $u \in \Gamma(v_0)$, by Observation 6, the event $X'(u) \neq Y'(u)$ occurs only if $u$ is active and $\{c_X(u), c_Y(u)\} \subseteq \{\text{Red}, \text{Blue}\}$. Vertex $u$ becomes active with probability $p$. Assuming that $u$ is active, we prove inequality (5) by exhausting the two cases:

- **Case 1:** $(c_X(u), c_Y(u))$ are coupled identically. Note that the event $X'(u) \neq Y'(u)$ occurs only if $\{c_X(u), c_Y(u)\} \subseteq \{\text{Red}, \text{Blue}\}$. However, by the part two of Observation 6, there must exist $w \in \Gamma(u)$ such that $X(w) = Y(w) \in \{\text{Red}, \text{Blue}\}$ or $c_X(w) = c_Y(w) \in \{\text{Red}, \text{Blue}\}$. Without loss of generality, assume that $X(w) = Y(w) = \text{Red}$ (other cases follow by symmetry). If $c_X(u) = c_Y(u) = \text{Red}$, then the edge $\{u, w\}$ cannot pass its check in either chain, which implies $X'(u) = X(u) = Y(u) = Y'(u)$. Thus, the event $X'(u) \neq Y'(u)$ occurs with probability at most $\frac{1}{q}$ conditioning on $u$ being active.

- **Case 2:** $(c_X(u), c_Y(u))$ are coupled with the roles of Red/Blue switched. Note that the event $X'(u) \neq Y'(u)$ occurs only if $\{c_X(u), c_Y(u)\} \subseteq \{\text{Red}, \text{Blue}\}$. However, if $c_X(u) = \text{Red} = X(v_0)$ and $c_Y(u) = \text{Blue} = Y(v_0)$, then the edge $\{u, v_0\}$ cannot pass its check neither in chain $X$ nor in chain $Y$, which implies $X'(u) = X(u) = Y(u) = Y'(u)$. Thus, the event $X'(u) \neq Y'(u)$ occurs with probability at most $\frac{1}{q}$ conditioning on $u$ being active.

Combining the two cases we have the inequality (5).

Now we prove (6). If $w$ is at distance 3 or more from $v_0$, then for all vertices $u \in \Gamma^+(w)$, it holds that $X(u) = Y(u)$; and furthermore, for all vertices $u \in \Gamma^+(w) \cap A$, it holds that $c_X(u) = c_Y(u)$, which implies $X'(w) = Y'(w)$. If $w$ is at distance 2 from $v_0$, then by Observation 6, the event $X'(w) \neq Y'(w)$ occurs only if $w$ is active and $\{c_X(w), c_Y(w)\} \subseteq \{\text{Red}, \text{Blue}\}$. Note that $w$ must propose color identically in the two chains. If $c_X(w) = c_Y(w) \in \{\text{Red}, \text{Blue}\}$, then by the coupling all vertices $u \in \Gamma^+(w) \cap A$ must propose color identically in the two chains. Note that for all vertices $u \in \Gamma^+(w)$, it holds that $X(u) = Y(u)$. Combining them together we have $X'(w) = Y'(w)$.

**Proof of Theorem 5.** Combining (4), (5) and (6) in Lemma 7 together and due to linearity of
expectation, we have
\[
\mathbb{E} \left[ |X' \oplus Y'| \mid X, Y \right] = \sum_{v \in V} \Pr[X'(v) \neq Y'(v) \mid X, Y] = \Pr[X'(v_0) \neq Y'(v_0) \mid X, Y] + \sum_{u \in \Gamma(v_0)} \Pr[X'(u) \neq Y'(u) \mid X, Y]
\leq 1 - \frac{p(q - \Delta)}{q} \left( 1 - \frac{3p}{q} \right)^\Delta + \frac{p\Delta}{q}
\]
\[
(q \geq (2 + \delta)\Delta) \leq 1 - p \left( \frac{1 + \delta}{2 + \delta} \left( 1 - \frac{3p}{(2 + \delta)\Delta} \right)^\Delta - \frac{1}{2 + \delta} \right).
\]
(Assume \( p \leq 1/2 \))

The last inequality is due to Bernoulli’s inequality \((1 + x)^r \geq 1 + rx \) for \( r \geq 1 \) and \( x \geq -1 \). For \( p = \min\{\frac{\delta}{3}, \frac{1}{2}\} \), it holds that
\[
\mathbb{E} \left[ |X' \oplus Y'| \mid X, Y \right] \leq \begin{cases} 
1 - \frac{\delta^2}{3(2+3)^2} & \text{if } \delta \leq \frac{3}{2}, \\
1 - \frac{2\delta^2 - \delta}{4(2+3)^2} & \text{if } \delta > \frac{3}{2}.
\end{cases}
\]

The Hamming distance between two colorings is at most \( n \). By the path coupling lemma 3, the mixing rate is \( \tau(\epsilon) = O(\log n + \log \frac{1}{\epsilon}) \), where the constant in \( O(\cdot) \) depends only on \( \delta \).

\[\square\]

5 Local Uniformity for Parallel Chain

In this section, we establish the so-called local uniformity property for the \( ll\)-Metropolis chain, with which we can prove Theorem 2 i.e. the mixing condition with few colors in graphs with large girth and large maximum degree.

To properly state this property for colorings, we need to define the notion of available colors.

**Definition 8.** Let \( G = (V, E) \) be a graph, and \( X \in [q]^V \) an arbitrary coloring, not necessarily proper. For any vertex \( v \in V \), the set of available colors at \( v \) under coloring \( X \) is defined as
\[
A(X, v) = [q] \setminus X(\Gamma(v)),
\]
where \( X(\Gamma(v)) = \{X_u \mid u \in \Gamma(v)\} \) is the set of colors used by \( v \)'s neighbors in the coloring \( X \).

Inequality (4) of the worst-case path coupling in last section can be generalized to:
\[
\Pr[X'(v_0) = Y'(v_0) \mid X, Y] \geq \frac{p \cdot |A(X, v_0)|}{q} \left( 1 - \frac{3p}{q} \right)^\Delta,
\]
where the inequality (4) is actually obtained by applying this general inequality with the naive bound \( |A(X, v_0)| \geq q - \Delta \) for the worst case colorings \( X, Y \).

When the current coloring \( X \) is produced by a Markov chain, especially after running for a while, it is conceivable that the number of available colors \( |A(X, v)| \) at each vertex \( v \) with high probability is much bigger than this worst case lower bound, and is closer to that in a uniform
random coloring, which is \( \approx q e^{-\deg(v)/q} \). This is guaranteed by the local uniformity properties established for the respective chains. More precisely, the local uniformity properties are a number of “local” properties of graph coloring which holds with high probability for a uniformly random coloring [27]. Here in particular, what we need is the lower bound on the number of available colors. The following theorem states a local uniformity for the \( \text{ll-Metropolis} \) chain on graphs with girth at least 9 and sufficiently large maximum degree.

**Theorem 9** (\( \text{ll-Metropolis} \) local uniformity). For all \( \delta > 0, 0 < \zeta < \frac{1}{10}, 0 < p < \frac{1}{2} \), there exists \( \Delta_0 = \Delta_0(p, \delta, \zeta), C = C(\delta, \zeta) \), such that for all graphs \( G = (V, E) \) with maximum degree \( \Delta \geq \Delta_0 \) and girth at least 9, all \( q \geq (1 + \delta)\Delta \), the following holds. Let \( (X_t)_{t \geq 0} \) be the \( \text{ll-Metropolis} \) chain with activeness \( p \) for \( q \)-colorings on graph \( G \). For any \( v \in V \),

\[
\Pr \left[ \forall t \in [t_0, t_\infty] : \frac{A(X_t, v)}{q} \geq (1 - 10\zeta)e^{-\deg(v)/q} \right] \geq 1 - \exp(-\Delta/C),
\]

where \( t_0 = \frac{1}{p} \left( \frac{1+\delta}{\delta} \right)^2 \ln \frac{1}{\zeta} \) and \( t_\infty = \exp(\Delta/C) \).

This is the first local uniformity result proved for a parallel chain. In fact, to the best of our knowledge, all previous local uniformity results were established for Glauber dynamics. Compared to typical local uniformity results [27, 14], the parallel chain acquires the local uniformity much faster: after \( O(1) \) steps instead of \( O(n) \) steps, and a \( t_\infty = \exp(\Delta/C) \) (instead of \( n \exp(\Delta/C) \)) is sufficient for applying the local uniformity in proving the mixing rate. Meanwhile, we need a bigger girth (\( \geq 9 \)) to deal with the local dependencies between adjacent vertices in the parallel chain.

The rest of this section is dedicated to the proof of this theorem.

### 5.1 The \( \text{ll-Metropolis} \) chain on a modified graph \( G^* \)

In order to prove the local uniformity property in Theorem 9, we construct a modified graph \( G^* \) and define a \( \text{ll-Metropolis} \) chain on the modified graph \( G^* \). We will show a local uniformity property for this process on \( G^* \). Then Theorem 9 can be proved by comparing the original \( \text{ll-Metropolis} \) chain on \( G \) with this modified process on \( G^* \).

Consider an undirected graph \( G = (V, E) \) with girth at least 9. Fix any vertex \( v \in V \). The graph \( G^* \) is a mixed graph, meaning that it has both directed and undirected edges. The mixed graph \( G^* \) is obtained by replacing all the undirected edges within the ball of radius 4 centered at \( v \) with directed edges towards \( v \). Since the girth of \( G \) is at least 9, each directed edge has a unique direction. The remaining edges in graph \( G \) are preserved and kept undirected in \( G^* \).

