Abstract. We present numerical methods to solve the generalized Hartree–Fock theory for fermionic systems in lattices, both in thermal equilibrium and out of equilibrium. Specifically, we show how one can determine the covariance matrix corresponding to the fermionic Gaussian state that optimally approximates the quantum state of fermions. The methods apply to relatively large systems, because their complexity only scales quadratically with the number of lattice sites. Moreover, they are specially suited to describe inhomogeneous systems, as those typically found in recent experiments with atoms in optical lattices, at least in the weak interaction regime. As a benchmark, we have applied them to the two-dimensional Hubbard model on a $10 \times 10$ lattice with and without external confinement.
## 1. Introduction

Recent experiments with cold atomic systems have attracted the interest of several scientific communities. Many physical phenomena, such as Bose–Einstein condensation, superfluidity and the formation of Cooper pairs, have been observed in seminal experiments and carefully analyzed and characterized [1, 2]. Over the last few years, the possibility of loading atoms in optical lattices offers a new avenue to the observation of many other intriguing phenomena [3].

There exist several theoretical tools in order to describe most of these phenomena. For the case of bosons, the Gross–Pitaevskii equation provides us with the basic tool to analyze many static and dynamic properties for cold atomic gases [4]. Such an equation is valid whenever the occupation number of a particular mode is large, and it is equivalent to a mean-field theory. Typically, it can be solved numerically, offering very accurate predictions and explanations of all the observed phenomena in the weak interacting regime. Furthermore, it can also be used to describe lattice systems, at least as long as strong correlations are absent. In the case of fermions, the basic tools at hand are Hartree–Fock and Bardeen, Cooper and Schreiffer (BCS) theory [5]. The first one assumes that the state of the particles can be approximated in terms of a Slater determinant, and thus it also corresponds to a mean-field theory. The latter assumes a specific form of the wavefunction, whereby pairing between fermions is allowed. For both approaches, a time-dependent version has been constructed [6]–[10].

Hartree–Fock and BCS theories can be unified in terms of a more general framework: the generalized Hartree–Fock theory (gHFT) [11]. The main idea is that both the
Slater-determinant- and BCS-states are members of a larger family of states, so-called fermionic Gaussian states (FGSs). Therefore, one may try to find the state within this family that best approaches the real state of the system under study. FGSs are those states whose density operator can be expressed as an exponential of a quadratic function of canonical creation and annihilation operators. This property immediately implies that they fulfill Wick’s theorem: that is, all correlation functions can be expressed in terms of the second moments of all creation and annihilation operators. Such moments are gathered in a matrix, the so-called covariance matrix (CM) that completely characterizes the state [12]. Thus, FGSs can be very efficiently described, because the number of parameters only scales quadratically with the number of available fermionic modes and the expectation values of observables can be easily computed. For the case of lattices, the number of modes is automatically finite, and thus it should be an ideal playground for such a gHFT. In fact, Bach et al [11] were the first who applied such a theory to a Hubbard model in two dimensions (2D), and were able to solve the corresponding equations exactly for the homogeneous case, both for the ground state and in thermal equilibrium.

gHFT can be easily applied to any lattice system, homogeneous or not. The resulting equations are, however, difficult to solve in general. In this paper, we derive such equations for the CM, and introduce different methods to solve them. First of all, we derive the equation for the real-time evolution of the CM. Secondly, we consider the state within the FGS that minimizes the total energy, and thus approximates the ground state. For that, we derive the evolution equation (in imaginary time) for the CM in the presence of a lattice Hamiltonian. We show that under such an equation, the CM converges to the one that minimizes the energy within the family of FGSs. Thus, the evolution equation provides us with a practical way of determining the approximation to the ground state. Finally, we derive the equation for the CM that minimizes the free energy, and apply a simple fixed-point iteration method to solve it.

Then we apply the methods to the spin-1/2 Hubbard model in a 10 × 10 lattice. Firstly, we benchmark them with exact solutions of the gHFT (for the homogeneous case) [11], finding extraordinary agreement for both attractive and repulsive interactions. Secondly, in order to test the validity of the gHFT itself, we compare the results for positive interactions, where strongly correlated effects are expected to be most pronounced, with the Monte Carlo results of [13, 14]. The results are obviously less precise than those obtained with such methods, other Monte Carlo approaches [15], or recently developed algorithms based on projected entangled pair states (PEPS) and other tensor network states [16]–[21]. Although we obtain good qualitative agreement with [13, 14] in many regimes, the FGSs are, as expected, not able to capture all possible fermionic phases in the strong-correlation regimes, as they constitute a subclass of all possible fermionic states. For example, the finite-temperature Mott phase cannot be approximated well as a Gaussian state, and is thus absent in the phase diagram.

At this point, we would like to warn the reader that in this work we will mainly concentrate on the possibilities offered by the numerical approaches, and not focus on the physics of the Hubbard model. To be precise, our goal is (a) to formulate the standard gHFT for fermionic systems with a two-body interaction in the lattice using the language of CMs, (b) to derive numerical methods to determine the ground and thermal states as well as the time evolution of these systems within the gHFT and (c) to benchmark our techniques by applying them to the 2D Hubbard model.

Strictly speaking, the CM converges to the solution for which the energy is extremal.
This paper is organized as follows. In section 2, we give a precise formulation of the problem we aim to solve, and introduce the concepts necessary for understanding FGSs and the gHFT. This section further includes a discussion on why FGSs are supposed to capture well the physical properties of some of the most relevant fermionic models. Next, we derive methods to approximate the real-time evolution, and the ground and thermal states of fermionic systems within the gHFT in sections 3.1–3.3. Then, we benchmark our methods by applying them to the 2D translationally invariant Hubbard model, in both the attractive and the repulsive regime, in section 4. In addition, motivated by the current possibility of implementing the Hubbard model in more than one dimension with the help of optical lattices, we also investigate the 2D Hubbard model with an external confinement in section 5, and close with a study of dynamical processes, for both the translationally invariant and the trapped system, in section 6.

2. Statement of the problem

In this section, we give a statement of the problem, summarize the properties of fermionic Gaussian states that are necessary for understanding our work (for more details, see e.g. [12]) and argue why these states capture the properties of many relevant physical models.

In our work, we aim to understand the physical properties of fermionic systems in a lattice, like

$$H = -\sum_{kl} t_{kl} a_k^+ a_l + \sum_{klmn} u_{klmn} a_k^+ a_l^+ a_m a_n,$$  \hspace{1cm} (1)

where the $a_k$ denote fermionic mode operators obeying canonical anti-commutation relations (CAR), $\{a_k, a_l\} = \delta_{kl}$ and $t_{kl}, u_{klmn} \in \mathbb{C}$. These models describe fermionic atoms in optical lattices [22], and one of the most prominent ones, the Hubbard model [23], is expected to describe high-$T_c$ superconductivity [24]. We approach the problem in the Majorana picture and define $c_k = a_k^+ + a_k$, $c_{k+M} = (-i)(a_k^+ - a_k)$, where $M$ is the number of modes and $k = 1, \ldots, M$. These operators satisfy the CAR $\{c_k, c_l\} = 2\delta_{kl}$. The Hamiltonian $H$ in this picture is given by

$$H(T, U) = i \sum_{kl} T_{kl} c_k c_l + \sum_{klmn} U_{klmn} c_k c_l c_m c_n,$$  \hspace{1cm} (2)

where $T_{kl}, U_{klmn} \in \mathbb{R}$. The CAR allow us to anti-symmetrize $T$ and $U$ such that $T^T = -T$, while $U$ is anti-symmetric under the exchange of any of two adjacent indices.

