The discovery and analysis of community structure in networks is a topic of considerable recent interest within the physics community, but most methods proposed so far are unsuitable for very large networks because of their computational cost. Here we present a hierarchical agglomeration algorithm for detecting community structure which is faster than many competing algorithms: its running time on a network with \( n \) vertices and \( m \) edges is \( O(md \log n) \) where \( d \) is the depth of the dendrogram describing the community structure. Many real-world networks are sparse and hierarchical, with \( m \sim n \) and \( d \sim \log n \), in which case our algorithm runs in essentially linear time, \( O(n \log^2 n) \). As an example of the application of this algorithm we use it to analyze a network of items for sale on the web-site of a large online retailer, items in the network being linked if they are frequently purchased by the same buyer. The network has more than 400 000 vertices and 2 million edges. We show that our algorithm can extract meaningful communities from this network, revealing large-scale patterns present in the purchasing habits of customers.

I. INTRODUCTION

Many systems of current interest to the scientific community can usefully be represented as networks [1–4]. Examples include the Internet [5] and the world-wide web [6, 7], social networks [8], citation networks [9, 10], food webs [11], and biochemical networks [12, 13]. Each of these networks consists of a set of nodes or vertices representing, for instance, computers or routers on the Internet or people in a social network, connected together by links or edges, representing data connections between computers, friendships between people, and so forth.

One network feature that has been emphasized in recent work is community structure, the gathering of vertices into groups such that there is a higher density of edges within groups than between them [14]. The problem of detecting such communities within networks has been well studied. Early approaches such as the Kernighan-Lin algorithm [15], spectral partitioning [16, 17], or hierarchical clustering [18] work well for specific types of problems (particularly graph bisection or problems with well defined vertex similarity measures), but perform poorly in more general cases [19].

To combat this problem a number of new algorithms have been proposed in recent years. Girvan and Newman [20, 21] proposed a divisive algorithm that uses edge betweenness as a metric to identify the boundaries of communities. This algorithm has been applied successfully to a variety of networks, including networks of email messages, human and animal social networks, networks of collaborations between scientists and musicians, metabolic networks and gene networks [20, 22–30]. However, as noted in [21], the algorithm makes heavy demands on computational resources, running in \( O(m^2 n) \) time on an arbitrary network with \( m \) edges and \( n \) vertices, or \( O(n^3) \) time on a sparse graph (one in which \( m \sim n \), which covers most real-world networks of interest). This restricts the algorithm’s use to networks of at most a few thousand vertices with current hardware.

More recently a number of faster algorithms have been proposed [31–33]. In [32], one of us proposed an algorithm based on the greedy optimization of the quantity known as modularity [21]. This method appears to work well both in contrived test cases and in real-world situations, and is substantially faster than the algorithm of Girvan and Newman. A naive implementation runs in time \( O((m+n)n) \), or \( O(n^2) \) on a sparse graph.

Here we propose a new algorithm that performs the same greedy optimization as the algorithm of [32] and therefore gives identical results for the communities found. However, by exploiting some shortcuts in the optimization problem and using more sophisticated data structures, it runs far more quickly, in time \( O(md \log n) \) where \( d \) is the depth of the “dendrogram” describing the network’s community structure. Many real-world networks are sparse, so that \( m \sim n \); and moreover, for networks that have a hierarchical structure with communities at many scales, \( d \sim \log n \). For such networks our algorithm has essentially linear running time, \( O(n \log^2 n) \).

This is not merely a technical advance but has substantial practical implications, bringing within reach the analysis of extremely large networks. Networks of ten million vertices or more should be possible in reasonable run times. As an example, we give results from the application of the algorithm to a recommender network of books from the online bookseller Amazon.com, which has more than 400,000 vertices and two million edges.