**Definition 10.** Let \( r \geq 1 \) and \( G = (V, E) \) an undirected graph with girth at least \( 2r + 1 \). Fix any vertex \( v \in V \). Let \( G_{in}(v, r) \) denote the mixed graph \( G^* = (V, E^*, F^*) \) with vertex set \( V \), undirected edge set \( E^* \), and directed edge set \( F^* \), where

- \( E^* = \{ \{u, w\} \in E \mid \text{dist}_G(v, u) > r \lor \text{dist}_G(v, w) > r \lor \text{dist}_G(v, u) = \text{dist}_G(v, w) = r \} \),
- \( F^* = \{ (u, w) \mid \{u, w\} \in E \land \text{dist}_G(v, w) < \text{dist}_G(v, u) \leq r \} \).

In particular, let \( G = (V, E) \) be an undirected graph with girth at least 9. Fix an arbitrary \( v \in V \). We define \( G^* = G_{in}(v, 4) \).
For any vertex $u$ in graph $G^*$, we define

$$\Gamma_{\text{un}}(u) \triangleq \{w \mid \{u, w\} \in E^*\},$$

$$\Gamma_{\text{in}}(u) \triangleq \{w \mid (w, u) \in F^*\},$$

$$\Gamma_{\text{out}}(u) \triangleq \{w \mid (u, w) \in F^*\}.$$

We have $\Gamma(u) = \Gamma_{\text{un}}(u) \cup \Gamma_{\text{in}}(u) \cup \Gamma_{\text{out}}(u)$ for the set of neighbors $\Gamma(u)$ of $u$ in $G^*$ (and also in $G$).

The $ll$-Metropolis chain $(X_t^*)_{t \geq 0}$ on $q$-colorings of graph $G^* = G_{\text{in}}(v, 4)$ is defined as follows. Initially, $X_0^* \in [q]^V$ is arbitrary. Given the current coloring $X_t^* \in [q]^V$, the $X_{t+1}^*$ is obtained as:

- Each vertex $u \in V$ becomes active independently with probability $p$, otherwise it becomes lazy. Let $A^* \subseteq V$ denote the set of active vertices.

- Each active vertex $u \in A^*$ independently proposes a color $c^*(u) \in [q]$ uniformly at random.

- For each vertex $u \in A^*$, for each $w \in \Gamma(u)$, we say that the pair $(u, w)$ passes the check initiated at $u$ if and only if

$$\begin{cases}
    c^*(u) \neq c^*(w) \land c^*(u) \neq X_t^*(w) \land X_t^*(u) \neq c^*(w) & \text{if } w \in A^* \text{ and } w \in \Gamma_{\text{un}}(u) \cup \Gamma_{\text{in}}(u), \\
    c^*(u) \neq X_t^*(w) & \text{if } w \notin A^* \text{ and } w \in \Gamma_{\text{un}}(u) \cup \Gamma_{\text{in}}(u), \\
    c^*(u) \neq c^*(w) \land X_t^*(u) \neq c^*(w) & \text{if } w \in A^* \text{ and } w \in \Gamma_{\text{out}}(u), \\
    \text{always pass check} & \text{if } w \notin A^* \text{ and } w \in \Gamma_{\text{out}}(u).
\end{cases}$$

- Let $R^* \subseteq A^*$ denote the subset of active vertices $u$ such that $\forall w \in \Gamma(u)$, the pair $(u, w)$ passed the check initiated at $u$. The coloring $X_{t+1}^* \in [q]^V$ at time $t + 1$ is constructed as

$$X_{t+1}^*(u) = \begin{cases}
    c^*(u) & \text{if } u \in R^*, \\
    X_t^*(u) & \text{if } u \notin R^*.
\end{cases}$$

Note that the original $ll$-Metropolis chain in Algorithm 1 can be seen as a special case of the above process when $\Gamma(u) = \Gamma_{\text{un}}(u)$ and $\Gamma_{\text{in}}(u) = \Gamma_{\text{out}}(u) = \emptyset$ for every vertex $u \in V$.

The only differences between this new Markov chain $(X_t^*)_{t \geq 0}$ on $G^*$ and the original $ll$-Metropolis chain $(X_t)_{t \geq 0}$ on graph $G$ are the trimmed local Metropolis filters on outgoing directed edges. Consider a directed edge $(u, w)$ in graph $G^*$. Vertex $u$ updates its color oblivious to the current color of vertex $w$. This makes the $ll$-Metropolis chain on graph $G^*$ not reversible, and may move from proper colorings to improper ones. Nevertheless, this $ll$-Metropolis chain on graph $G^*$ has two nice features. First, the random colors assigned to $u \in \Gamma(v)$ are conditional independent, which helps establishing the local uniformity property (proved in Section 5.2). Second, there is a coupling between this new process and the original $ll$-Metropolis chain on $G$ that preserves the local uniformity (proved in Section 5.3).

### 5.2 Local uniformity for the $ll$-Metropolis chain on $G^*$

We prove a local uniformity property for the $ll$-Metropolis chain on the modified graph $G^*$, in terms of the lower bound on the number of available colors. For the mixed graph $G^*$, we override the definition of the set of available colors $A(X, u)$ in (7) by assuming $\Gamma(u) = \Gamma_{\text{un}}(u) \cup \Gamma_{\text{in}}(u) \cup \Gamma_{\text{out}}(u)$.
Lemma 11. For all $\delta, \ell, \zeta > 0, 0 < p < 1/2$, there exists $\Delta_1 = \Delta_1(\ell, p, \delta, \zeta)$, such that for all graphs $G = (V, E)$ with maximum degree $\Delta \geq \Delta_1$ and girth at least 9, all $q \geq (1 + \delta)\Delta$, the following holds. Fix any vertex $v \in V$ and let $G^*_v = G_{in}(v, 4)$.

Let $(X_t^v)_{t \geq 0}$ be the $ll$-Metropolis chain with activeness $p$ for $q$-colorings on graph $G^*_v$.

$$\Pr\left[|A(X_t^v, v)| \geq (q - \ell) \left(\frac{1 - \gamma}{e}\right)^{d_g(v)/(q - \ell)} - \zeta q\right] \geq 1 - \exp(-\zeta^2 q/2),$$

where

$$\gamma = \exp\left(-p\left(\frac{\delta}{1 + \delta}\right)^2 \ell\right) + \frac{1}{q} \left(\frac{1 + \delta}{\delta}\right)^2.$$

To prove the lemma, we need Chernoff bounds of various forms.

Theorem 12 (Chernoff bound). Let $X_1, X_2, \ldots, X_n \in \{0, 1\}$ be mutually independent or negatively associated random variables, let $X = \sum_{i=1}^{n} X_i$ and $\mu = \mathbb{E}[X]$. For any $\delta > 0$, it holds that

$$\Pr[X \geq (1 + \delta)\mu] \leq \left(\frac{e^\delta}{(1 + \delta)^{1+\delta}}\right)^{\mu} \leq \left(\frac{e}{1 + \delta}\right)^{(1+\delta)\mu}.$$  \hspace{1cm} (8)

In particular, if $k \geq e^2 \mu$, then

$$\Pr[X \geq k] \leq \exp(-k).$$  \hspace{1cm} (9)

Let $t > 0$, it holds that

$$\Pr[X \leq \mu - t] \leq \exp\left(-\frac{2t^2}{n}\right).$$  \hspace{1cm} (10)

We also need the following technical lemma due to Dyer and Frieze [11], and refined by Hayes [27] for proving the local uniformity property for Glauber Dynamics. We use a slightly modified version here, which says that for a sequence of independent random colors, if there exists a subset of colors, in which no color is very likely to be sampled in any step, then with high probability, there are many missed colors. The proof is very similar to the ones in [11] and [27], which we include here for completeness.

Lemma 13 (Dyer and Frieze). Let $q, s$ be positive integers, and let $c_1, \ldots, c_s$ be independent (but not necessarily identically distributed) random variables taking values in $[q]$. Let $S \subseteq [q]$ with size $|S| = m$. Suppose that there is a $\gamma < 1$ such that $\Pr[c_i = j] \leq \gamma$ for every $1 \leq i \leq s$ and $j \in S$. Let $A = [q] \setminus \{c_1, \ldots, c_s\}$ be the set of missed colors. Then

$$\mathbb{E}[|A|] \geq m(1 - \gamma)^{s/m} \geq m \left(\frac{1 - \gamma}{e}\right)^{s/m},$$

and for every $a > 0$, $\Pr[|A| \leq \mathbb{E}[|A|] - a] \leq e^{-a^2/2q}$. 

14
Proof. For each $1 \leq i \leq s$ and $1 \leq j \leq q$, let random variable $\eta_{ij}$ indicate the event $c_i = j$, thus

$$|A| = \sum_{j=1}^{q} \prod_{i=1}^{s} (1 - \eta_{ij}).$$

By the linearity of expectation and the independence of the colors $c_i$, we have

$$\mathbb{E} [|A|] = \sum_{j=1}^{q} \prod_{i=1}^{s} (1 - \mathbb{E} [\eta_{ij}])$$

$$(0 \leq \eta_{ij} \leq 1) \geq \sum_{j \in S} \prod_{i=1}^{s} (1 - \mathbb{E} [\eta_{ij}])$$

(AM-GM inequality) $\geq m \prod_{i=1}^{s} \prod_{j \in S} (1 - \mathbb{E} [\eta_{ij}])^{\frac{1}{m}}$.