Our goal is to derive ground and thermal states as well as the time evolution of systems characterized by the Hamiltonian given in equation (1) within the family of FGSs. These are states that can be represented as an exponential of a quadratic form in the Majorana operators, and thus they are fully characterized by their second moments collected in the real and anti-symmetric CM $\Gamma_{kl} = \{\frac{1}{2}[c_k, c_l]\}$ from which all higher correlations can be obtained via Wick’s theorem (see e.g. [12]),

$$i^p \text{tr}[\rho c_{j_1} \cdots c_{j_{2p}}] = \text{Pf}(\Gamma_{j_1 \cdots j_{2p}}),$$  \hspace{1cm} (3)

where $1 \leq j_1 < \ldots < j_{2p} \leq 2M$ and $\Gamma_{j_1 \cdots j_{2p}}$ is the corresponding $2p \times 2p$ submatrix of $\Gamma$. $\text{Pf}(\Gamma_{j_1 \cdots j_{2p}})^2 = \text{det}(\Gamma_{j_1 \cdots j_{2p}})$ is called the Pfaffian$^3$. $\Gamma$ is the CM of a physical state iff

$^3$ The sign of the Pfaffian is determined by the condition that the term $\Gamma_{j_1 j_2} \Gamma_{j_3 j_4} \cdots \Gamma_{j_{2p-1} j_{2p}}$ appears with positive sign.
i\Gamma - 1 \leq 0, \text{ while pure states have to fulfill } \Gamma^2 = -1. \text{ Every pure FGS is the ground state of a quadratic Hamiltonian, }

\[ H_Q = i \sum_{kl} h_{kl} c_k c_l, \]  

with real and anti-symmetric Hamiltonian matrix \( h \). All Gaussian states remain Gaussian under the time evolution governed by a quadratic Hamiltonian, and the CM transforms according to \( \Gamma(t) = O(t) \Gamma(0) O(t)^T \), where \( O(t) = e^{iht} \) is an orthogonal transformation.

Let us now explain why FGSs provide a very powerful technique for the description of fermionic many-body systems. Firstly, note that all pure states within this family can be brought into a standard form \( |\Psi\rangle = \prod_k (u_k + v_k a_k^{\dagger} a_k) |0\rangle \), where \( |u_k|^2 + |v_k|^2 = 1 \forall k \) via a change of basis \[25\]. Thus, the pure Gaussian states include the BCS states introduced in the theory of superconductivity as well as all Hartree–Fock states. Secondly, FGSs also include all mixed states for which Wick’s theorem \[3\] applies, e.g. thermal states of quadratic Hamiltonians. Thus, all together, we see that FGSs include a variety of states that form the basis of several many-body phenomena.

3. Interacting fermions in generalized Hartree–Fock theory (gHFT)

In the following section, we derive the theoretical framework that will allow us later on to simulate fermionic many-body problems, such as the Hubbard model, for large system sizes. This is achieved by approximating the state of the fermions by an FGS, something that is implemented by means of Wick’s theorem.

3.1. Real-time evolution

We start the section deriving an evolution equation that allows us to describe the time evolution of a system at zero and finite temperature evolving under the interaction Hamiltonian \( (1) \) within the gHFT. The key idea is to use the CM for description of the dynamical evolution. In the Heisenberg picture, where the time evolution of the Majorana operators is given by \( c_k(t) = e^{iH(T,U)t} c_k e^{-iH(T,U)t} \), the CM evolves according to

\[ \frac{d}{dt} \Gamma_{\alpha\beta}(t) = \langle [c_\alpha(t)c_\beta(t), H(T, U)] \rangle . \]  

As \( H(T, U) \) involves terms quartic in the Majorana operators, this evolution clearly takes us out of the Gaussian setting. We truncate this transformation imposing that Wick’s theorem holds, i.e. we write

\[ \langle c_i c_j c_k c_l \rangle = - (\Gamma_{ij} \Gamma_{kl} - \Gamma_{ik} \Gamma_{jl} + \Gamma_{il} \Gamma_{jk}) . \]  

With the help of the commutation relation

\[ [c_\alpha c_\beta, c_i c_j] = 2(c_i c_\alpha \delta_{j\beta} - c_j c_\alpha \delta_{i\beta} - c_\beta c_j \delta_{i\alpha} + c_\alpha c_j \delta_{i\beta}), \]

we can calculate contributions for the quadratic term \( H_q = \sum_{kl} T_{kl} c_k c_l \) and the interaction term \( H_I = \sum_{klmn} U_{klmn} c_k c_l c_m c_n \) to be

\[ \langle [c_\alpha c_\beta, H_q] \rangle = 4[T, \Gamma]_{\alpha\beta} , \]

\[ \langle [c_\alpha c_\beta, H_I] \rangle = 24[\text{tr}_B[U \Gamma], \Gamma]_{\alpha\beta} . \]
This implies the following time evolution of the CM,

\[
\frac{d}{dt} \Gamma(t) = 4[\tilde{h}(\Gamma(t)), \Gamma(t)],
\]

\[
\tilde{h}(\Gamma(t)) = T + 6 \text{tr}_B[U \Gamma(t)],
\]

where we have defined \( \text{tr}_B[U \Gamma]_{ij} \equiv \sum_{kl} U_{ijkl} \Gamma_{lk} \). This equation can be formally integrated,

\[
\Gamma(t) = O(t) \Gamma(0) O(t)^T,
\]

\[
O(t) = \mathcal{T} \exp \left( 4 \int_0^t \tilde{h}(\Gamma(t')) dt' \right),
\]

where \( \mathcal{T} \) denotes the time-ordering operator. Note that due to the anti-symmetry of \( \tilde{h}(\Gamma(t')) \) equation (9) guarantees that the matrix \( O(t) \) is an orthogonal transformation. Hence, when starting with a valid CM \( \Gamma(0) \), this approximation scheme ensures that we remain within the set of Gaussian states. Further, it follows from what we said in section 3 that dynamical evolution under the interaction Hamiltonian \( H(T, U) \) can be understood as time evolution under a quadratic but state-dependent Hamiltonian,

\[
H_Q(\Gamma) = i \sum_{kl} \tilde{h}(\Gamma(t))_{kl} c_k^c l.
\]

Further, this approximation scheme ensures that we always remain within the set of Gaussian states. Also, a short calculation shows that it conserves energy and, for a number-conserving Hamiltonian, the particle number. We start with the energy, which is given by \( E(t) = \text{tr}[H \rho] = -\text{tr}[(T + 3 \text{tr}_B[U \Gamma] \Gamma)] \), and hence, with the help of equation (7), it follows that

\[
\dot{E}(t) = \sum_{kl} \frac{\partial E}{\partial \Gamma_{kl}} \dot{\Gamma}_{kl} = 4 \text{tr}[\tilde{h}(\Gamma)[\tilde{h}(\Gamma), \Gamma]] = 0.
\]