II. THE ALGORITHM

Modularity [21] is a property of a network and a specific proposed division of that network into communities. It measures when the division is a good one, in the sense that there are many edges within communities and only a few between them. Let \( A_{vw} \) be an element of the ad-
The adjacency matrix of the network thus:

\[ A_{vw} = \begin{cases} 1 & \text{if vertices } v \text{ and } w \text{ are connected,} \\ 0 & \text{otherwise.} \end{cases} \quad (1) \]

and suppose the vertices are divided into communities such that vertex \( v \) belongs to community \( c_v \). Then the fraction of edges that fall within communities, i.e., that connect vertices that both lie in the same community, is

\[ \frac{\sum_{vw} A_{vw} \delta(c_v, c_w)}{\sum_{vw} A_{vw}} = \frac{1}{2m} \sum_{vw} A_{vw} \delta(c_v, c_w), \quad (2) \]

where the \( \delta \)-function \( \delta(i, j) \) is 1 if \( i = j \) and 0 otherwise, and \( m = \frac{1}{2} \sum_{vw} A_{vw} \) is the number of edges in the graph. This quantity will be large for good divisions of the network, in the sense of having many within-community edges, but it is not, on its own, a good measure of community structure since it takes its largest value of 1 in the trivial case where all vertices belong to a single community. However, if we subtract from it the expected value of the same quantity in the case of a randomized network, we do get a useful measure.

The degree \( k_v \) of a vertex \( v \) is defined to be the number of edges incident upon it:

\[ k_v = \sum_w A_{vw}. \quad (3) \]

The probability of an edge existing between vertices \( v \) and \( w \) if connections are made at random but respecting vertex degrees is \( k_v k_w / 2m \). We define the modularity \( Q \) to be

\[ Q = \frac{1}{2m} \sum_{vw} \left[ A_{vw} - \frac{k_v k_w}{2m} \right] \delta(c_v, c_w). \quad (4) \]

If the fraction of within-community edges is no different from what we would expect for the randomized network, then this quantity will be zero. Nonzero values represent deviations from randomness, and in practice it is found that a value above about 0.3 is a good indicator of significant community structure in a network.

If high values of the modularity correspond to good divisions of a network into communities, then one should be able to find such good divisions by searching through the possible candidates for ones with high modularity. While finding the global maximum modularity over all possible divisions seems hard in general, reasonably good solutions can be found with approximate optimization techniques. The algorithm proposed in [32] uses a greedy optimization in which, starting with each vertex being the sole member of a community of one, we repeatedly join together the two communities whose amalgamation produces the largest increase in \( Q \). For a network of \( n \) vertices, after \( n - 1 \) such joins we are left with a single community and the algorithm stops. The entire process can be represented as a tree whose leaves are the vertices of the original network and whose internal nodes correspond to the joins. This dendrogram represents a hierarchical decomposition of the network into communities at all levels.

The most straightforward implementation of this idea (and the only one considered in [32]) involves storing the adjacency matrix of the graph as an array of integers and repeatedly merging pairs of rows and columns as the corresponding communities are merged. For the case of the sparse graphs that are of primary interest in the field, however, this approach wastes a good deal of time and memory space on the storage and merging of matrix elements with value 0, which is the vast majority of the adjacency matrix. The algorithm proposed in this paper achieves speed (and memory efficiency) by eliminating these needless operations.

To simplify the description of our algorithm let us define the following two quantities:

\[ e_{ij} = \frac{1}{2m} \sum_{vw} A_{vw} \delta(c_v, i) \delta(c_w, j), \quad (5) \]

which is the fraction of edges that join vertices in community \( i \) to vertices in community \( j \), and

\[ a_i = \frac{1}{2m} \sum_v k_v \delta(c_v, i), \quad (6) \]

which is the fraction of ends of edges that are attached to vertices in community \( i \). Then, writing \( \delta(c_v, c_w) = \sum_j \delta(c_v, i) \delta(c_w, i) \), we have, from Eq. (4)

\[ Q = \frac{1}{2m} \sum_{vw} A_{vw} \delta(c_v, w) - \frac{1}{2m} \sum_i \delta(c_v, i) \delta(c_w, i) \]

\[ = \sum_i \left[ \frac{1}{2m} \sum_{vw} A_{vw} \delta(c_v, i) \delta(c_w, i) - \frac{1}{2m} \sum_v k_v \delta(c_v, i) \right] \]

\[ = \sum_i (e_{ii} - a_i^2). \quad (7) \]

The operation of the algorithm involves finding the changes in \( Q \) that would result from the amalgamation of each pair of communities, choosing the largest of them, and performing the corresponding amalgamation. One way to envisage (and implement) this process is to think of network as a multigraph, in which a whole community is represented by a vertex, bundles of edges connect one vertex to another, and edges internal to communities are represented by self-edges. The adjacency matrix of this multigraph has elements \( A'_{ij} = 2ne_{ij} \), and the joining of two communities \( i \) and \( j \) corresponds to replacing the \( i \)th and \( j \)th rows and columns by their sum. In the algorithm of [32] this operation is done explicitly on the entire matrix, but if the adjacency matrix is sparse (which we expect in the early stages of the process) the operation can be carried out more efficiently using data structures for sparse matrices. Unfortunately, calculating \( \Delta Q_{ij} \) and
finding the pair $i, j$ with the largest $\Delta Q_{ij}$ then becomes
time-consuming.