Note that for each $1 \leq i \leq s$, it holds that $\sum_{j \in S} \mathbb{E} [\eta_{ij}] = \sum_{j=1}^{q} \mathbb{E} [\eta_{ij}] = 1$ and for all $j \in S$, $0 \leq \mathbb{E} [\eta_{ij}] \leq \gamma$. For each $1 \leq i \leq s$, suppose that $\sum_{j \in S} \mathbb{E} [\eta_{ij}] = \beta_i \leq 1$, the minimum of the $\prod_{j \in S} (1 - \mathbb{E} [\eta_{ij}])$ is achieved when as many as possible of $\mathbb{E} [\eta_{ij}]$ equal $\gamma$, hence

$$\prod_{j \in S} (1 - \mathbb{E} [\eta_{ij}]) \geq (1 - \gamma)^{\frac{\beta_i}{\gamma}} (1 - (\beta_i - \gamma \beta_i / \gamma))$$

$$(r = \beta_i / \gamma - \lfloor \beta_i / \gamma \rfloor < 1) = \frac{(1 - \gamma)^{\beta_i / \gamma}}{(1 - \gamma)^r} (1 - \gamma r)$$

$$(*) \geq (1 - \gamma)^{\beta_i / \gamma}$$

$$(\beta_i \leq 1) \geq (1 - \gamma)^{1 / \gamma},$$

where $(*)$ is due to Bernoulli’s inequality $(1 + x)^t \leq 1 + xt$ when $0 \leq t \leq 1$ and $x \geq -1$. Thus

$$\mathbb{E} [|A|] \geq m (1 - \gamma)^{s / m \gamma} \geq m \left(\frac{1 - \gamma}{e}\right)^{s / m}.$$

For each $1 \leq i \leq s$, since $\sum_{j=1}^{q} \eta_{ij} = 1$, the random 0-1 variables $\eta_{i1}, \eta_{i2}, \ldots, \eta_{iq}$ are negatively associated. Since the color choices are mutually independent, then all $\eta_{ij}$ are negatively associated. Because decreasing functions of disjoint subsets of a family of negatively associated variables are also negatively associated [7], the $q$ random variables $\{\prod_{i=1}^{s} (1 - \eta_{ij})\}_{1 \leq j \leq q}$ are negatively associated. Then by the Chernoff bound for negatively associated variables (10), for every $a > 0$ it holds that $\Pr[|A| \leq \mathbb{E} [|A|] - a] \leq e^{-a^2 / 2q}$. \hfill \Box

Proof of Lemma 11. Recall that $B_r(v) \subseteq V$ and $S_r(v) \subseteq V$ denote the $r$-ball and $r$-sphere centered at vertex $v$ in graph $G$, which contains the same set of vertices as the $r$-ball in $G^*$. And we use notation $\Gamma^+(v)$ denote $\Gamma(v) \cup \{v\}$.

Let $\mathcal{F}$ denote the random choices for the laziness and proposed colors of all vertices in $(V \setminus B_2(v)) \cup \{v\}$ during the time interval $[1, \ell]$ in the chain $(X_t^*)_{t \geq 0}$. Note that given any $\mathcal{F}$, the followings hold.
• For all vertices in $V \setminus B_3(v)$, the whole procedure of $ll$-Metropolis on graph $G^*$ during the time interval $[0, t]$ is fully determined. Because the procedure outside the ball $B_3(v)$ requires no information in $B_3(v)$ except the laziness and the random proposed colors of vertices in $S_3(v)$, which are given by condition $F$.

• The laziness and random proposed colors of vertex $v$ are given by condition $F$.

• The subgraph reduced by $B_3(v)$ is a tree because the girth of graph is at least 9.

Hence, given the condition $F$, for each vertex $u \in \Gamma(v)$, the random color $X^*_t(u)$ only depends on the random choices of laziness and proposed colors of vertices $w \in \Gamma^+(u) \setminus \{v\}$ during $[1, \ell]$. Since the laziness and proposed colors are fully independent, then given condition $F$, the neighbor colors $X^*_t(u)$ for $u \in \Gamma(v)$ are conditionally fully independent.

Next, we describe the conditional distribution of $X^*_t(u)$ given $F$, where $u$ is a neighbor of $v$. Let $S_F$ be the set of colors proposed by vertex $v$ during the time interval $[1, \ell]$, which is uniquely determined by the condition $F$. For each color $c \in [q] \setminus S_F$, we bound the probability of the event $X^*_t(u) = c$. We say vertex $u$ successfully updates its color at step $t$ if and only if $u$ accepts its proposed color at step $t$. The event $X^*_t(u) = c$ occurs only if one of following two events occurs.

• Vertex $u$ never successfully updates its color in time interval $[1, \ell]$ and $X^*_0(u) = c$. Then, in each step $t$, $X^*_t(u) = c$. Note that $c \notin S_F$, which implies the color proposed by $v$ cannot coincide with color $c$. Thus, the event that $u$ successfully updates its color at step $t$ occurs if following three events occur simultaneously:

1. vertex $u$ is not lazy at step $t$, which occurs with probability $p$;
2. vertex $u$ proposes a color $\sigma$ such that $\sigma \notin X^*_{t-1}(\Gamma(w) \setminus \{v\})$ and $\sigma$ does not coincide with the color proposed by $v$ if $v$ is not lazy at step $t$, which occurs with probability at least $(q - \Delta)/q$ condition on previous event;
3. each vertex $w \in \Gamma(u) \setminus \{v\}$ either becomes lazy or does not propose $X^*_{t-1}(u) = c$ or $\sigma$, which occurs with probability at least $(1 - 2p/q)^\Delta$ condition on previous events.

Thus, the probability that $u$ successfully updates its color at each step $t$ is at least

$$\frac{p(q - \Delta)}{q} \left(1 - \frac{2p}{q}\right)^\Delta \geq \frac{p^\delta}{1 + \delta} \left(1 - \frac{2p}{(1 + \delta)\Delta}\right)^\Delta$$

(p < 1/2)

where $(\ast)$ is because Bernoulli’s inequality $(1 + x)^r \geq 1 + rx$ for $r \geq 1$ and $x \geq -1$. Hence, the probability of the event that $X^*_0(u) = c$ and $u$ never successfully updates its color in the time interval $[1, \ell]$ is at most

$$\left(1 - p \left(\frac{\delta}{1 + \delta}\right)^2\right)^\ell \leq \exp\left(-p \left(\frac{\delta}{1 + \delta}\right)^2 \ell\right).$$

• Vertex $u$ successfully updates its color in the time interval $[1, \ell]$, and at the last time when $u$ successfully updates its color, $u$ updates it into color $c$. For each $1 \leq i \leq \ell$, let $\mathcal{U}_i$ be the event
that vertex $u$ successfully updates its color into $c$ at time $i$ and $u$ never makes any successful update during $[i+1, \ell]$. Then this event is $\bigcup_{1 \leq i \leq \ell} U_i$. The event $U_i$ occurs only if vertex $u$ is not lazy and proposes color $c$ at step $t$ and $u$ never successfully updates its color during $[i+1, \ell]$. The event $U_i$ implies $X_t(u) = c$ for all $i + 1 \leq t \leq \ell$, thus we have

$$\Pr[U_i \mid F] \leq \frac{p}{q} \left(1 - p \left(\frac{\delta}{1 + \delta}\right)^2\right)^{\ell - i}.$$ 

Take a union bound over all $1 \leq i \leq \ell$, we have

$$\Pr\left[\bigcup_{1 \leq i \leq \ell} U_i \mid F\right] \leq \frac{p}{q} \sum_{i=1}^{\ell} \left(1 - p \left(\frac{\delta}{1 + \delta}\right)^2\right)^{\ell - i} \leq \frac{1}{q} \left(\frac{1 + \delta}{\delta}\right)^2.$$

Combine two cases together and use the union bound, we have

$$\Pr[X^*_t(u) = c \mid F] \leq \exp\left(-p \left(\frac{\delta}{1 + \delta}\right)^2 \ell\right) + \frac{1}{q} \left(\frac{1 + \delta}{\delta}\right)^2.$$

Recall that the above probability bound holds for all color $c \in [q] \setminus S_F$. Note that $|[q] \setminus S_F| \geq q - \ell$ because the size of $S_F$ is at most $\ell$. Apply Lemma 13 with $\gamma = \exp\left(-p \left(\frac{\delta}{1 + \delta}\right)^2 \ell\right) + \frac{1}{q} \left(\frac{1 + \delta}{\delta}\right)^2$, $a = \zeta q$, $m = q - \ell$ and $s = \deg(v)$. Note that if we take $\Delta > \frac{1 + \delta}{\delta^{(1 - \exp(-\rho \delta^2 \ell/(1 + \delta)^2))}}$, then $\gamma < 1$; if we take $\Delta > \frac{\ell}{1 + \delta}$, then $m > 0$. Thus, for $\Delta$ sufficiently large, we have

$$\Pr\left[|A(X^*_t, v)| \leq (q - \ell) \left(\frac{1 - \gamma}{e}\right)^{\deg(v)/(q - \ell)} - \zeta q \mid F\right] \leq \exp(-\zeta^2 q/2).$$

Finally, by the law of total probability, summing over all conditions $F$ yields

$$\Pr\left[|A(X^*_t, v)| \leq (q - \ell) \left(\frac{1 - \gamma}{e}\right)^{\deg(v)/(q - \ell)} - \zeta q\right] \leq \exp(-\zeta^2 q/2).$$

\[ \square \]

### 5.3 Comparison of the ll-Metropolis chains

Next, we show that there is a coupling between the ll-Metropolis chains respectively on $G$ and $G^*$ that preserves the local uniformity.

