(Received 4 April 2016; accepted 3 May 2016; published online 1 June 2016)

$\text{Bi}_2\text{Te}_3$-based compounds are a well-known class of outstanding thermoelectric materials, $\beta$-$\text{As}_2\text{Te}_3$, another member of this family, exhibits promising thermoelectric properties around 400 K when appropriately doped. Herein, we investigate the high-temperature thermoelectric properties of the $\beta$-$\text{As}_{2-x}\text{Bi}_x\text{Te}_3$ solid solution. Powder X-ray diffraction and scanning electron microscopy experiments showed that a solid solution only exists up to $x = 0.035$. We found that substituting Bi for As has a beneficial influence on the thermopower, which, combined with extremely low thermal conductivity values, results in a maximum $ZT$ value of 0.7 at 423 K for $x = 0.017$ perpendicular to the pressing direction. © 2016 Author(s). The efficiency with which thermoelectric materials convert a thermal gradient into electricity and vice-versa at an operating temperature $T$, is governed by the dimensionless figure of merit $ZT = \alpha^2T/\rho(\kappa_e + \kappa_L)$. High $ZT$ values are synonymous with high efficiency and are achieved in materials exhibiting a fine balance between the thermopower $\alpha$, the electrical resistivity $\rho$, and the electronic and lattice thermal conductivities, $\kappa_e$ and $\kappa_L$, respectively. Heavily doped semiconductors with carrier concentrations ranging from $10^{19}$ to $10^{21}$ cm$^{-3}$ and crystallizing with a complex unit cell usually achieve the best compromise between these three transport properties.

Depending on the synthesis conditions, the polymorphic compound $\text{As}_2\text{Te}_3$ crystallizes with either monoclinic (space group $C2/m$) or rhombohedral symmetry (space group $R\bar{3}m$), referred to as the $\alpha$ and $\beta$ form, respectively. $\alpha$-$\text{As}_2\text{Te}_3$ undergoes several phase transitions at high pressures driving this insulator into a semi-metallic phase before eventually entering a metallic regime. At ambient pressure, $\beta$-$\text{As}_2\text{Te}_3$ transforms into the $\alpha$ form above 473 K and undergoes a subtle lattice distortion near 190 K that breaks the rhombohedral symmetry and leads to a novel monoclinic unit cell exhibiting a fourfold modulation along the $b$ axis (named $\beta'$). Interestingly, both $\alpha$-$\text{As}_2\text{Te}_3$ and $\beta$-$\text{As}_2\text{Te}_3$ phases are semiconductors that meet the aforementioned requirements. In particular, they share the remarkable feature of being poor thermal conductors with lattice thermal conductivities well below 1 W m$^{-1}$ K$^{-1}$ above 300 K. Maximum $ZT$ values of 0.8 at 523 K and 0.65 at 423 K were achieved in $\alpha$-$\text{As}_2\text{Te}_3$ and $\beta$-$\text{As}_2\text{Te}_3$, respectively, using the substitution of Sn for As as a tuning parameter of the hole concentration.

The $\beta$-As$_2$Te$_3$ compound is isomorphous to the well-known Bi$_2$Te$_3$-based thermoelectric materials used in solid-state cooling applications.\(^\text{1,2}\) First reported as a high-pressure phase,\(^\text{7}\) polycrystalline samples could be obtained with high purity by conventional melting-quenching techniques allowing for a detailed investigation of its transport properties and of the influence of substitution on either the As or Te site.\(^\text{10}\) Our prior work on Sn-substituted $\beta$-As$_2$Te$_3$ has provided hints at the presence of defects in this material,\(^\text{10}\) akin to the Bi$_2$Te$_3$-based alloys where defect chemistry plays a central role in determining the thermoelectric performances.\(^\text{1,2}\) In addition, this compound has been suggested to harbor topological insulating properties when an uniaxial strain is applied along the $c$ axis,\(^\text{14,15}\) which could be experimentally realized by applying either an external pressure or a chemical pressure through substitutions.