In our new algorithm, rather than maintaining the adjac-
cency matrix and calculating $\Delta Q_{ij}$, we instead main-
tain and update a matrix of value of $Q_{ij}$. Since joining
two communities with no edge between them can never
produce an increase in $Q$, we need only store $\Delta Q_{ij}$ for
those pairs $i, j$ that are joined by one or more edges.
Since this matrix has the same support as the adjacency
matrix, it will be similarly sparse, so we can again rep-
resent it with efficient data structures. In addition, we
make use of an efficient data structure to keep track of
the largest $\Delta Q_{ij}$. These improvements result in a con-
siderable saving of both memory and time.

In total, we maintain three data structures:

1. A sparse matrix containing $\Delta Q_{ij}$ for each pair $i, j$
of communities with at least one edge between
them. We store each row of the matrix both as
a balanced binary tree (so that elements can be
found or inserted in $O(\log n)$ time) and as a max-
heap (so that the largest element can be found in
constant time).

2. A max-heap $H$ containing the largest element of
each row of the matrix $\Delta Q_{ij}$ along with the labels
$i, j$ of the corresponding pair of communities.

3. An ordinary vector array with elements $a_i$.

As described above we start off with each vertex being
the sole member of a community of one, in which case
e_{ij} = 1/2m$ if $i$ and $j$ are connected and zero otherwise,
and $a_i = k_i/2m$. Thus we initially set

$$\Delta Q_{ij} = \begin{cases} 1/2m - k_i k_j/(2m)^2 & \text{if } i, j \text{ are connected,} \\ 0 & \text{otherwise,} \end{cases}$$

and

$$a_i = \frac{k_i}{2m}$$

for each $i$. (This assumes the graph is unweighted;
weighted graphs are a simple generalization [34].)

Our algorithm can now be defined as follows.

1. Calculate the initial values of $\Delta Q_{ij}$ and $a_i$ accord-
ing to (8) and (9), and populate the max-heap with
the largest element of each row of the matrix $\Delta Q$.

2. Select the largest $\Delta Q_{ij}$ from $H$, join the corre-
sponding communities, update the matrix $\Delta Q$, the
heap $H$ and $a_i$ (as described below) and increment
$Q$ by $\Delta Q_{ij}$.

3. Repeat step 2 until only one community remains.

Our data structures allow us to carry out the updates
in step 2 quickly. First, note that we need only adjust
a few of the elements of $\Delta Q$. If we join communities $i$
and $j$, labeling the combined community $j$, say, we need
only update the $j$th row and column, and remove the
$i$th row and column altogether. The update rules are as
follows. If community $k$ is connected to both $i$ and $j$, then

$$\Delta Q'_{jk} = \Delta Q_{ik} + \Delta Q_{jk}$$  \hspace{1cm} (10a)

If $k$ is connected to $i$ but not to $j$, then

$$\Delta Q'_{jk} = \Delta Q_{ik} - 2a_j a_k$$  \hspace{1cm} (10b)

If $k$ is connected to $j$ but not to $i$, then

$$\Delta Q'_{jk} = \Delta Q_{jk} - 2a_i a_k.$$  \hspace{1cm} (10c)

Note that these equations imply that $Q$ has a single peak
over the course of the algorithm, since after the largest
$\Delta Q$ becomes negative all the $\Delta Q$ can only decrease.

To analyze how long the algorithm takes using our
data structures, let us denote the degrees of $i$ and $j$
in the reduced graph—i.e., the numbers of neighboring
communities—as $|i|$ and $|j|$ respectively. The first op-
eration in a step of the algorithm is to update the $j$th
row. To implement Eq. (10a), we insert the elements of
the $i$th row into the $j$th row, summing them wherever an
element exists in both columns. Since we store the rows
as balanced binary trees, each of these $|i|$ insertions takes
$O(|i| \log |j|) \leq O(\log n)$ time. We then update the other
elements of the $j$th row, of which there are at most $|i| + |j|$,,
according to Eqs. (10b) and (10c). In the $k$th row, we
update a single element, taking $O(|k| \log |k|) \leq O(\log n)$
time, and there are at most $|i| + |j|$ values of $k$ for which
we have to do this. All of this thus takes $O((|i| + |j|) \log n)$
time.