**Lemma 14.** For all $C, \delta, \zeta > 0, 0 < p < 1$, there exists $\Delta_2 = \Delta_2(C, p, \delta, \zeta)$, such that for all graphs $G = (V, E)$ with maximum degree $\Delta \geq \Delta_2$ and girth at least 9, all $q \geq (1 + \delta)\Delta$, the following holds. Fix any vertex $v \in V$ and let $G^* = G_{in}(v, 4)$. Let $(X_t)_{t \geq 0}$ and $(X^*_t)_{t \geq 0}$ be the ll-Metropolis chains with activeness $p$ for $q$-colorings on $G$ and $G^*$ respectively, where $X_0 = X^*_0 \in [q]^V$. There exists a coupling $(X_t, X^*_t)_{t \geq 0}$ of the processes $(X_t)_{t \geq 0}$ and $(X^*_t)_{t \geq 0}$ such that

$$\Pr[\forall t \leq C, \forall u \in V : \left|(X_t \oplus X^*_t) \cap \Gamma(u)\right| \leq \zeta \Delta] \geq 1 - \exp(-\Delta).$$
Proof. Define the identical coupling \((X_t, X_t')\) as follows: In each step, two chains sample the same active vertex set \(A = A^*\) and all active vertices propose the same random colors \(c = c^*\).

Let random variable \(D_{\leq t} = \bigcup_{t' \leq t} (X_t' \oplus X_t')\) denote the set of all disagreeing vertices appeared before time \(t\). We prove the Lemma by showing that with probability at least \(1 - \exp(-\Delta)\), for all \(u \in V\), it holds that \(|D_{\leq t} \cap \Gamma(u)| \leq \zeta \Delta\).

Let \(R = C + 6\). The bad events \(B_1\) and \(B_2\) defined as follows:
\[
\begin{align*}
B_1 & : \quad D_{\leq t} \not\subseteq B_{R-3}(v); \\
B_2 & : \quad |D_{\leq t}| \geq \Delta^{13/4}.
\end{align*}
\]
we then show that \(B_1\) can never occur and \(B_2\) occurs with very small probability.

We begin by showing that disagreements cannot percolate outside the ball \(B_{R-3}(v)\), i.e.:
\[
\Pr[B_1] = 0. \tag{11}
\]
Consider any vertex \(u \notin B_1(v)\). Since no directed edge is incident to \(u\) in graph \(G^*\), then the updating rule for vertex \(u\) is identical in two chains. Vertex \(u\) becomes a new disagreeing vertex at step \(t\) only if there exists a vertex \(w \in \Gamma(u)\), such that \(X_{t-1}(w) \neq X_{t-1}^*(w)\). Since \(X_0 = X_0^*\), then it must hold that \(D_{\leq t} \subseteq B_1(v)\). Furthermore, for all \(t \geq 1\), it must hold that \(D_{\leq t} \subseteq B_{t+3}(v)\). In particular, \(D_{\leq C} \subseteq B_{C+3}(v)\), which implies (11).

To bound the probability of bad event \(B_2\), consider the random variable
\[
\mathcal{N}(D_t) = |(X_t \oplus X_t') \setminus (X_{t-1} \oplus X_{t-1}^*)|,
\]
which gives the number of new disagreements contributed at time \(t\). Any \(u\) with \(X_{t-1}(u) = X_{t-1}^*(u)\) but becomes a disagreement at time \(t\) only if it is incident to following two types of bad edges:

- **Type-1 bad edge:** An undirected edge \(\{u, w\} \in F^*\) or a directed edge \((w, u) \in F^*\) such that \(X_{t-1}(w) \neq X_{t-1}^*(w)\). For such bad edges, \(u\) becomes a new disagreement only if \(u\) is active at time \(t\) and proposes \(X_{t-1}(w)\) or \(X_{t-1}^*(w)\).
- **Type-2 bad edge:** A directed edge \((u, w) \in F^*\). For such bad edges, \(u\) becomes a new disagreement only if \(u\) is active at time \(t\) and proposes \(X_{t-1}(w)\). In this case, the pair \((u, w)\) may pass the check initiated at vertex \(u\) in chain \(X^*\) but the undirected edge \(\{u, w\}\) cannot pass the check in chain \(X\).

Suppose vertex \(u\) is incident to \(k\) bad edges, then the probability that \(u\) becomes a new disagreement is at most \(2kp/q\). Since the maximum degree is at most \(\Delta\) and \(|F^*| \leq \Delta^4\), then the total number of bad edges is at most \(\Delta |D_{\leq t-1}| + \Delta^4\). Hence, we have
\[
\mathbb{E}\left[\mathcal{N}(D_t) \mid D_{\leq t-1}\right] \leq \frac{2p(\Delta |D_{\leq t-1}| + \Delta^4)}{1 + \delta} \leq \frac{2p(|D_{\leq t-1}| + \Delta^3)}{1 + \delta}.
\]
Furthermore, the laziness and proposed colors are mutually independent, which implies \(\mathcal{N}(D_t)\) is stochastically dominated by the sum of independent random 0-1 variables. Then by the Chernoff bound (9), together with \(|D_{\leq t}| \leq |D_{\leq t-1}| + \mathcal{N}(D_t)\) we have
\[
\Pr\left[D_{\leq t} \geq |D_{\leq t-1}| + \frac{20p(|D_{\leq t-1}| + \Delta^3)}{1 + \delta} \mid D_{\leq t-1}\right] \leq \Pr\left[\mathcal{N}(D_t) \geq \frac{20p(|D_{\leq t-1}| + \Delta^3)}{1 + \delta} \mid D_{\leq t-1}\right]
\]
(Chevron bound) \quad \leq \exp\left(-\frac{20p(|D_{\leq t-1}| + \Delta^3)}{1 + \delta}\right) \quad \leq \exp(-\Delta^2),
\]
Solving above recurrence, we have

\[
\begin{cases}
|D_{<t}| \leq |D_{<t-1}| + 20p(|D_{<t-1}| + \Delta^3)/(1 + \delta) & \forall 1 \leq t \leq C \\
|D_0| = 0
\end{cases}
\]

Hence, with probability at least \(1 - C \exp(-\Delta^2)\), it holds that

\[
\Pr \left[ \forall 1 \leq t \leq C : |D_{\leq t}| \leq \Delta^3 \left( \frac{20p}{1 + \delta} + 1 \right)^{t} - \Delta^3 \right] \geq 1 - C \exp(-\Delta^2).
\]

If we take \(\Delta > \left( \left( \frac{20p}{1 + \delta} + 1 \right)^{C} - 1 \right)^{4}\), then it holds that \(\Delta^{13/4} > \Delta^3 \left( \frac{20p}{1 + \delta} + 1 \right)^{C} - \Delta^3\). Thus

\[
\Pr[B_2] = \Pr \left[ |D_{\leq C}| \geq \Delta^{13/4} \right] \leq \Pr \left[ |D_{\leq C}| \geq \Delta^3 \left( \frac{20p}{1 + \delta} + 1 \right)^{C} - \Delta^3 \right] \leq C \exp(-\Delta^2). \tag{12}
\]

Finally, we define four more bad events \(C_1, C_2, C_3, C_4\) as follows

- \(C_4 : \exists u \in V : |D_{\leq C} \cap B_4(u)| \geq \Delta^{13/4} = \Delta^{3 + 1/4}\).
- For \(k \in \{2, 3\}\), define \(C_k = \left( \bigcap_{k \leq j \leq 4} \overline{C_j} \right) \cap \{ \exists u \in V : |D_{\leq C} \cap B_k(u)| \geq \Delta^{k-1+1/k} \} \).
- \(C_1 : \left( \bigcap_{1 \leq j \leq 4} \overline{C_j} \right) \cap \{ \exists u \in V : |D_{\leq C} \cap \Gamma(u)| \geq \zeta \Delta \} \).

If none of bad events \(C_1, C_2, C_3, C_4\) occurs, then for all \(u \in V : |D_{\leq C} \cap \Gamma(u)| < \zeta \Delta\). Thus we prove the Lemma by bounding the probability of bad events \(C_1, C_2, C_3, C_4\).

Note that the bad event \(C_4\) implies the bad event \(B_2\), thus by (12) we have

\[
\Pr[C_4] \leq \Pr[B_2] \leq C \exp(-\Delta^2). \tag{13}
\]

For \(k = 1, 2, 3\) we show that the bad event \(C_k\) occurs with low probability. Assuming that none of events \(C_j\) with \(j > k\) occurs, otherwise the bad event \(C_k\) can not occur. Fix a vertex \(u \in V\), let random variable \(Z = |D_{\leq C} \cap B_k(u)|\) count the number of disagreements formed in \(B_k(u)\) during time interval \([0, C]\). Let random variable \(Z_t = |(X_t \oplus X_t^*) \setminus (X_{t-1} \oplus X_{t-1}^*) \cap B_k(u)|\) count the number of new disagreements in \(B_k(u)\) generated at step \(t\). Since \(X_0 = X_0^*\), then \(Z \leq \sum_{t=1}^{C} Z_t\). By (11), any disagreements can not percolate outside the ball \(B_{R-3}(v)\) which implies \(Z = 0\) if \(u \notin B_R(v)\). Assuming \(u \in B_R(v)\), let us bound the expected value of each \(Z_t\). As is stated in previous proof, a vertex \(w \in B_k(u)\) satisfies \(X_{t-1}(w) = X_{t-1}^*(w)\) but becomes a disagreement at step \(t\) only if vertex \(w\) is incident to bad edges, vertex \(w\) is active at step \(t\) and vertex \(w\) proposes specific colors (which are determined by bad edges). We bound the total number of two types of bad edges incident to vertices in \(B_k(u)\) at step \(t\) as follows:

- Type-1 bad edges within \(B_k(u)\): There are at most \(\Delta^k\) edges with both endpoints in \(B_k(u)\). Each of these edges should be counted as a bad edge at most once, because we only consider the type of bad edges that join an existing disagreement to a vertex \(w \in B_k(u)\) such that \(X_{t-1}^*(w) = X_{t-1}(w)\).
• Type-1 bad edges at the boundary of $B_k(u)$: Since none of bad events $C_j$ with $j > k$ occurs, then there are at most $\Delta^{k+1/(k+1)}$ disagreements in $B_{k+1}(u) \setminus B_k(u)$. Each of disagreements has at most one neighbor in $B_k(u)$ because the girth is at least 9. There are at most $\Delta^{k+1+1/k}$ such bad edges in total.