To prove the conservation of the mean particle number \( N \), as long as \([H, \hat{N}] = 0\), we write the particle number operator \( \hat{N} = \sum_k a_k^\dagger a_k = M + \frac{i}{4} \sum_{k,l} v_{kl} c_k^c l \), where \( \nu \) is real and anti-symmetric, and obtain \( N(t) = M - \frac{i}{4} \text{tr}[\nu \Gamma] \). Thus (cf equation (5))

\[
\frac{d}{dt} N(t) = -\frac{1}{4} \text{tr}[\nu \Gamma] = -\frac{1}{4} \sum_{kl} v_{kl} \text{tr}[\rho[c_k^c l, H]] = -i \text{tr}[\rho[\hat{N}, H]] = 0.
\]

Hence, we have shown that applying Wick’s theorem to the evolution equation of a system governed by a two-body interaction Hamiltonian leads to a consistent dynamical equation for the CM. The truncation of the evolution is equivalent to evolution under an effective state-dependent quadratic Hamiltonian within the set of Gaussian states, as depicted in figure 1(a). We remark that this approach works for pure as well as mixed FGSs. Note also that the remaining equation resembles in some way the Gross–Pitaevskii equation for bosons because that can
Figure 1. (a) The time evolution under the interaction Hamiltonian (1) within the set of Gaussian states (purple) can be reformulated as the time evolution under a quadratic but state-dependent Hamiltonian $H_{\text{eff}} = i \sum_{ij} \tilde{h}_{ij}(\Gamma) c_i c_j$, where $\tilde{h}$ is given in equation (8), that respects the Gaussian structure. (b) The minimization of the energy within the set of Gaussian states can be mapped to an imaginary time evolution within the set of Gaussian states with the effective, state-dependent Hamiltonian given by $H_{\text{eff}} = i \sum_{ij} \tilde{h}_{ij}(\Gamma) c_i c_j$, with $\tilde{h}$ defined in equation (8). (c) The minimization of the free energy leads to the implicit equation $\Gamma = i \tanh[2i \beta \tilde{h}(\Gamma)]$ (cf (26)) for the CM, which can be solved e.g. by a fixed-point iteration.

also be interpreted as giving the evolution in terms of a Hamiltonian that depends on the state. However, the main difference is that in the case of bosons such an equation is obtained for the first moments of the field operators. Note that in the case of bosons one could also perform the same approximation for the first and second moments, obtaining a set of coupled equations that would include the condensate part as well as thermal particles.

3.2. Ground states

In principle, the ground state in the gHFT can be found via a direct minimization,

$$\min_{\rho, \text{Gaussian}} \text{tr}[H \rho] = \min_{i \leq j} \left\{ T_{ij} \Gamma_{ij} - 3 \sum_{i,j,k,l} U_{ijkl} \Gamma_{ij} \Gamma_{kl} \right\}. \quad (12)$$

For the translationally invariant Hubbard model, this problem can be reduced to an optimization over two parameters only [11]. Generically, this constrained quadratic minimization problem is a daunting task. We attack this problem from a different perspective. A well-known approach for the determination of the ground state $|\phi_0\rangle$ of a Hamiltonian $H$ is imaginary time evolution.
Because of the exponential growth of state space with the number of modes, this approach can be applied to small systems only. The idea is to apply the Gaussian approximation (in the form of Wick’s theorem) to derive an evolution equation for the CM. In this way, we obtain a simple quadratic scaling in computational time with respect to the number of modes.

Naively, one would think of obtaining the evolution equation in imaginary time by replacing \( t \mapsto it \) in the real-time evolution equation of the CM, equation (7). However, as it turns out, this is not the right road to take. However, as we will show below, the following approach will lead us to the desired ground state: we start with an arbitrary pure Gaussian state \( \rho(0) \), and evolve it according to

\[
\rho(t) = \frac{e^{-Ht} \rho(0) e^{-Ht}}{\text{tr}[e^{-2Ht} \rho(0)]},
\]

where the normalization of the density operator for any time, i.e. the denominator \( \text{tr}[e^{-2Ht} \rho(0)] \), is crucial for obtaining the correct equations. Because we apply the non-quadratic operator \( H \) to the Gaussian state \( \rho \), this procedure clearly takes us out of the setting of Gaussian states. One way around would consist of discretizing the evolution and finding for small time steps \( \Delta t \) the best Gaussian approximation at each step. However, because of the truncation, it is not clear that this procedure will converge. And even if we find a steady state, it is not clear that this will be the ground state of the system. Another possible approach is to use the quadratic but state-dependent effective Hamiltonian \( H_Q(\Gamma) \) that is derived from \( H(T, U) \) for the imaginary time evolution. As \( H_Q(\Gamma) \) is a quadratic operator, we will stay in the space of Gaussian states. But as the Hamiltonian is state dependent, the outcome of this procedure is not clear. However, as we will show below, both approaches are equivalent and lead indeed to the desired solution. To be precise, we show that the following is equivalent:

1. Direct minimization of the energy equation (12) in the gHFT.
2. Imaginary time evolution of the state \( \rho \) with the full Hamiltonian \( H(T, U) \) for small time steps \( \Delta t \) followed by an approximation of \( \rho(t + \Delta t) \) by a Gaussian state.
3. Imaginary time evolution of \( \rho \) with the quadratic but state-dependent Hamiltonian \( H_Q(\Gamma) \).

**3.2.1. Minimization of the energy.** In order to obtain the generalized Hartree–Fock (gHF) ground state, we have to solve the minimization problem,

\[
\min_{\rho \text{ Gaussian}} E(\rho) = \min_{\rho \text{ Gaussian}} \text{tr}[H \rho] = \min_{\bar{\pi} \leq 1} \left\{ \sum_{ij} T_{ij} \Gamma_{ij} - 3 \sum_{i,j,k,l} U_{ijkl} \Gamma_{ij} \Gamma_{kl} \right\}.
\] (14)

It has been proved in [11] that the HF ground state is always pure, i.e. \( \Gamma^2 = -\mathbb{1} \). Using Lagrange multipliers, we arrive at the following necessary conditions for a local minimum (see appendix A): \(^4\)

\[
\tilde{h}(\Gamma), \Gamma = 0,
\] (15)

\[
\Gamma^2 = -\mathbb{1}.
\] (16)

\(^4\) Note that equations (15) and (16) describe all minima, local and global ones. However, for the particular problems studied in the next sections, our numerical investigations show that our algorithms lead in general to the global minimum, i.e. the ground state.
These two equations are nonlinear matrix equations and thus hard to solve, both analytically and numerically, for large systems. But we show next that these equations appear as the steady-state conditions of imaginary time evolution.