We also have to update the max-heaps for each row and
the overall max-heap $H$. Reforming the max-heap corre-
sponding to the $j$th row can be done in $O(|j|)$ time [35].
Updating the max-heap for the $k$th row by inserting, rais-
ing, or lowering $\Delta Q_{kj}$ takes $O(|k|) \leq O(\log n)$
time. Since we have changed the maximum element on at most
$|i| + |j|$ rows, we need to do at most $|i| + |j|$ updates of
$H$, each of which takes $O(\log n)$ time, for a total of
$O((|i| + |j|) \log n)$.

Finally, the update $a'_j = a_j + a_i$ (and $a_i = 0$) is trivial
and can be done in constant time.

Since each join takes $O((|i| + |j|) \log n)$ time, the total
running time is at most $O(\log n)$ times the sum over all
nodes of the dendrogram of the degrees of the correspond-
ing communities. Let us make the worst-case assumption
that the degree of a community is the sum of the degrees
of all the vertices in the original network comprising it.
In that case, each vertex of the original network contributes
its degree to all of the communities it is a part of, along
the path in the dendrogram from it to the root. If the
dendrogram has depth $d$, there are at most $d$ nodes in
this path, and since the total degree of all the vertices
is $2m$, we have a running time of $O/md \log n$ as stated.

We note that, if the dendrogram is unbalanced, some
time savings can be gained by inserting the sparser row
into the less sparse one. In addition, we have found that
FIG. 1: The modularity $Q$ over the course of the algorithm (the $x$ axis shows the number of joins). Its maximum value is $Q = 0.745$, where the partition consists of 1684 communities.

in practical situations it is usually unnecessary to maintain the separate max-heaps for each row. These heaps are used to find the largest element in a row quickly, but their maintenance takes a moderate amount of effort and this effort is wasted if the largest element in a row does not change when two rows are amalgamated, which turns out often to be the case. Thus we find that the following simpler implementation works quite well in realistic situations: if the largest element of the $k$th row was $Q_{ki}$ or $Q_{kj}$ and is now reduced by Eq. (10b) or (10c), we simply scan the $k$th row to find the new largest element. Although the worst-case running time of this approach has an additional factor of $n$, the average-case running time is often better than that of the more sophisticated algorithm. It should be noted that the dendrograms generated by these two versions of our algorithm will differ slightly as a result of the differences in how ties are broken for the maximum element in a row. However, we find that in practice these differences do not cause significant deviations in the modularity, the community size distribution, or the composition of the largest communities.

III. AMAZON.COM PURCHASING NETWORK

The output of the algorithm described above is precisely the same as that of the slower hierarchical algorithm of [32]. The much improved speed of our algorithm however makes possible studies of very large networks for which previous methods were too slow to produce useful results. Here we give one example, the analysis of a co-purchasing or “recommender” network from the online vendor Amazon.com. Amazon sells a variety of products, particularly books and music, and as part of their web sales operation they list for each item A the ten other items most frequently purchased by buyers of A. This information can be represented as a directed network in which vertices represent items and there is an edge from item A to another item B if B was frequently purchased by buyers of A. In our study we have ignored the directed nature of the network (as is common in community structure calculations), assuming any link between two items, regardless of direction, to be an indication of their similarity. The network we study consists of items listed on the Amazon web site in August 2003. We concentrate on the largest component of the network, which has 409,687 items and 2,464,630 edges.

The dendrogram for this calculation is of course too big to draw, but Fig. 1 illustrates the modularity over the course of the algorithm as vertices are joined into larger and larger groups. The maximum value is $Q = 0.745$, which is high as calculations of this type go [21, 32] and indicates strong community structure in the network. The maximum occurs when there are 1684 communities with a mean size of 243 items each. Fig. 2 gives a visualization of the community structure, including the major communities, smaller “satellite” communities connected to them, and “bridge” communities that connect two major communities with each other.