• Type-2 bad edges: For each vertex $w \in B_k(u)$ such that $X^*_{t-1}(w) = X_{t-1}(w)$, the event that $w$ becomes a new disagreement at step $t$ may be caused by a directed edge $(w, w')$ in graph $G^*$. By the definition of graph $G^*$, there is at most one such edge incident to each vertex $w$. Hence, the total number of such edges is at most $\Delta^k$.

Thus, the expected value of random variable $Z_t$ is upper bounded by

$$\mathbb{E}[Z_t] \leq \frac{2p(2\Delta + \Delta^{k+1/(k+1)})}{q} \leq \frac{2p(2\Delta^{k-1} + \Delta^{k-1+1/(k+1)})}{1 + \delta}.$$ 

Further, the laziness and proposed colors are fully independent, which implies $Z_t$ is stochastically dominated by the sum of independent random 0-1 variables. For $k \in \{2, 3\}$, if we take large $\Delta$ such that $\Delta^{1/k} \geq \frac{20Cp(2+\Delta^{1/(k+1)})}{1+\delta}$, then $\Delta^{k+1+1/k} \geq 10\mathbb{E}[Z_t]$. Thus by Chernoff bound (9), we have

$$\operatorname{Pr}\left[Z \geq \Delta^{k-1+1/k}\right] \leq \operatorname{Pr}\left[\exists t : Z_t \geq \frac{\Delta^{k-1+1/k}}{C}\right] \leq C \exp\left(-\frac{\Delta^{k-1+1/k}}{C}\right) \leq \exp(-\Delta \log \Delta).$$

The last equality holds when $\Delta$ is sufficiently large such that $\Delta^{3/2} \geq C \ln C + C \Delta \log \Delta$. For $k = 1$, we use Chernoff bound (8), then

$$\operatorname{Pr}\left[Z \geq \zeta\Delta\right] \leq \operatorname{Pr}\left[\exists t : Z_t \geq \frac{\zeta\Delta}{C}\right] \leq C \left(\frac{2Ce(2 + \Delta^{1/2})}{\zeta(1 + \delta)\Delta}\right)^{\zeta\Delta/C} = \exp\left(-\Omega(\Delta \log \Delta)\right),$$

where the constant factor in $\Omega(\cdot)$ depends only on $C, p, \delta, \zeta$. For $k = 1, 2, 3$, take a union bound over the $\Delta^R = \Delta^{C+6}$ vertices $u \in B_R(v)$, then

$$k = 1, 2, 3 : \quad \operatorname{Pr}[C_k] = \Delta^{C+6} \exp(-\Omega(\Delta \log \Delta)) = \exp(-\Omega(\Delta \log \Delta)), \quad (14)$$

where the constant factor in nation $\Omega(\cdot)$ depends only on $C, p, \delta, \zeta$. Summing the bounds in inequalities (13) and (14) completes the proof.

### 5.4 Proof of local uniformity (Theorem 9)

Finally, the local uniformity property for the $ll$-Metropolis chain on graph $G$ can be proved by combining Lemma 11 and Lemma 14.

Let $\ell = \frac{1}{p} \left(\frac{1 + \delta}{\delta}\right)^2 \ln \frac{1}{\zeta}$. Remark that $\ell$ is determined by $p, \delta, \zeta$. Consider any time $T \in [t_0, t_\infty]$, where $t_0 = \ell$ and $t_\infty = \exp(\Delta/C)$. Fix any coloring $X_{T-\ell}$ at time $(T - \ell)$, we apply the identical coupling $(X_t, X^*_t)$ for $T - \ell \leq t \leq T$ from the same initial coloring $X_{T-\ell} = X^*_{T-\ell}$, where $X^*$ is given by the $ll$-Metropolis chain on graph $G^* = G_{in}(v, 4)$. Note that, during the coupling, the $ll$-Metropolis on graph $G^*$ starts from the coloring $X_{T-\ell}$ and runs for $\ell$ steps. By Lemma 11, if $\Delta \geq \Delta_1(\ell, p, \delta, \zeta) = \Delta_1(p, \zeta, \delta)$, then with probability at least $1 - \exp\left(-\zeta^2(1 + \delta)\Delta/2\right)$, we have

$$|A(X^*_T, v)| > (q - \ell) \left(\frac{1 - \gamma}{e}\right)^{\deg(v)/(q-\ell)} - \zeta q, \quad (15)$$
where γ = \exp\left(-p\left(\frac{\delta}{1+\delta}\right)^2\ell \right) + \frac{1}{q}\left(\frac{1+\delta}{\delta}\right)^2. By the definition of \ell, if we take Δ ≥ \frac{1+\delta}{\zeta\delta^2}, then ζ ≤ γ ≤ 2ζ. Note that γ < 1 because ζ < 1/10. Furthermore, it holds that
\[ \Delta > \frac{2\ell}{(\delta + 1)\zeta} \implies \frac{q - \ell}{q} ≥ 1 - \zeta/2. \] (16)

It can be verified that there exists Δ' = Δ'(γ, ζ, p) such that if Δ ≥ Δ', it holds that
\[ \left(1 - \frac{\gamma}{e}\right)^{\deg(v)/(q-\ell)} ≥ \left(1 - \frac{2\zeta}{e}\right)^{\frac{\ell}{(1+\delta)(q-\ell)}} ≥ 1 - \zeta/2. \] (17)

Combining (16), (17) together, if Δ ≥ \max\left\{\frac{1+\delta}{\zeta\delta^2}, \Delta' \right\}, then it holds that
\[ (q - \ell)\left(1 - \frac{\gamma}{e}\right)^{\deg(v)/(q-\ell)} ≥ (1 - \zeta/2)q\left(1 - \frac{\gamma}{e}\right)^{\deg(v)/q}. \] (18)

Combining (15) and (18) implies
\[ \frac{|A(X_T^*, v)|}{q} > (1 - \zeta/2)^2\left(1 - \frac{\gamma}{e}\right)^{\deg(v)/q} - \zeta \]
\[ (\deg(v) < q) \geq (1 - \zeta)(1 - \gamma)e^{-\deg(v)/q} - \zeta \]
\[ (\gamma < 2\zeta) ≥ (1 - 3\zeta)e^{-\deg(v)/q} - \zeta. \] (19)

Two chains are coupled for \ell steps. Note that \ell is determined by \(p, \delta, \zeta\). By Lemma 14, if Δ ≥ Δ_2(ℓ, p, \delta, ζ) = Δ_2(p, \delta, ζ), then with probability at least 1 − \exp(−Δ), it holds that
\[ |A(X_T, v)| ≥ |A(X_T^*, v)| - \zeta Δ. \]

Thus, condition on any coloring \(X_{T-\ell}\), with probability at least 1 − \exp(−ζ^2(1 + \delta)Δ/2) − \exp(−Δ), it holds that
\[ \frac{|A(X_T, v)|}{q} ≥ \frac{|A(X_T^*, v)|}{q} - \frac{\zeta Δ}{q} \]

(By (19) and q > Δ)
\[ ≥ (1 - 3\zeta)e^{-\deg(v)/q} - 2\zeta \]
\[ (q > \deg(v)) ≥ (1 - 10\zeta)e^{-\deg(v)/q}. \]

By the law of total probability, summing over all possible coloring \(X_{T-\ell}\) implies
\[ \Pr\left[ \frac{|A(X_T, v)|}{q} ≤ (1 - 10\zeta)e^{-\deg(v)/q} \right] ≤ \exp\left(−\zeta^2(1 + \delta)\Delta/2\right) + \exp(−Δ) \]
\[ (C' = 2/\min\{\zeta^2(1 + \delta)/2, 1\}) \leq 2\exp(-2\Delta/C') \]
\[ (\Delta ≥ C'\ln 2) \leq \exp(−\Delta/C'). \]

Finally, let \(C = 2C'\). The theorem is proved by taking a union bound over all the steps \(T ∈ [t_0, t_∞]\), where \(t_0 = \ell \left(\frac{1+\delta}{\delta}\right)^2 \ln \frac{1}{\zeta}\) and \(t_∞ = \exp(\Delta/C)\).
6 Coupling with Local Uniformity

In this section, we use local uniformity property to avoid the worst case analysis in (4) and obtain a better mixing condition for graphs with girth at least 9 and maximum degree is greater than a sufficiently large constant.

We define the constant $\alpha^* \approx 1.763$ to be the positive solution of

$$\alpha^* = e^{1/\alpha^*}.$$ 

We consider $q$-colorings of graphs $G$ with maximum degree $\Delta$, where $q \geq (\alpha^* + \delta)\Delta$ for an arbitrary constant $\delta > 0$. Without loss of generality we assume $\delta < 0.3$ because bigger $\delta$ is already covered by Theorem 5 on general graphs.

**Theorem 15.** For all $0 < \delta < 0.3$, there exists $\Delta_3 = \Delta_3(\delta)$, $C' = C'(\delta)$, such that for every graph $G$ on $n$ vertices with maximum degree $\Delta \geq \Delta_3$ and girth $\geq 9$, if $q \geq (\alpha^* + \delta)\Delta$, then the mixing rate of the ll-Metropolis chain with activeness $p = \frac{\delta}{30}$ on $q$-colorings of graph $G$ satisfies

$$\tau(\epsilon) \leq C' \log \frac{n}{\epsilon}.$$ 

Given the local uniformity property guaranteed by Theorem 9, the mixing rate in above theorem is proved by following a similar framework as in [8]. We modify the framework to make it adaptive to the parallel chain, where the experiments carried on in a time scale of $O(n)$ steps in a sequential chain, are now in $O(1)$ steps, and a disagreement may percolate to many vertices in one step.

We begin with constructing a grand coupling of the ll-Metropolis as below.