3.2.2. Imaginary time evolution. From equation (13), we see that the evolution of the density operator $\rho$ under any Hamiltonian $H$ in imaginary time is given by

$$\dot{\rho}(t) = -\{H, \rho(t)\} + 2\rho(t)\text{tr}[H\rho(t)],$$

so that the CM evolves according to

$$\frac{d}{dt} \Gamma_{kl}(t) = -i\text{tr}[\{H, c_k c_l\} \rho(t)] + 2\Gamma_{kl} \text{tr}[H\rho(t)].$$

We show in appendix B that both approaches for imaginary time evolution, number 2 and 3, lead to the same evolution equation of the CM,

$$\frac{d}{dt} \Gamma = -4(\bar{\Gamma}\bar{h}(\Gamma)\Gamma + \bar{h}(\Gamma)).$$

First, note that equation (19) ensures that a pure state remains pure under the evolution, because

$$\frac{d}{dt} \Gamma^2 = \Gamma \dot{\Gamma} + \dot{\Gamma} \Gamma = -4(\bar{\Gamma}^2\bar{h}\Gamma + \Gamma\bar{h} + \bar{h}\Gamma^2 + \bar{h}\Gamma) = 0,$$

as all pure states fulfill $\Gamma^2 = -\mathbb{1}$. Next, we show that the energy always decreases under the evolution

$$\frac{d}{dt} E(t) = \sum_{kl} \frac{\partial E}{\partial \Gamma_{kl}} \dot{\Gamma}_{kl} = \sum_{kl} \bar{h}(\Gamma)_{kl} \Gamma_{kl} = 4\text{tr}[\bar{h}(\Gamma\bar{h}\Gamma + \bar{h})] = 2\text{tr}([\bar{h}, \Gamma]^2) \leq 0.$$

Here, we have used the fact that the matrix $[\bar{h}, \Gamma]$ is anti-symmetric, implying that $([\bar{h}, \Gamma]^2)$ is negative-definite. Further, it follows from equation (20) that the steady state is reached iff $[\bar{h}, \Gamma] = 0$. Thus, we are sure to reach the gHF ground state via an evolution with equation (19) with initial condition $\Gamma(0)^2 = -\mathbb{1}$.

Finally, if we start in a pure input state, i.e. $\Gamma(0)^2 = -\mathbb{1}$, equation (19) can be formally integrated (see also figure 1(b)),

$$\Gamma(t) = O(t)\Gamma(0)O(t)^T,$$

$$O(t) = T \exp \left[ \int_{0}^{t} A(\Gamma(t')) dt' \right],$$

$$A(\Gamma(t)) = 2[\bar{h}(\Gamma), \Gamma].$$

The evolution of $\Gamma$ with the orthogonal $O(t)$ has turned out to be especially fast and stable in numerical implementations compared to the direct integration of equation (19) via e.g. a Runge–Kutta solver, and we have used it for our numerical applications.

3.3. Thermal states

As we have seen in the last section, the gHF ground state can be obtained via an imaginary time evolution. To learn about the finite-temperature properties in the gHFT, we have to consider the
approximation to the Gibbs state \( \rho \sim e^{-\beta H} \), where \( \beta = 1/k_B T \) is the inverse temperature. We recall that the Gibbs state minimizes the free energy, \( F(\rho) = E(\rho) - \beta^{-1} S(\rho) \). Thus, we have to solve

\[
\min_{\rho \text{ Gaussian}} F(\rho) = \min_{\rho \text{ Gaussian}} \left\{ E(\rho) - \beta^{-1} S(\rho) \right\}.
\]

As in the case of the minimization of the energy, we reformulate the problem as an optimization problem using Lagrange multipliers. As we show in appendix C, this approach leads to the following necessary conditions for a minimum of the free energy,

\[
[h_F(\Gamma), \Gamma] = 0, \tag{23}
\]

\[
h_F(\Gamma) (1 + \Gamma^2) = 0, \tag{24}
\]

where

\[
 h_F(\Gamma) = \tilde{h} - \frac{i}{4\beta} \ln \frac{1 + i\Gamma}{1 - i\Gamma}. \tag{25}
\]

Now, assume for the moment that \( \det(1 + \Gamma^2) \neq 0 \). Then, according to equation (24), \( h_F = 0 \) is the only possible solution. Hence, the CM has to be of the form

\[
 \Gamma = i \tanh \left[ 2i\beta\tilde{h}(\Gamma) \right]. \tag{26}
\]

Now, a CM of this form always fulfills equations (23) and (24), and includes, in the limit \( \beta \to \infty \), the zero-temperature case, so that equation (26) is indeed a solution of equations (23) and (24).

Note that from the perspective of numerical implementation, we can solve equation (26) e.g. via a fixed-point iteration (see figure 1(c)).

4. Benchmark: the two-dimensional (2D) translationally invariant Hubbard model

In the following section, we apply our method to the 2D translationally invariant Hubbard model with periodic boundary conditions,

\[
 H = t \sum_{(x,y) \in \Lambda, \sigma} a_{x,\sigma}^\dagger a_{y,\sigma} + u \sum_{x \in \Lambda} \left( n_{x\uparrow} - \frac{1}{2} \right) \left( n_{x\downarrow} - \frac{1}{2} \right) + \mu \sum_{x,\sigma} n_{x,\sigma}, \tag{27}
\]

where \( x \) and \( y \) are points on a 2D lattice, \( (i, j) \) denote nearest neighbors and \( \sigma = \uparrow, \downarrow \) denotes the spin degree of freedom. We consider only the case where we have the same number of spin-up and spin-down particles, so that we can use the same chemical potential for the two species. For \( u < 0 \) (\( u > 0 \)), the second term in \( H \) is an attractive (repulsive) on-site interaction between particles of opposite spin. In the following, we set \( t = 1 \) as the energy scale of the system. Note that the case of half-filling is characterized by \( \mu = 0 \).

The goal of this section is twofold. In the first part, section 4.1, we benchmark our numerical method by considering physical quantities for which an exact solution within gHFT is known. In the case of the translationally invariant Hubbard model, it can be proved in [11] that the (free) energy for the (thermal) ground state can be found via a two-parameter optimization, and we will compare our numerical results with the numbers obtained from the optimization. After demonstration of the power of our approach, we continue in the second part, section 4.2, with a comparison of the gHFT itself to more powerful and sophisticated methods, such as quantum Monte Carlo (QMC).

In the following, all calculations are performed for a \( 10 \times 10 \) lattice.
Figure 2. Ground state energy of the translationally invariant Hubbard model (cf equation (27)) for an interaction strength $u \in [-10, 10]$ at half-filling, i.e. $\mu = 0$. The blue line shows the exact gHF ground state energy, $E_{\text{exact}}$, obtained from [11], while the triangles correspond to the energy obtained via imaginary time evolution, $E_{\text{imag}}$.

Figure 3. Energy as a function of chemical potential for the attractive Hubbard model at various values of the interaction strength $u$. The dotted lines depict the exact gFH solution, while the triangles and diamonds correspond to the solutions obtained via our approach. We find excellent agreement between the two approaches.

4.1. Comparison with the exact generalized Hartee–Fock (gHF) solution

For the translationally invariant Hubbard model equation (27), the exact results for the energy of ground and thermal state within gHFT were presented in [11]. In figure 2, we compare the ground state energy for half-filling obtained via imaginary time evolution according to equation (21) (triangles) with the exact gHF solution (blue line) and find excellent agreement. The relative error in the energy is given by $(dE)_{\text{rel}} = |E_{\text{imag}} - E_{\text{exact}}|/|E_{\text{exact}}| < 2 \times 10^{-8}$.

In figure 3, we show the results away from half-filling. In this case, a closed solution for the energy could only be provided for the attractive Hubbard model in [11]. We have compared the exact gHF solution (dotted lines) with the results obtained via our approach (triangles and diamonds).
Figure 4. Free energy of the translationally invariant Hubbard model (cf. equation \((27)\)) in the temperature range \(\beta \in [0.4, 1.6]\) for \(u = -1, \ldots, -10\) at half-filling. The lines depict the gHFT solution given in [11], while the triangles and diamonds show the results obtained via the fixed-point iteration.

diamonds) for \(u = -2, -6, -10\), proving that our numerical method also works well for a doped system.