Looking at the largest communities in the network, we find that they tend to consist of items (books, music) in similar genres or on similar topics. In Table I, we give informal descriptions of the ten largest communities, which account for about 87% of the entire network. The remainder is generally divided into small, densely connected communities that represent highly specific co-purchasing habits, e.g., major works of science fiction (162 items), music by John Cougar Mellencamp (17 items), and books...
TABLE I: The 10 largest communities in the Amazon.com network, which account for 87% of the vertices in the network.

| Rank | Size  | Description                                                                 |
|------|-------|-----------------------------------------------------------------------------|
| 1    | 114538| General interest: politics; art/literature; general fiction; human nature;   |
|      |       | technical books; how things, people, computers, societies work, etc.        |

| 3    | 78661 | Hobbies and interests I: self-help; self-education; popular science fiction; |
|      |       | popular fantasy; leisure; etc.                                              |
| 4    | 54582 | Hobbies and interests II: adventure books; video games/comics; some sports; |
|      |       | some humor; some classic fiction; some western religious material; etc.      |
| 5    | 9872  | classical music and related items                                           |
| 6    | 1904  | children’s videos, movies, music and books                                  |
| 7    | 1493  | church/religious music; African-descent cultural books; homoerotic imagery  |
| 8    | 1101  | pop horror; mystery/adventure fiction                                       |
| 9    | 1083  | jazz; orchestral music; easy listening                                      |
| 10   | 947   | engineering; practical fashion                                              |

FIG. 3: Cumulative distribution of the sizes of communities when the network is partitioned at the maximum modularity found by the algorithm. The distribution appears to follow a power law form over two decades in the central part of its range, although it deviates in the tail. As a guide to the eye, the straight line has slope \(-1\), which corresponds to an exponent of \(\alpha = 2\) for the raw probability distribution.

We have described a new algorithm for inferring community structure from network topology which works by greedily optimizing the modularity. Our algorithm runs in time \(O(md \log n)\) for a network with \(n\) vertices and \(m\) edges where \(d\) is the depth of the dendrogram. For networks that are hierarchical, in the sense that there are communities at many scales and the dendrogram is roughly balanced, we have \(d \sim \log n\). If the network is also sparse, \(m \sim n\), then the running time is essentially linear, \(O(n \log^2 n)\). This is considerably faster than most previous general algorithms, and allows us to extend community structure analysis to networks that had been considered too large to be tractable. We have demonstrated our algorithm with an application to a large network of co-purchasing data from the online retailer Amazon.com. Our algorithm discovers clear communities within this network that correspond to specific topics or genres of books or music, indicating that the co-purchasing tendencies of Amazon customers are strongly correlated with subject matter. Our algorithm should allow researchers to analyze even larger networks with millions of vertices and tens of millions of edges using current computing resources, and we look forward to seeing such applications.

**IV. CONCLUSIONS**

We have described a new algorithm for inferring community structure from network topology which works by greedily optimizing the modularity. Our algorithm runs in time \(O(md \log n)\) for a network with \(n\) vertices and \(m\) edges where \(d\) is the depth of the dendrogram. For networks that are hierarchical, in the sense that there are communities at many scales and the dendrogram is roughly balanced, we have \(d \sim \log n\). If the network is also sparse, \(m \sim n\), then the running time is essentially linear, \(O(n \log^2 n)\). This is considerably faster than most previous general algorithms, and allows us to extend community structure analysis to networks that had been considered too large to be tractable. We have demonstrated our algorithm with an application to a large network of co-purchasing data from the online retailer Amazon.com. Our algorithm discovers clear communities within this network that correspond to specific topics or genres of books or music, indicating that the co-purchasing tendencies of Amazon customers are strongly correlated with subject matter. Our algorithm should allow researchers to analyze even larger networks with millions of vertices and tens of millions of edges using current computing resources, and we look forward to seeing such applications.

**Acknowledgments**

The authors are grateful to Amazon.com and Eric Promislow for providing the purchasing network data. This work was funded in part by the National Science Foundation under grant PHY-0200909 (AC, CM) and by a grant from the James S. McDonell Foundation (MEJN).

[14] Community structure is sometimes referred to as “clustering” in sociology or computer science, but this term is commonly used to mean something else in the physics literature [36], so to prevent confusion we avoid it here. We note also that the problem of finding communities in a network is somewhat ill-posed, since we haven’t defined precisely what a community is. A number of definitions have been proposed [8, 31, 37], but none is standard.