### 6.1 Coupling of arbitrary pair of colorings

In Section 4, we give a local coupling $(X, Y) \rightarrow (X', Y')$ for $X, Y$ that differ only at a single vertex. Here, we use the path coupling to extend this coupling to a coupling of arbitrary pair of colorings.

Let $X, Y \in [q]^V$ be an arbitrary pair of colorings, not necessarily proper. Suppose that $X$ and $Y$ differ on precisely $\ell$ vertices $v_1, v_2, \ldots, v_\ell$. A sequence of colorings $X = Z_0 \rightarrow Z_1 \rightarrow \ldots \rightarrow Z_\ell = Y$ is constructed as follows: for every $0 \leq i \leq \ell$,

$$Z_i(v) = \begin{cases} X(v) = Y(v) & \text{if } v \notin (X \oplus Y), \\ X(v) & \text{if } v \in (X \oplus Y) \land v \in \{v_j \mid i < j \leq \ell\}, \\ Y(v) & \text{if } v \in (X \oplus Y) \land v \in \{v_j \mid 1 \leq j \leq i\}. \end{cases}$$

Each coloring $Z_i$ is not necessarily proper, and $Z_{i-1} \oplus Z_i = \{v_i\}$. A coupling $(X, Y) \rightarrow (X', Y')$ is then constructed by the path coupling:

- Sample a pair $(X', Z'_1)$ of colorings according to the local coupling $(X, Z_1) \rightarrow (X', Z'_1)$ defined in Section 4.

- For $i = 2, 3, \ldots, \ell$, conditioning on the sampled coloring $Z'_{i-1}$, sample coloring $Z'_i$ according to the local coupling $(Z_{i-1}, Z_i) \rightarrow (Z'_{i-1}, Z'_i)$ defined in Section 4. Finally, let $Y' = Z'_\ell$.

Note that the local coupling in Section 4 is constructed by coupling active vertex set and random proposed colors. Hence, a sequence of active vertex sets and random proposed colors $(A_{Z_i}, c_{Z_i})$ for $0 \leq i \leq \ell$ is constructed by the above process.
Observation 16. Let $X, Y \in [q]^V$ be two colorings, and $X \oplus Y$ the set of vertices on which $X$ and $Y$ disagree. The followings hold for the coupling $(X, Y) \rightarrow (X', Y')$ defined above:

1. If $\text{dist}_G(v, X \oplus Y) \geq 2$, then $X'(v) = Y'(v)$.
2. If $\text{dist}_G(v, X \oplus Y) = 1$, then $X'(v) \neq Y'(v)$ occurs only if vertex $v$ is active and proposes color $c_X(v) \notin \{ X(u), Y(u) \mid u \in \Gamma(v) \cap (X \oplus Y) \}$ in chain $X$.

Proof. By the local coupling defined in Section 4, two chains $X$ and $Y$ must select the same set of active vertices. If vertex $v \notin X \oplus Y$ is lazy in chain $X$, then it must be lazy in chain $Y$, which implies that $X'(v) = Y(v) = Y'(v)$.

Assume that vertex $v$ is active in chain $X$. We prove a stronger Claim which implies both claims in the observation:

Claim. If $v \notin (X \oplus Y)$ and $c_X(v) \notin \{ X(u), Y(u) \mid u \in \Gamma(v) \cap (X \oplus Y) \}$, then it must hold that $X(v) = Y(v)$ and $c_X(v) = c_Y(v)$.

Note that if $\text{dist}_G(v, X \oplus Y) \geq 2$, then $c_X(v) \notin \emptyset$ holds trivially. Thus it covers the first part of the Observation. Suppose that $|X \oplus Y| = k$, we prove it by induction on $k$.

• Base case $k = 1$. Suppose $X \oplus Y = \{ v_1 \}$. If $\text{dist}_G(v, X \oplus Y) \geq 2$, then by (6) in Lemma 7, we have $X'(v) = Y(v)$, and by construction of the coupling, it holds that $c_X(v) = c_Y(v)$. If $\text{dist}_G(v, X \oplus Y) = 1$, then by Observation 6, $X'(v) \neq Y'(v)$ occurs only if $\{ c_X(v), c_Y(v) \} \subseteq \{ X(v_1), Y(v_1) \}$. If $c_X(v) \notin \{ X(v_1), Y(v_1) \}$, then $X'(v) = Y'(v)$ and $c_X(v) = c_Y(v)$ regardless of which distribution $(c_X(v), c_Y(v))$ is sampled from.

• Suppose the Claim holds for all pairs of colorings that differ on no more than $k$ vertices. For any $X, Y$ differ at $k + 1$ vertices, consider the coloring sequence $X = Z_0 \sim \ldots \sim Z_{k+1} = Y$. Then $(X', Z'_k)$ is sampled from the coupling $(X, Z_k) \rightarrow (X', Z'_k)$ and $Y'$ is sampled from the coupling $(Z_k, Y) \rightarrow (Z'_k, Y')$ condition on $Z'_k$. Note that $v \notin (X \oplus Y)$ implies $v \notin (X \oplus Z_k)$ and $v \notin (Z_k \oplus Y)$. Since $v \notin (X \oplus Z_k)$ and $c_X(v) \notin \{ X(u), Z_k(u) \mid u \in \Gamma(v) \cap (X \oplus Z_k) \}$, then by I.H., it must hold that $X'(v) = Z'_k(v)$ and $c_X(v) = c_{Z_k}(v)$. Further, since $v \notin (Z_k \oplus Y)$ and $c_{Z_k}(v) = c_X(v) \notin \{ Z_k(u), Y(u) \mid u \in \Gamma(v) \cap (Z_k \oplus Y) \}$, then by I.H., it must hold that $Z'_k(v) = Y'(v)$ and $c_{Z_k}(v) = c_Y(v)$. Combine them together, we have $X'(v) = Y'(v)$ and $c_X(v) = c_Y(v)$.

We then consider the coupling $(X_t, Y_t) = (X_t, Y_t)_{t \geq 0}$ of two ll-Metropolis chains starting from initial colorings $(X_0, Y_0)$, constructed by applying the coupled transition $(X, Y) \rightarrow (X', Y')$ defined above at each step.

The following corollary of Observation 16 says that if the initial colorings $X_0, Y_0$ differ at single vertex $v$, then disagreements can not percolate too fast in the coupled chains.

Corollary 17. Let $v \in V$ and $X_0, Y_0 \in [q]^V$ be two colorings that differ only at vertex $v$. For the coupling $(X_t, Y_t)$ of two ll-Metropolis chains, it holds that $X_t \oplus Y_t \subseteq B_t(v)$ for all $t \geq 0$.

The next corollary bounds the expectation and the deviation from expectation, for the number of new disagreements generated at each step of the couple chains.
Corollary 18. Let \((X_t, Y_t)\) be the coupling of two ll-Metropolis chains with activeness \(p\) on \(q\)-colorings of graph \(G\) with maximum degree \(\Delta\). Let \(\mathcal{N}(D_t) = |(X_t \oplus Y_t) \setminus (X_{t-1} \oplus Y_{t-1})|\) be the number of new disagreements generated at step \(t\). Then it holds that

\[
\mathbb{E}[\mathcal{N}(D_t) \mid X_{t-1}, Y_{t-1}] \leq \frac{2p\Delta |X_{t-1} \oplus Y_{t-1}|}{q}.
\]

Furthermore, for any \(\ell \geq \frac{20p\Delta |X_{t-1} \oplus Y_{t-1}|}{q}\), we have

\[
\Pr[\mathcal{N}(D_t) \geq \ell \mid X_{t-1}, Y_{t-1}] \leq \exp(-\ell).
\]

Proof. Let \(\partial(X_{t-1} \oplus Y_{t-1}) = \{v \in V \mid v \notin (X_{t-1} \oplus Y_{t-1}) \land \Gamma(v) \cap (X_{t-1} \oplus Y_{t-1}) \neq \emptyset\}\). From Observation 16, vertex \(v\) becomes a new disagreement at step \(t\) only if \(v \in \partial(X_{t-1} \oplus Y_{t-1})\), \(v\) is active and proposes the color \(c_X(v) \in \{X_{t-1}(u), Y_{t-1}(u) \mid u \in \Gamma(v) \cap (X_{t-1} \oplus Y_{t-1})\}\). Hence, the expected number of new disagreements is at most \(2p\Delta |X_{t-1} \oplus Y_{t-1}|/q\).

Furthermore, the laziness and proposed colors are fully independently. Thus, the number of new disagreements is stochastically dominated by the sum of independent 0-1 random variables. The second inequality holds by the Chernoff bound (9).

\section{6.2 Analysis of the coupling}

Next, we show that starting from any two colorings that differ at a single vertex \(v\), after constant many steps of coupling, the Hamming distance contracts with a constant factor in expectation.

Lemma 19. For all \(0 < \delta < 0.3\), there exists \(\Delta_4 = \Delta_4(\delta)\), such that for every graph \(G = (V, E)\) with maximum degree \(\Delta \geq \Delta_4\) and girth at least 9, if \(q \geq (\alpha^* + \delta)\Delta\), then for any vertex \(v \in V\), any initial colorings \(X_0, Y_0 \in [q]^V\) that differ only at \(v\), the coupling \((X_t, Y_t)\) of two ll-Metropolis chains with activeness \(p = \frac{\delta}{30}\) on \(q\)-colorings of graph \(G\) satisfies

\[
\mathbb{E}[X_{T_m} \oplus Y_{T_m}] \leq 1/3,
\]

where \(T_m = \frac{1200}{\delta} \ln \frac{600}{\delta} = \Theta(1)\).