Next, we consider the case of finite temperature, where the gHF Gibbs state is given by the implicit equation \((26)\). Starting from the ground state, we change the temperature in steps \(\Delta \beta = 0.01\) and compute the new thermal state via a fixed-point iteration. In figure 4, we present a comparison of our solutions (triangles and diamonds) for half-filling with the exact results (lines) for various values of \(u\) in a temperature range of \(\beta \in [0.4, 1.6]\) and find excellent agreement.

One of the most interesting questions concerning the Hubbard model is the appearance of superconductivity. As already pointed out in section 2, FGSs describe, among others, superfluid and normal states, since every pure state of this family can be brought into the standard Bardeen–Cooper–Schrieffer (BCS) form \(|\Psi\rangle = \prod_k (u_k a_k^\dagger a^\dagger_{-k}) |0\rangle\) via a change of basis. On this basis, the gap parameter \(\Delta = \sum_k u_k v_k\) is an order parameter for the superfluid phase. To consider superfluidity independent of the basis, it is more appropriate to consider the normalized pairing measure derived in [26],

\[
P = \frac{2}{M} \sum_{kl} |\langle a_k^\dagger a_l^\dagger \rangle|^2.
\]

Then, a positive value of \(P\) indicates that we are in a paired phase, while a normal state is characterized by \(P = 0\).

It has been shown in [11] that within the gHFT the attractive Hubbard model exhibits a phase transition from a paired phase to an unpaired normal phase at a critical temperature \(\beta_c\) for any finite lattice size, and the corresponding transition temperature has been derived. In figure 5, we have depicted the pairing as a function of the inverse temperature for various values of interaction \(u\), and find a breakdown at a finite value \(\beta_c\) that depends on the interaction strength. The values of \(\beta_c\) that we obtain via our numerical method agree well with the results presented in [11], and are depicted as circles in figure 5. Further, we give a list of the critical exponent \(\gamma\) defined via \(P = a(T_c - T)^\gamma\) for various values of \(u\) in table 1.
Critical exponent $\gamma$ for the phase transition from a paired to an unpaired phase for various values of $u$. We have fitted $P$ around the critical temperature $T_c$ to a curve of the form $P = a(T_c - T)^\gamma$ for lattice sizes $8 \times 8, 10 \times 10$ and $12 \times 12$, finding the same values of $\gamma$ for the given precision.

| $u$  | $-5$ | $-6$ | $-7$ | $-8$ | $-9$ | $-10$ |
|------|------|------|------|------|------|-------|
| $\gamma$ | 0.87 | 0.90 | 0.80 | 1.04 | 1.14 | 1.00 |

Figure 5. Temperature dependence of the pairing (see equation (28)) for various values of interaction $u$ at half-filling. We observe the occurrence of a phase transition from a paired phase to an unpaired normal state. Circles indicate the value of the transition temperature derived for gHFT in [11].

Finally, we give in figure 6 a phase diagram of the pairing for the ground state as a function of chemical potential and interaction strength. (Note that the value of the pairing is not unique in the case of half-filling because of the gauge symmetries of the Hamiltonian (see [11]). We have restricted ourselves to representing the phase diagram for negative values of $u$, because we find that $P = 0$ for $u$ positive.

In summary, we have demonstrated that our numerical methods are capable of obtaining the correct gHF ground and Gibbs state for the translationally invariant Hubbard model, both in the attractive and in the repulsive regime. Having demonstrated the validity of our approach, the next obvious question is how the gHFT itself compares with more powerful and sophisticated methods, such as QMC.

4.2. Comparison with quantum Monte Carlo (QMC)

In this section, we compare the results obtained via our algorithm with numerical data from QMC simulations. To this end, we will concentrate on the repulsive Hubbard model at half-filling. The reason for this choice is twofold. First, as has been shown in [27, 28], the physics of the attractive Hubbard model is well described by BCS theory, which is included in the gHFT. This motivates us to consider primarily the repulsive Hubbard model, and compare our results with those obtained from QMC. While QMC suffers from the notorious sign problem when applied to fermionic systems, it can be shown that in the case of a half-filled lattice, the sign
Figure 6. Pairing (see equation (28)) of the ground state as a function of the interaction strength and the chemical potential in the translationally invariant case obtained from gHFT with the QMC results of [30] and [31] for half-filled lattices. As a guide for the eye, we have added lines for the particle numbers 50, 100 (half filling) and 150.

problem does not occur [29], and thus QMC becomes exact. As a consequence, the 2D repulsive Hubbard model at half-filling has undergone an intense investigation in recent years. A partial list of these results is given in [30]–[40] and references therein. In this section, we compare our results obtained in the gHFT with the recent QMC results obtained in [13] and [14] for half-filled (figure 7) and doped lattices.

4.2.1. Ground state properties for half-filling. We start with a comparison of our approach with the results presented in [13], where a half-filled system is considered. Because in the latter work the numerical results are presented for various lattice sizes, whereas our results are always given for a 10 × 10 lattice, we have to restrict ourselves to a qualitative comparison in certain cases. As the first physical quantity, we consider the momentum distribution \( n(\mathbf{k}) \) that has been depicted for \( u = 2, 3, 4, 5, 6 \) and 8 and very small, but non-zero temperature in [13]. In figure 8, we show our results for the momentum distribution \( n(\mathbf{k}) \) for an interaction \( u = 1, \ldots, 10 \) at half-filling in the entire Brioullin zone. Our results show excellent qualitative agreement with figure 1(a) of [13]. As in [13], we find that with increasing \( u \), the momentum distribution fulfills \( n(0, 0) \rightarrow 1 \) and \( n(\pi, 0) = 1/2 \) for all values of the interaction strength, and \( n(\mathbf{k}) \) grows with increasing \( u \) for \( k \in [\!(\pi, \pi), (\pi, 0)\!] \). Further, as in [13], we observe a broadening of the Fermi surface with growing interaction strength, i.e. the momentum distribution gets smeared out.

In the following, we consider two-particle properties of the system. To this end, we study as in [13] the following magnetic properties of the system,

- The equal-time spin–spin correlation function \( C(\mathbf{y}) = \langle (n_{(\vec{x}+\vec{y})\uparrow} - n_{(\vec{x}+\vec{y})\downarrow})(n_{\vec{x}\uparrow} - n_{\vec{x}\downarrow}) \rangle \).
- The local moment \( C(0, 0) = \langle (n_{\vec{x}\uparrow} - n_{\vec{x}\downarrow})^2 \rangle \).
- The magnetic correlation function \( S(k) = \sum_{\vec{x}} e^{i\mathbf{k} \cdot \vec{x}} C(\vec{x}) \).
Figure 7. Comparison of the ground state energy obtained from gHFT with the QMC results of [30] and [31]. We have depicted the relative error $e(u) = |E_{QMC}(u) - E_{gHFT}(u)|/|E_{QMC}(u)|$ for lattice sizes $8 \times 8$, $10 \times 10$ and $12 \times 12$ and interaction strengths $u = 2, 4, 8$ and 10.

Figure 8. Momentum distribution $n(k)$ of the ground state of the repulsive Hubbard model with an interaction ranging from $u = 1, \ldots, 10$ at half-filling. While the Fermi surface is sharp for a weak coupling, we find a broadening with increasing $u$. (Compare with the QMC result, figure 1(a) of [13].)