Despite the large number of isovalent and aliovalent substitutions that can be envisaged, alloying $\beta$-As$_2$Te$_3$ with isomorphous Bi$_2$Te$_3$ appears as a natural route to further improve the $ZT$ values in this family. The possibility to form a solid solution between these two compounds is of particular interest for both practical and fundamental reasons. Continuously varying the As/Bi ratio could act as a tuning parameter of the spin-orbit coupling that would give rise to a transition from a trivial band insulator to a topological insulator, as observed, for instance, in the Pb$_{1-x}$Sn$_x$Se or TlBiSe$_{2-x}$S$_x$ systems.\(^\text{16–19}\) On a more practical point of view, alloying with Bi may help to increase the power factor of $\beta$-As$_2$Te$_3$ and to push the maximum $ZT$ values of $\beta$-As$_2$Te$_3$ closer to room temperature.

Our preliminary investigation of the low-temperature thermoelectric properties of the $\beta$-As$_{2-x}$Bi$_x$Te$_3$ compounds has revealed that Bi helps to decrease the electrical resistivity without being at the expense of a significant increase in the thermal conductivity.\(^\text{12}\) Remarkably, the $ZT$ values achieved at 300 K were similar to those measured in Sn-substituted samples, suggesting that interesting thermoelectric performances could be obtained at higher temperatures.\(^\text{12}\) Herein, we extend these investigations with a detailed study of the thermoelectric properties at moderately high temperatures (300–423 K) of polycrystalline $\beta$-As$_{2-x}$Bi$_x$Te$_3$ samples in the homogeneity range. The substitution of Bi for As results in a significant increase in the $ZT$ values with respect to the unsubstituted phase $\beta$-As$_2$Te$_3$ with a peak $ZT$ of 0.7 at 423 K for $x = 0.017$ perpendicular to the pressing direction. All synthetic procedures were carried out in a dry, argon-filled glove box. Caution is required for preparing and handling samples made with arsenic and for their disposal. More specifically, the As vapor pressure may become significant at high temperatures thereby possibly resulting in an explosion of the quartz tube and releasing toxic As vapor. Polycrystalline $\beta$-As$_{2-x}$Bi$_x$Te$_3$ samples ($x = 0.0, 0.015, 0.025, 0.035, 0.1, 0.2$) were prepared by direct reactions of stoichiometric quantities of pure elements (99.99% As Goodfellow, 99.999% Te, 99.9999% Bi 5 N, all in shots). The mixtures were loaded in quartz tubes sealed under secondary vacuum and heated up to 923 K at a rate of 10 K min$^{-1}$. The tubes were maintained at this temperature for 2 h before being quenched in icy water. The resulting ingots were ground into fine powders and consolidated at room temperature under a pressure of 750 MPa yielding dense cylindrical pellets (∼10 mm in diameter and ∼7 mm in thickness). No further annealing step has been applied to the pellets after consolidation. The remarkable mechanical properties of this family of compounds led to geometric densities higher than 95% of the theoretical densities.

The phase purity and crystal structure were verified by powder X-ray diffraction (PXRD) using a Bruker D8 Advance diffractometer (CuK$_{\alpha1}$ radiation). The lattice parameters were determined at 300 K by Rietveld refinements of the PXRD patterns using the Fullproff software (Table I). The chemical homogeneity and spatial distribution of the elements were assessed by scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDXS) using a Quanta FEG (FEI). The chemical compositions were determined by electron probe microanalysis (EPMA) on mirror-polished surface of bulk pieces with a JEOL JXA 8530F instrument equipped with wavelength-dispersive spectrometers. $\beta$-As$_2$Te$_3$ and Bi were used as standards to determine the As, Te, and Bi contents. The binary $\beta$-As$_2$Te$_3$ compound was used to lower the mismatch between these samples and other As and Te standards owing to differing chemical environments of these elements. Because the absence of secondary phases in $\beta$-As$_2$Te$_3$ was confirmed by EDXS analyses, this sample was considered as stoichiometric for these measurements. With these standards, the total weight densities higher than 95% of the theoretical densities.
TABLE I. Nominal and actual compositions measured by EPMA on the polycrystalline series $\beta$-As$_{2-x}$Bi$_x$Te$_3$. The compositions have been normalized to five atoms per formula unit. The lattice parameters ($a$ and $c$) were determined from Rietveld refinements against PXRD patterns collected at 300 K. The Hall carrier concentration ($p_H$) and the Hall mobility ($\mu_H$) measured at 300 K in samples cut perpendicular to the pressing direction are also mentioned.