The main theorem regarding the mixing rate (Theorem 15) is then an easy consequence of this lemma. Let \(\Delta_3(\delta) = \Delta_4(\delta)\), where \(\Delta_4\) is the threshold in Lemma 19. For arbitrary two colorings differ at a single vertex, there exists a coupling such that the expected Hamming distance between them is at most \(1/3\) after \(C'' = \frac{1200}{\delta} \ln \frac{600}{\delta} = \Theta(1)\) steps. Since the Hamming distance between any two colorings is at most \(n\), by the path coupling lemma, we have

\[
\tau(\epsilon) \leq \frac{3C''}{2} \log \frac{n}{\epsilon}.
\]

The rest of the section is dedicated to the proof of Lemma 19.

We use the technique developed in [8] to prove Lemma 19, which partitions the time interval \([0, T_m]\) into to two disjoint phases \([0, T_b]\) and \([T_b + 1, T_m]\), the first phase is called the burn-in phase. After the burn-in phase, typically, the Hamming distance between two chains are bounded, all disagreements are near vertex \(v\), and the local uniformity properties is guaranteed. Then we can prove that the expected Hamming distance will decrease in each step during \([T_b + 1, T_m]\). A crude upper bound is applied on the Hamming distance if non-typical events occur.
Proof of Lemma 19. For two colorings $X_t, Y_t$, define their difference as
$$D_t = \{u \mid X_t(u) \neq Y_t(u)\}.$$  Let $H_t = |D_t|$ denote their Hamming distance. Also, denote their cumulative difference by
$$D_{\leq t} = \bigcup_{\nu \leq t} D_{\nu},$$  and denote their cumulative Hamming distance as $H_{\leq t} = |D_{\leq t}|$.
Let $\delta', p', \zeta'$ and $C' = C'(\delta', \zeta')$ denote the parameters $\delta, p, \zeta$ and $C = C(\delta, \zeta)$ in Theorem 9, respectively. We apply Theorem 9 with $p' = \frac{\delta}{30}$, $\delta' = 1.7$ and $\zeta' = p/20$. Define
$$T_b = \frac{1}{p} \left(\frac{2.7}{1.7}\right)^2 \ln \frac{20}{p}.$$  Note that $C' = C'(\delta', \zeta')$ now depends only on $\delta$. Recall that $T_m = \frac{1200}{\delta^2} \ln \frac{600}{\delta}$. If we take $\Delta \geq C' \ln T_m$, then $T_m < \exp(\Delta/C')$. Thus we can assume that the local uniformity property in Theorem 9 holds for all time $t \in [T_b, T_m]$. If $\Delta \geq \Delta_0(p, \delta', \zeta') = \Delta_0(\delta)$, then it holds that
$$\Pr \left[ \forall t \in [t_b, t_m] : \frac{|A(X_t, v)|}{q} \geq (1 - p/2)e^{-\deg(v)/q} \right] \geq 1 - \exp(-\Delta/C'). \quad (20)$$  For each $t \geq T_b$, we define following bad events:
- $\mathcal{E}(t)$: there exists some time $s < t$, such that $|X_s \oplus Y_s| > \Delta^{2/3}$.
- $\mathcal{B}_1(t)$: $D_{\leq t} \not\subseteq B_{T_m}(v)$.
- $\mathcal{B}_2(t)$: there exists some time $T_b \leq \tau \leq t$ and a vertex $z \in B_{T_m}(v)$ such that
$$|A(X_\tau, z)| \leq (1 - p/2)q e^{-d(z)/q}.$$  Define bad event $\mathcal{B}(t)$ as
$$\mathcal{B}(t) = \mathcal{B}_1(t) \cup \mathcal{B}_2(t).$$  Define good event $\mathcal{G}(t)$ as
$$\mathcal{G}(t) = \overline{\mathcal{E}(t)} \cap \overline{\mathcal{B}(t)}.$$  For all events when the time $t$ is dropped, we are referring to the event at time $t = T_m$. Then the Hamming distance between $X_{T_m}$ and $Y_{T_m}$ can be bounded as follows
$$\mathbb{E} [H_{T_m}] = \mathbb{E} [H_{T_m} \mathbf{1}(\mathcal{E})] + \mathbb{E} [H_{T_m} \mathbf{1} (\overline{\mathcal{E}}) \mathbf{1}(\mathcal{B})] + \mathbb{E} [H_{T_m} \mathbf{1}(\mathcal{G})] \leq \mathbb{E} [H_{T_m} \mathbf{1}(\mathcal{E})] + \Delta^{2/3} \Pr[\mathcal{B}] + \mathbb{E} [H_{T_m} \mathbf{1}(\mathcal{G})]. \quad (21)$$  Since the bad events (non-typical events) occur with small probability, then we have following Claims.
**Claim 20.** $\Pr[\mathcal{B}] \leq \exp(-\sqrt{\Delta})$ and $\mathbb{E} [H_{T_m} \mathbf{1}(\mathcal{E})] \leq \exp(-\sqrt{\Delta})$.  

If the good event (typical event) $G$ occurs, then we can use local uniformity property to prove that the Hamming distance decreases by a constant factor during $[T_b + 1, T_m]$. Thus we have following Claim.

Claim 21. $\mathbb{E} [H_{T_m} 1 (G)] \leq 1/9$.

Lemma 19 follows by combining (21), Claim 20 and Claim 21.

Proof of Claim 20. At first, we prove that

$$\Pr[\mathcal{B}] \leq \exp(-\sqrt{\Delta}).$$

By Corollary 17, we know that disagreements can not percolate outside the ball $B_{T_m}(v)$, which implies $\Pr[\mathcal{B}_1] = 0$. The probability of bad event $\mathcal{B}_2$ can be bounded by (20). Thus, we have

$$\Pr[\mathcal{B}] = \Pr[\mathcal{B}_1] + \Pr[\mathcal{B}_2]
\leq \Pr[\mathcal{B}_2]
\leq \Delta^{T_m} \exp(-\Delta/C')
\leq \exp(-\sqrt{\Delta}),$$

where inequality (*) is a union bound over all vertices $z \in B_{T_m}(v)$. The last inequality holds for sufficiently large $\Delta$ such that $\Delta \geq C' (T_m \ln \Delta + \sqrt{\Delta})$. Note the $C'$ and $T_m$ depends only on $\delta$.

Next, we prove that

$$\mathbb{E} [H_{T_m} 1 (\mathcal{E})] \leq \exp(-\sqrt{\Delta}).$$

We will prove that for every $\ell \geq \Delta^{2/3}$, there exists $C'' = C''(\delta) > 0$ such that

$$\Pr[H_{\leq T_m} \geq \ell] \leq \exp(-C''\ell). \quad (22)$$

Then, we bound the expected Hamming distance between $X_{T_m}$ and $Y_{T_m}$ as follows

$$\mathbb{E} [H_{T_m} 1 (\mathcal{E})] \leq \mathbb{E} [H_{\leq T_m} 1 (\mathcal{E})]
\leq \sum_{\ell \geq \Delta^{2/3}} \ell \Pr[H_{\leq T_m} = \ell]
= \Delta^{2/3} \Pr[H_{\leq T_m} \geq \ell] + \sum_{\ell \geq \Delta^{2/3} + 1} \Pr[H_{\leq T_m} \geq \ell]
\leq \Delta^{2/3} \sum_{\ell \geq \Delta^{2/3}} \Pr[H_{\leq T_m} \geq \ell]
\leq \Delta^{2/3} \sum_{\ell \geq \Delta^{2/3}} \exp(-\ell C'')
= \frac{\Delta^{2/3} \exp(-\Delta^{2/3} C'')}{1 - \exp(-C'')},
\leq \exp(-\sqrt{\Delta}).$$

The last inequality holds for large $\Delta$ such that $C''\Delta^{2/3} \geq \frac{2}{3} \ln \Delta + \sqrt{\Delta} - \ln(1 - \exp(-C'')).$

Now we prove inequality (22). Define a sequence $c_0, c_1, \ldots, c_{T_m}$ as follows
• \( c_{T_m} = 1 \);
• For each \( 1 \leq t \leq T_m \), \( c_t = (1 + 12p) c_{t-1} = (1 + \frac{24}{3\delta}) c_{t-1} \).

For every \( \ell \geq \Delta^{2/3} \), we bound the probability of the event \( H_{\leq t} \geq c_t \ell \) for \( 0 \leq t \leq T_m \), where \( T_m = \frac{1200}{\delta^2} \ln \frac{600}{\delta} \). Note that \( H_{\leq 0} = 1 \), if we take \( \Delta > (1 + \frac{24}{3\delta})^{3T_m/2} \), then

\[
\Pr[H_{\leq 0} \geq c_0 \ell] = 0. \tag{23}
\]

Then for each \( 1 \leq t \leq T_m \), by the law of total probability, we have

\[
\Pr[H_{\leq t} \geq c_t \ell] = \Pr[H_{\leq t} \geq c_t \ell \mid H_{\leq t-1} \geq c_{t-1} \ell] \Pr[H_{\leq t-1} \geq c_{t-1} \ell] + \Pr[H_{\leq t} \geq c_t \ell \mid H_{\leq t-1} < c_{t-1} \ell] \Pr[H_{\leq t-1} \geq c_{t-1} \ell] \leq \Pr[H_{\leq t-1} \geq c_{t-1} \ell] + \Pr[H_{\leq t} \geq c_t \ell \mid H_{\leq t-1} < c_{t-1} \ell].
\]

Let \( N(D_t) = |(X_t \oplus Y_t) \setminus (X_{t-1} \oplus Y_{t-1})| \) be the number of new disagreements generated at step \( t \), then it holds that

\[
\Pr[H_{\leq t} \geq c_t \ell \mid H_{\leq t-1} < c_{t-1} \ell] \leq \Pr[N(D_t) \geq (c_t - c_{t-1}) \ell \mid H_{\leq t-1} < c_{t-1} \ell] = \Pr[N(D_t) \geq 12pc_{t-1} \ell \mid H_{\leq t-1} < c_{t-1} \ell] \leq \exp(-12pc_{t-1} \ell).
\]