In figure 9, we have depicted the local magnetic moment of the ground state, $C(0, 0) = \langle (n_{\uparrow} - n_{\downarrow})^2 \rangle$, for an interaction strength $u = 0, \ldots, 10$ at half-filling. The purple squares depict the results obtained via our algorithm, while the blue diamonds represent the QMC results of [13]. Singly occupied sites fulfill $C(0, 0) = 1$, while for empty or doubly occupied sites, $C(0, 0) = 0$. In the non-interacting regime, all four states (full, empty, singly occupied in the two spin states) are equally probable, so that $C(0, 0) = \frac{1}{2}$. We find that the on-site repulsion suppresses doubly occupied and, for a half-filled lattice, also the empty configuration. With increasing $u$, the singly occupied configuration is enhanced, leading to a well-formed moment at each site.
Figure 9. Local moment $C(0, 0) = \langle (n_{\uparrow} - n_{\downarrow})^2 \rangle$ of the ground state of the repulsive Hubbard model for an interaction $u = 0, \ldots, 10$ at half-filling. Starting from the non-interacting limit, where $C(0, 0) = \frac{1}{2}$, the system approaches a value of $C(0, 0) = 1$ with increasing interaction, corresponding to a phase with no double occupancy. While the purple lines and squares depict the values of the magnetic moment obtained with our algorithm, the blue triangles represent the QMC results of [13], figure 4.

Figure 10. Equal-time spin–spin correlation function $C(\vec{y}) = \langle (n_{\uparrow}(\vec{x} + \vec{y})_1 n_{\uparrow}(\vec{x} + \vec{y})_1)(n_{\uparrow}(\vec{x} + \vec{y})_1 n_{\downarrow}(\vec{x} + \vec{y})_1) \rangle$ of the ground state for an interaction $u = 1, \ldots, 10$ and half-filling. Anti-ferromagnetic correlations increase with the interaction strength, but extend even for small interactions over the entire lattice. Compare with [13] figure 7, where $C(\vec{y})$ has been obtained for a $24 \times 24$ lattice.

Next, we study the equal-time spin–spin correlation function $C(\vec{y}) = \langle (n_{\uparrow}(\vec{x} + \vec{y})_1 n_{\uparrow}(\vec{x} + \vec{y})_1)(n_{\downarrow}(\vec{x} + \vec{y})_1 n_{\downarrow}(\vec{x} + \vec{y})_1) \rangle$. This quantity measures the extent to which two spins on sites $\vec{x}$ and $\vec{x} + \vec{y}$ are aligned. Note that the definition of $C(\vec{y})$ is rotationally invariant. Our results are presented in figure 10. The correlations extend, already for small values of $u$, over the entire lattice, as is predicted for a half-filled lattice. As one would expect intuitively, the anti-ferromagnetic correlations are enhanced with growing interaction strength. Our results show
the same qualitative behavior as in [13], where $C(\vec{y})$ has been calculated for a $24 \times 24$ square lattice.

Finally, we consider the magnetic correlation function $S(k) = \sum_{\vec{l}} e^{i\vec{k} \cdot \vec{l}} C(\vec{l})$ in figure 11. A sharp peak occurs at momentum $(\pi, \pi)$, emphasizing the anti-ferromagnetic correlations (compare with figure 8 of [13], where $S(k)$ is depicted for $u = 2$). Further, we see that the magnetic correlations depend strongly on the interaction strength.

4.2.2. Ground state properties of a doped system. Next, we consider the case of a doped system, i.e. $\mu \neq 0$. This instance has been studied e.g. in [14]. There, the local density $n_x$ was calculated as a function of the chemical potential. The results obtained via our approach (see figure 12) show a qualitative agreement with figure 2(a) of [14], where a density of $n(\mu) = 1$
Figure 13. Anti-ferromagnetic correlation $A = \langle n_{x\uparrow} n_{x+d\downarrow} \rangle$ in the repulsive Hubbard model at half-filling as a function of the inverse temperature $\beta \in [0, 1]$ for an interaction strength $u = 10$ and lattice spacing $d = 1, \ldots, 10$. We find that the anti-ferromagnetic order is destroyed with increasing temperature because of thermal fluctuations.

is found for $\mu \approx -1, \ldots, 1$. We find that for $\mu = 0$ we have half-filling, as expected, while an increase in the chemical potential results finally in doubly occupied sites.

We include here a remark on the limitations of the gHFT. It is believed that the doped Hubbard model with repulsive interaction is a highly correlated state, exhibiting pairing for some value of the doping. However, for $u \in [0, 10]$ and $\mu \in [-5, 5]$ we only find an unpaired phase. This is in agreement with theorem 2.11 of [11], where it has been proved that for any positive-definite potential $U$ the gHF ground state is unpaired, independent of the doping.

4.2.3. Thermal state properties for half-filling. In this section, we consider some finite-temperature properties of the repulsive Hubbard model, and concentrate again on the case of half-filling. We have seen in the last section that the gHFT provides us with a powerful tool to study the magnetic properties of fermions with repulsive interactions in a lattice. In particular, we have seen that the ground state of the system shows anti-ferromagnetic correlations, already for small values of the interaction strength. These are expected to decrease with increasing temperature, because the thermal fluctuations destroy the anti-ferromagnetic order. We find indeed this behavior, which is depicted in figure 13. There, we have plotted the order parameter

$$A(d) = \langle n_{x\uparrow} n_{x+d\downarrow} \rangle$$

as a function of the inverse temperature for $u = 10$. We have also derived the critical exponent $\alpha$ given by $A(T) \sim (T - T_c)^{\alpha}$ for lattice sizes $8 \times 8$ and $10 \times 10$, leading to $\alpha \approx 1.3 - 1.4$.

The anti-ferromagnetic phase is further characterized by the fact that local fluctuations in the particle number vanish, i.e. we are in a Mott phase. This phase is predicted to last for even higher temperatures than the anti-ferromagnetic phase (‘Mott gap’), because additional energy is needed to delocalize the fermions [41]. We investigate this behavior in figure 14. There,
the solid purple line shows the value of $A_{1,2} = A(1)$ (cf equation (29)), the anti-ferromagnetic correlations of nearest neighbors, while the blue dotted line is the order parameter for the Mott phase, $O_M = \langle (n_x)^2 \rangle - \langle n_x \rangle^2$. We see that independent of the interaction strength, the Mott phase as well as the anti-ferromagnetic phase break down at the same temperature, i.e. we do not find a Mott gap. This observation can be explained by the fact that the FGS cannot represent the Mott phase, as already stated in the introduction.

The fact that there exists no Gaussian state corresponding to the Mott phase except the state of the antiferromagnetic phase also leads to an incorrect transition temperature from the anti-ferromagnetic to the normal phase. For the exact solution of the Hubbard model, the anti-ferromagnetic correlations are predicted to be destroyed at a temperature $T_c \sim t^2/u$, which is the energy scale of the superexchange energy. However, in our approach the anti-ferromagnetic correlations appear as soon as we find one particle per site, leading to a transition temperature $T_c \sim u$ (cf figure 14).