| Nominal composition | EPMA | $a$ (Å) | $c$ (Å) | $p_H$ ($10^{19}$ cm$^{-3}$) | $\mu_H$ (cm$^2$ V$^{-1}$ s$^{-1}$) |
|---------------------|------|---------|---------|-----------------------------|-------------------------------|
| As$_2$Te$_3$        | As$_{1.985}$Te$_{0.015}$ | 4.0473(2), 29.502(3) | 8.4 | 48.6 |
| As$_{1.985}$Bi$_{0.015}$Te$_3$ | As$_1$Te$_{0.017}$Bi$_{0.983}$ | 4.0503(2), 29.538(2) | 7.1 | 81.2 |
| As$_{1.975}$Bi$_{0.025}$Te$_3$ | As$_1$Te$_{0.024}$Bi$_{0.976}$ | 4.0518(2), 29.554(2) | 6.8 | 69.5 |
| As$_{1.965}$Bi$_{0.035}$Te$_3$ | As$_1$Te$_{0.035}$Bi$_{0.965}$ | 4.0531(2), 29.566(1) | 8.0 | 57.8 |

The crystal structure and phase purity of the $\beta$-As$_{2-x}$Bi$_x$Te$_3$ samples were confirmed by PXRD and SEM experiments. Figure 1 shows a representative Rietveld refinement of the PXRD pattern of the $x = 0.017$ sample. Except for an additional reflection near $2\theta = 31^\circ$ visible in all PXRD patterns.
and identified as the binary AsTe phase, no other secondary phases are visible for Bi contents up to $x = 0.035$. Above this concentration, additional reflections appear suggesting that $\beta$-As$_{2-x}$Bi$_x$Te$_3$ is a solid solution up to only $x = 0.035$. SEM images collected in backscattering electron mode confirmed the phase-pure nature of the samples for $x \leq 0.035$. Hence, only the chemical compositions and transport properties of single-phase samples ($x \leq 0.035$) were subsequently studied. EPMA measurements confirmed the very good chemical homogeneity of the matrix and revealed an excellent correlation between the nominal and actual compositions (see Table I). Hereafter, we use the actual Bi content to label the samples.

The trends in the crystal structure upon alloying with Bi were determined by Rietveld refinements against PXRD data. The variations in the lattice parameters $a$ and $c$, shown in the inset of Figure 1 as a function of the actual Bi content, indicate a monotonous expansion of the unit cell with $x$ in agreement with the larger ionic radii of Bi with respect to As. Both parameters increase with $x$ in a non-linear manner with a tendency to saturate at high Bi concentrations.

Figure 2(a) shows the evolution of $\rho$ as a function of temperature as the Bi content varies from $x = 0$ up to 0.035. The linear increase in the $\rho$ values with temperature indicates that all samples have a metallic character. While all the samples share the common characteristic to exhibit significantly lower $\rho$ in the perpendicular direction than in the parallel direction, the $\rho$ values...
of the $x = 0.017$ and 0.035 samples are lower than for $x = 0.0$. The fact that $\rho$ does not evolve monotonically with $x$ is tied to the non-monotonic variations in the Hall carrier concentration $p_H$ and Hall mobility $\mu_H$ revealed by Hall effect measurements (Table I). $p_H$ first decreases from $8.4 \times 10^{19}$ cm$^{-3}$ to $6.8 \times 10^{19}$ cm$^{-3}$ on going from $x = 0.0$ to 0.024 before increasing to $8.4 \times 10^{19}$ cm$^{-3}$ for $x = 0.035$. Concomitantly, $\mu_H$ increases from $49 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ up to $81 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ in the $x = 0.017$ sample. Further alloying with Bi results in a gradual decrease in $\mu_H$ to $58 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ in the $x = 0.035$ specimen. These results suggest that the activity of Bi as a dopant is non-trivial and could reflect a strong influence of Bi atoms on the native defects induced by non-stoichiometry that exist in $\beta$-As$_2$Te$_3$, a situation similar to Bi$_2$Te$_3$-based materials where defect chemistry plays a prominent role.\cite{2,21}