The last inequality is due to Corollary 18 (Note that \( q \geq 1.7\Delta \) and \( |X_{t-1} \oplus Y_{t-1}| \leq H_{\leq t-1} \)). Thus

\[
\Pr[H_{\leq t} \geq c_t \ell] \leq \Pr[H_{\leq t-1} \geq c_{t-1} \ell] + \exp(-12pc_{t-1} \ell). \tag{24}
\]

Combining (23), (24) and the definition of sequence \( c \) (note that \( c_{T_m} = 1 \)) implies

\[
\Pr[H_{\leq T_m} \geq \ell] \leq \sum_{i=1}^{T_m} \exp(-12pc_{t-1} \ell) \leq T_m \exp(-12pc_0 \ell) = \exp(-12pc_0 \ell + \ln T_m).
\]

Note that \( \ell \geq \Delta^{2/3} \) and \( c_0 = (1 + 12p)^{-T_m} \). If \( \Delta \geq \sqrt[3]{\frac{\ln T_m}{12pc_0}} \) (note that \( T_m, c_0, p \) depend only on \( \delta \)), then we have \(-12pc_0 \ell + \ln T_m \leq -pc_0 \ell \), which implies

\[
\Pr[H_{\leq T_m} \geq \ell] \leq \exp(-pc_0 \ell) = \exp\left(-\frac{\ell\Delta}{(1 + 12p)^{T_m}}\right) = \exp(-\ell C'').
\]

Recall that \( p = \frac{\delta}{30} \) and \( T_m = \frac{1200}{\delta^2} \ln \frac{600}{\delta} \), thus \( C'' = C''(\delta) \). This proves inequality (22).

**Proof of Claim 21.** Condition on \( X_t, Y_t \), we will bound the expected value of \( H_{t+1} \) by path coupling. Suppose \( X_t, Y_t \) differ at \( h \) vertices \( v_1, v_2, \ldots, v_h \). Then, according to the coupling, we construct a sequence of colorings \( X = Z_0 \sim Z_1 \sim \ldots \sim Z_h = Y, \) such that each \( Z_i \) and \( Z_{i-1} \) differ only at vertex \( v_i \). Consider the coupling \((Z_{i-1}, Z_i) \rightarrow (Z'_{i-1}, Z'_i)\), by Lemma 7, we have

\[
E\left[Z'_{i-1} \oplus Z'_i \mid Z_{i-1}, Z_i\right] \leq 1 - \frac{p(q - \Delta)}{q} \left(1 - \frac{3p}{q}\right)^\Delta + \frac{p\Delta}{q} \quad (q > \alpha^{*}\Delta) \quad \leq 1 + \frac{p}{\alpha^{*}}
\]
Therefore, give $X_t, Y_t$, the expected value of $H_{t+1}$ can be bounded by triangle inequality as follows

$$
\mathbb{E} [H_{t+1} \mid H_t] \leq \left( 1 + \frac{p}{\alpha^*} \right) H_t.
$$

(25)

The inequality shows that the number of disagreements increases in each step. However, this bound will only be used during the burn-in phase $[0, T_b]$.

For each time $t \in [T_b, T_m]$, given $X_t, Y_t$, assuming the good event $G(t)$ occurs, we bound the the expected value of $H_{t+1}$ by path coupling. Suppose $X_t, Y_t$ differ at $h$ vertices $v_1, v_2, \ldots, v_h$. According to the coupling, we construct the path $H = Z_0 \sim Z_1 \sim \ldots \sim Z_h = Y$. Since we assume that the good event $G(t)$ occurs, then for each $0 \leq i \leq h$, it holds that $|X \oplus Z_i| \leq \Delta^{2/3}$, $v_i \in B_{T_m}(v)$ and $|A(X, v_i)| \geq (1 - p/2)q e^{-\deg(v_i)/q}$. Thus we have

$$
|A(Z_i, v_i)| \geq |A(X, v_i)| - \Delta^{2/3} \geq (1 - p/2)q e^{-\deg(v_i)/q} - \Delta^{2/3} \geq (1 - p/2)q e^{-\Delta/q} - \Delta^{2/3}.
$$

Together with inequalities (5) and (6), we have

$$
\mathbb{E} [\left| Z_{i-1}^t \oplus Z_i^t \right| \mid Z_{i-1}, Z_i] \leq 1 - \frac{p|A(Z_i, v_i)|}{q} \left( 1 - \frac{3p}{\alpha^*} \right) + \frac{p\Delta}{q}
$$

$$
\leq 1 - p \left( (1 - p/2)e^{-\Delta/q} - \frac{1}{\alpha^*\Delta^{1/3}} \right) \left( 1 - \frac{3p}{\alpha^*} \right) + \frac{p\Delta}{q},
$$

where the last inequality is because $q > \alpha^*\Delta$ and $\left( 1 - \frac{3p}{\alpha^*} \right)^{\Delta} \geq 1 - \frac{3p}{\alpha^*}$ due to Bernoulli’s inequality.

Note that, if we take $\Delta \geq \left( \frac{2e^{1/\alpha^*}}{p\alpha^*} \right)^3 \geq \left( \frac{2e^{\Delta/q}}{p\alpha^*} \right)^3$, then $\frac{1}{\alpha^*\Delta^{1/3}} \leq \frac{p}{2} e^{-\Delta/q}$. It holds that

$$
\mathbb{E} [\left| Z_{i-1}^t \oplus Z_i^t \right| \mid Z_{i-1}, Z_i] \leq 1 - p(1 - p)e^{-\Delta/q} \left( 1 - \frac{3p}{\alpha^*} \right) + \frac{p\Delta}{q}
$$

$$
\leq 1 - p \left( (1 - 3p)e^{-1/(\alpha^* + \delta)} - \frac{1}{\alpha^* + \delta} \right)
$$

$$
= 1 - p \left( \left( e^{-1/(\alpha^* + \delta)} - \frac{1}{\alpha^* + \delta} \right) - 3pe^{-\alpha^*/3} \right)
$$

$$
\leq 1 - p \left( \frac{\delta}{5} - 3p \right),
$$

where the last inequality is because for $0 < \delta < 0.3$, $e^{-1/(\alpha^* + \delta)} - \frac{1}{\alpha^* + \delta} \geq \frac{\delta}{5}$ and $e^{-\alpha^*/3} \leq 1$.

For $p = \frac{\delta}{30}$, it holds that

$$
\mathbb{E} [\left| Z_{i-1}^t \oplus Z_i^t \right| \mid Z_{i-1}, Z_i] \leq 1 - \frac{\delta^2}{300}.
$$

Hence, for each $t \in [T_b, T_m - 1]$, given $X_t, Y_t$, assuming the good event $G(t)$ holds, we have

$$
\mathbb{E} [H_{t+1} \mid X_t, Y_t] \leq \left( 1 - \frac{\delta^2}{300} \right) H_t.
$$

(26)
For each \( t \in [T_b, T_m - 1] \), it holds that
\[
\mathbb{E}[H_{t+1}1(G(t))] = \mathbb{E}[\mathbb{E}[H_{t+1}1(G(t)) \mid X_0, Y_0, \ldots, X_t, Y_t]]
\]
\[
\leq \mathbb{E}[\mathbb{E}[H_{t+1} \mid X_0, Y_0, \ldots, X_t, Y_t]1(G(t))]
\]
\[
(\text{By (26)}) \leq \left(1 - \frac{\delta^2}{300}\right) \mathbb{E}[H_t1(G(t))]
\]
\[
(\ast) \leq \left(1 - \frac{\delta^2}{300}\right) \mathbb{E}[H_t1(G(t - 1))]
\]
Inequality (\ast) is because the event \( G(t) \) is determined by \( X_0, Y_0, \ldots, X_t, Y_t \). Inequality (\ast\ast) is because the event \( G(t) \) implies the event \( G(t - 1) \). By induction, it holds that
\[
\mathbb{E}[H_{T_m}1(G)] \leq \mathbb{E}[H_{T_m}1(G(T_m - 1))] \leq \left(1 - \frac{\delta^2}{300}\right)^{T_m - T_b} \mathbb{E}[H_{T_b}1(G(T_b - 1))].
\]
Note that \( \mathbb{E}[H_{T_b}1(G(T_b - 1))] \leq \mathbb{E}[H_{T_b}], \) and apply (25) for \( t \in [0, T_b - 1] \), we have
\[
\mathbb{E}[H_{T_m}1(G)] \leq \left(1 - \frac{\delta^2}{300}\right)^{T_m - T_b} \left(1 + \frac{p}{\alpha^*}\right)^T_h H_0.
\]
Note that \( 1 < \delta < 0.3, \) \( p = \frac{\delta}{30} \). It holds that \( T_b = \frac{1}{p} \left(\frac{2.7}{T_1}\right)^2 \ln \frac{20}{p} \leq \frac{1200}{\delta^2} \ln \frac{600}{\delta} \). Since \( T_m = \frac{1200}{\delta^2} \ln \frac{600}{\delta} \), then we have \( T_m - T_b \geq \frac{960}{\delta^2} \ln \frac{600}{\delta} \). Note that \( H_0 = 1 \). We have
\[
\mathbb{E}[H_{T_m}1(G)] \leq \left(1 - \frac{\delta^2}{300}\right)^{\frac{960}{\delta^2} \ln \frac{600}{\delta}} \left(1 + \frac{p}{\alpha^*}\right)^{\frac{4}{p} \ln \frac{600}{\delta}}
\]
\[
\leq \left(\frac{\delta}{600}\right)^{3-4/\alpha^*}
\]
\[
\leq \frac{1}{9}.
\]
\[\Box\]