5. The Hubbard model in an external trap

While the translationally invariant Hubbard model allows for an elegant analytic solution within the gHFT, experimental setups break this symmetry because the particles have to be spatially confined: an external trapping potential is needed. In many setups, this trapping is realized via a harmonic confinement. The Hamiltonian of the system is then altered by a position-dependent chemical potential, i.e.

$$H = t \sum_{(x,y) \in \Lambda} a_{x,\sigma}^\dagger a_{y,\sigma} + u \sum_{i \in \Lambda} n_{x \uparrow} n_{x \downarrow} + \sum_{x,\sigma} \mu_x n_{x,\sigma},$$

where for $x = x(h, v)$ with coordinates $(h, v)$ we have

$$\mu_x = \mu + V_t \left[ \left( \frac{N_h + 1}{2} - h \right)^2 + \left( \frac{N_v + 1}{2} - v \right)^2 \right].$$

Figure 14. Value of the anti-ferromagnetic order parameter $A_{1,2} = A(1)$ (cf equation (29)) of nearest neighbors (solid purple line) and order parameter for the Mott phase, $O_M = \langle (n_x)^2 \rangle - \langle n_x \rangle^2$ (dash-dotted blue line), for the attractive Hubbard model with interaction strength $u = 25, 50, 75, 100$ as a function of the inverse temperature, $\beta \in [0, 0.4]$. We find an absence of the Mott gap.
In the following, we investigate how the external confinement alters the physical properties of the attractive Hubbard model (with open boundary conditions) at zero and finite temperature. To gain first insights into the behavior of the system, we have depicted in figure 15 the density at the center of the trap as a function of the interaction strength and the chemical potential for three different trapping potentials \( V_t = 0.05, 0.1, 0.25 \) (b)–(d) as well as for the translationally invariant case (a). We see that the filling in the center of the trap is only altered slightly by the external potential. In the following, we call a system half-filled if there is one particle at the center of the trap. We find that the condition for half-filling does not depend much on the trapping potential, and we can use the results from figure 15 to adjust the chemical potential in order to obtain half-filling in the following.

### 5.1. Attractive Hubbard model in a trap

We start with a closer investigation of the effects of an external trapping potential on the physics of the attractive Hubbard model. In figure 16, we present the density distribution for \( u = -5 \) at half-filling for four different trapping potentials \( V_t = 0.01, 0.05, 0.1 \) and 0.25. We see that for \( V_t = 0.01 \), the density distribution is close to that of a free system with open boundary conditions, so that boundary effects are expected in this case. Hence, we will consider only \( V_t = 0.05, 0.1 \) and 0.25 from now on, and compare the results with the translationally invariant model with periodic boundary conditions.

Now we investigate how the phase diagram of the pairing changes under the influence of an external confinement. In figure 17, we have depicted how the pairing per particle as a function of interaction strength \( u \) and chemical potential \( \mu \) changes under the influence of an external trap. We have added lines for 50, 100 and 150 particles as a guide to the eye.

To gain further insight into the influence of the trap, we have depicted in figure 18 the pairing per particle for a half-filled trap, i.e. a setting where we find one particle at the center

---

**Figure 15.** Density at the center of the trap for the ground state as a function of chemical potential \( \mu \) and interaction strength \( u \) for three different trapping potentials \( V_t = 0.05, 0.1, 0.25 \) (b)–(d) as well as for the translationally invariant case (a).

---

*New Journal of Physics 12* (2010) 113004 (http://www.njp.org/)*
Figure 16. Density profiles for the ground state ($T = 0$) for the four different trapping potentials $V_t = 0.01, 0.05, 0.1$ and $0.25$ at half-filling (i.e. one particle at the center of the trap) and $u = -5$.

Figure 17. Pairing of the ground state ($T = 0$) of the attractive Hubbard model with an external confinement $V_t = 0.05, 0.1$ and $0.25$, as well as for the translationally invariant case ($V_t = 0$), for an interaction range of $u \in [-10, 0]$ and for a chemical potential $\mu \in [0, 5]$. 

New Journal of Physics 12 (2010) 113004 (http://www.njp.org/)
Figure 18. Pairing per particle for the ground state \((T = 0)\) for the attractive Hubbard model with an external confinement \(V_t = 0, 0.05, 0.1\) and 0.25 at half-filling, as well as for the translationally invariant case \((V_t = 0)\). (Note that in that case the absolute value of the pairing is not uniquely determined due to an additional gauge freedom—see text.) If the external trapping potential becomes too strong, the paired phase is suppressed.

of the trap, and compare it with the translationally invariant case. Note that for a translationally invariant system an additional gauge symmetry emerges at half-filling [11], and the underlying gauge transformation does not leave the pairing invariant. However, this gauge symmetry is broken for an inhomogeneous system, and we can only perform a qualitative comparison of the translationally invariant and trapped system. In this respect, we observe that the pairing decreases with decreasing interaction strength, both in the translationally invariant and in the trapped system, as expected. Further, we see that a very strong confinement can lead to a slight decrease in the pairing per particle. This effect can be understood in the following way: because we fix the number of particles at the center of the trap as one, and the external trap acts like a position-dependent chemical potential, a strong trap will significantly reduce the number of particles at the boundary of the lattice, and the paired phase is suppressed.

We continue our investigations into the influence of the external trapping potential by analyzing the temperature dependence of the pairing in an external trap. In figure 19, we consider interactions \(u = -10\) and \(-5\) and a temperature regime of \(\beta \in [0, 2]\). First, we observe that the external trapping alters only slightly the temperature dependence of the pairing. Further, the value of \(\beta_c\), where a phase transition from a paired to a normal state occurs, is not altered by the external confinement, and is identical to the translationally invariant case. At this point we would also like to mention that the gauge freedom of the ground state is lifted with increasing temperature, and a unique gHF ground state is expected if the temperature becomes high enough [11]. With the results depicted in figure 19, we can now conclude that for high enough temperature, the pairing as well as the transition from a paired to an unpaired phase in a trap are also approximated well quantitatively by a translationally invariant system.

Finally, we address another question related to superconductivity, namely the symmetry of the pair wave function, i.e. the question of whether we have an s- or p-wave
superconductor. Every pure Gaussian state has a wave function of the form $|\Psi\rangle = \exp\left\{\sum_{\vec{x},\vec{y}} \phi_{\sigma,\sigma'}(\vec{x}, \vec{y}) a_{\vec{x},\sigma}^\dagger a_{\vec{y},\sigma'}^\dagger\right\} |0\rangle$. Because we consider a translationally invariant system, we have $\phi_{\sigma,\sigma'}(\vec{x}, \vec{y}) = \phi_{\sigma,\sigma'}(\vec{r})$, where $\vec{r} = \vec{x} - \vec{y}$. In figure 20, we have depicted the pair wave function in momentum space, $|\phi_{\uparrow,\downarrow}(k_1, k_2)|^2$, for a translationally invariant and trapped system for $u = -6$ and half-filling. We find for all trapping potentials a spherically symmetric wave function in agreement with s-wave superconductivity.

In summary, we find that a weak external confinement alters only slightly the physics of the ground and thermal state of the attractive Hubbard model, so that experiments that require only a weak confinement will be well suited to gain a further understanding of the 2D Hubbard model.

6. Dynamical properties of the Hubbard model

Current experimental setups with ultra-cold gases in optical lattices have opened the door to an investigation of the dynamical behavior of Fermionic lattice systems. To this end, it has become possible to study processes such as the BEC–BCS crossover or dynamical quenches in the laboratory. Unfortunately, existing numerical techniques, such as QMC, are not capable of describing the physics of time evolution, so that numerical benchmark results for these processes are still missing.

In this section, we apply the machinery of time evolution within the gHFT derived in section 3.1 to dynamical processes as they can be realized by current experimental setups.
following we consider both the case of a translationally invariant system with periodic boundary conditions and the case of an external trapping potential.