The linear dependence of $\alpha(T)$, shown in Figure 2(b), is consistent with the diffusive regime expected in metals and degenerate semiconductors. In contrast to $\rho$, $\alpha$ appears independent of the direction of the measurement to within experimental uncertainty with $\alpha$ values varying from $115 \mu\text{V K}^{-1}$ at 300 K for $x = 0.0$ up to $170 \mu\text{V K}^{-1}$ at 423 K for $x = 0.035$. The maximum $\alpha$ values reached at 423 K are similar to those measured in the Sn-substituted series for similar hole concentrations.

The temperature dependence of the total thermal conductivity is shown in Figure 2(c). The electronic contribution to the thermal conductivity $\kappa_e$ was calculated by the Wiedemann-Franz law $\kappa_e = L T/\rho$ where the Lorentz number $L$ determined for $\beta$-As$_2$Te$_3$ (1.9 $\times 10^{-8}$ V$^2$ K$^{-2}$ at 300 K) has been considered.\cite{14} Despite a limited structural complexity, the resulting lattice thermal conductivity $\kappa_L$ (not shown) of the samples is extremely low, of the order of 0.7 and 0.4 W m$^{-1}$ K$^{-1}$ in the perpendicular and parallel directions, respectively. Because of this extremely low thermal transport, Bi does not have a strong influence on $\kappa_L$. Of note, these values are significantly lower than those measured in Bi$_2$Te$_3$-based alloys but similar to those achieved in $\alpha$-As$_2$Te$_3$ or in other chalcogenides.\cite{2,10,22-27} In the parallel direction, $\kappa_L$ approaches the lowest limit of the thermal conductivity (Figure 2(c)) estimated using the model developed by Cahill and Pohl and the measured longitudinal and transverse sound velocities.\cite{13,28-30}

Figure 2(d), which shows the variations in temperature of the $ZT$ values, indicates that $ZT$ increases with temperature for all samples. The peak $ZT$ of 0.7 at 423 K achieved in the $x = 0.017$ sample in the perpendicular direction represents an increase of 40% compared to the parent compound and evidences the beneficial influence of Bi on the thermoelectric properties of $\beta$-As$_2$Te$_3$. However, due to the narrow compositional range that can be reached in the $\beta$-As$_2$-Bi$_x$Te$_3$ solid solution, Bi does not push the peak $ZT$ closer to room temperature. As noted in our prior study,\cite{12} the anisotropy in the electrical resistivity and in the thermal conductivity of $\beta$-As$_2$-Bi$_x$Te$_3$ does not compensate each other, giving rise to different $ZT$ values in the parallel and perpendicular directions. Although the hole concentration only slightly changes with the Bi content, the $ZT$ increases thanks to enhanced power factors achieved at 423 K upon Bi alloying.

In summary, $\beta$-As$_2$Te$_3$ was found to form a solid solution with Bi$_2$Te$_3$ in only a narrow compositional window. The alloyed $\beta$-As$_2$-Bi$_x$Te$_3$ samples are homogeneous up to $x = 0.035$ as revealed by PXRD and SEM experiments. In this concentration range, the samples behave as heavily doped semiconductors with hole concentrations of the order of $8 \times 10^{19}$ cm$^{-3}$ at 300 K. Because the lattice thermal conductivity in $\beta$-As$_2$Te$_3$ nears the minimum thermal conductivity, alloying with Bi did not influence significantly the thermal transport. The measured values smoothly decrease below 1 W m$^{-1}$ K$^{-1}$ at 423 K for all samples. The beneficial effect of Bi on the power factor combined with very low thermal conductivity values led to a peak $ZT$ of 0.7 at 423 K for $x = 0.017$ perpendicular to the pressing direction. The complex evolution of the transport properties of $\beta$-As$_2$Te$_3$ with the nature of the substituting elements requires further theoretical insights to better understand their influence on the electronic band structure. $\beta$-As$_2$Te$_3$ finally appears as an interesting class of compounds that clearly warrants further investigations due to its good thermoelectric performances.