6.1. Dynamical process of the translationally invariant Hubbard model

In this section, we want to learn more about the dynamical processes of the translationally invariant Hubbard model with periodic boundary conditions. To this end, we have investigated a linear ramp of the interaction strength $u$ for various ramping times $T_f$, addressing the question of whether we can achieve an adiabatic evolution of the system. As an example, we have started from the ground state for $u = -7$ and have increased $u$ linearly to the final value $u = 7$. We have used ramping times $T_f = 1, 10, 100, 200$ and $400$, and have compared the energy of the evolving system, $E(u, T_f)$, with its ground state energy, $E_0(u)$, for a given $u$.

As a result, we observe first that $E(u, T_f)$ has the same form for $T_f = 100, 200, 400$, so that we have only depicted the evolutions for $T_f = 1, 10, 100$ in figure 21. We find that for $T_f = 100$ the evolution is adiabatic for all negative $u$. However, from $u = 0$ onwards, the energy starts to deviate more and more from the true ground state energy. An increase in ramping time does not help to resolve this problem (figure 21(a)). In figure 21(b), we have depicted a ramp from $u = 2$ to $u = -2$, and also find that adiabaticity is destroyed when we cross the value $u = 0$.

We can gain an understanding of this phenomenon by looking at figure 18: we see that for $u = 0$, the ground state undergoes a phase transition from a paired to an unpaired phase. However, as we have depicted in figure 22, the dynamical evolution of the system does not show this transition: when we start from $u = -2$, where we are in a paired phase, the system remains paired even when we ramp to the repulsive side (solid lines). On the other hand, the unpaired system from which we start for $u = 2$ remains unpaired even when we ramp to positive values of $u$ (dashed lines).

Figure 20. Pair wave function in momentum space, $|\phi(k_1, k_2)|^2$, for the translationally invariant ($V_t = 0$) and trapped ($V_t = 0.05, 0.1$ and $0.25$) system for $u = -6$ at half-filling. The wave function is always spherically symmetric, in agreement with s-wave superconductivity.
Figure 21. BEC–BCS crossover for the translationally invariant Hubbard model at half-filling. Starting from the ground state for $u = -7$, we perform a linear ramp to the final value $u = 7$ with ramping times $T_f = 1, 10$ and 100, and compare the energy during evolution with the ground state energy for various $u$ values (black triangles). The evolution is adiabatic for all negative $u$ when $T_f = 100$, while adiabaticity is no longer given for $u$ positive. This problem cannot be resolved by longer ramping times (a). Further, starting from $u > 0$ and ramping to $u < 0$ leads to the same observation: as soon as $u = 0$ is reached, the evolution of the system does not follow the ground state energy anymore (b).

Figure 22. Evolution of the pairing per particle during a linear ramp. The solid lines indicate the evolution of the pairing under a linear ramp from $u = -2$ to $u = 2$. We see that the pairing survives even on the repulsive side. Conversely, when we start in the unpaired regime at $u = 2$ and ramp to negative $u$, the pairing remains zero (dashed lines).

6.2. Dynamical process for the Hubbard model in a trap

Finally, we investigate the dynamical properties of the Hubbard model in a trap. Here, we want to investigate how the attractive Hubbard model reacts to a change in the trapping potential $V_t$. 

New Journal of Physics 12 (2010) 113004 (http://www.njp.org/)
To this end, we start with the ground state of the system in a shallow trap of strength $V_t = 0.1$ and then squeeze the trap, by changing the trapping potential linearly in time to a final trapping potential of $V_t = 0.25$. As an example, we have considered an interaction strength of $u = -6$ and have set the chemical potential to half-filling (here $\mu = 3$) (I). When we reach the final value $V_t = 0.25$, we reverse the process and now decrease the trapping potential linearly to its initial value of $V_t = 0.1$ (II).

As the first question, we study whether our algorithm allows for an adiabatic evolution, i.e. the energy of the system for processes (I) and (II) is the same. To this end, we have investigated ramping times of $T_f = 100$ and $T_f = 200$, and find a reversible process in both cases (see figure 23).

Next, we are interested in the evolution of pairing under the change in trapping potential. The result is depicted in figure 24. We find that the process becomes reversible when we go to longer ramping times, and that the evolution of the pairing gets smoother. Further, we can understand the decrease (increase) in the pairing strength with increasing (decreasing) trapping potential by looking at figure 6: the change in the trapping potential can be understood as a change in the chemical potential $\mu$ for fixed values of $u$.

7. Conclusion

In this work, we have formulated the gHFT for fermionic lattice systems with a two-body interaction in terms of the CM, and have derived numerical methods to find the time evolution, and the ground and thermal states in this framework. We have benchmarked our methods with the 2D translationally invariant Hubbard model, and have found that our numerical methods work very well to solve the gHFT. Our algorithms run fast, are stable and can be applied to inhomogeneous systems and to large system sizes, because all algorithms are formulated in terms of the CM, leading to quadratic scaling in system size. However, we also found certain limitations of our approach because the gHFT is intrinsically not capable of describing certain strongly correlated phases, such as the Mott phase at finite temperature.

*New Journal of Physics* 12 (2010) 113004 (http://www.njp.org/)
Figure 24. Evolution of pairing for the half-filled Hubbard model with $u = -6$, $\mu = 3$ (i.e. half-filling) under a change of external trapping potential for ramping times $T_f = 100$ (left) and $T_f = 200$ (right). Starting from the ground state for $V_t = 0.1$, we change the trapping potential $V_t$ linearly to its final value $V_t = 0.25$ (blue line). Then we reverse the process, decreasing $V_t$ again to $V_t = 0.1$ (purple line). We see that the process becomes reversible when we go to longer ramping times, and that the evolution of the pairing gets smoother.

In this respect, we believe that the numerical methods developed in this work represent a powerful tool to simulate fermionic systems in optical lattices, at least in the weakly interacting regime. Further, we have demonstrated that our algorithms can be easily applied to inhomogeneous systems, because they are realized e.g. by the Hubbard model with an external trapping potential.

Concerning the question of whether properties of the system in the thermodynamic limit can be obtained via finite-size scaling, the results presented in figure 7 and table 1 suggest that already a moderate system size of about 100 sites is enough to get a good estimate of the properties of the attractive Hubbard model in the thermodynamic limit. In addition, our numerics performed for a lattice size of up to $16 \times 16$ show that energies can be obtained with only a slight increase in the running time, while correlation functions need some more effort but can still be obtained in a reasonable amount of time.

Thus, in future work, we aim to apply our approach to some particular experimental setup, which will require an extension of our current algorithms to much larger system sizes, and will constitute a further benchmark of our methods.

Appendix A. Minimization of the energy

In order to obtain the gHF ground state, we have to solve the minimization problem

$$\min_{\rho \text{ Gaussian}} E(\rho) = \min_{\rho \text{ Gaussian}} \text{tr}[H\rho] = \min_{\mathcal{I}^2 \leq 1} \left\{ \sum_{ij} T_{ij} \Gamma_{ij} - 3 \sum_{i,j,k,l} U_{ijkl} \Gamma_{ij} \Gamma_{kl} \right\} .$$
The condition $i\Gamma \leq 1$ is fulfilled iff $1 - i\Gamma = (A + iB)(A + iB)^\dagger$, where $A$ and $B$ are real matrices [42], from which we derive

\begin{equation}
\Gamma = AB^T - BA^T, \tag{A.1}
\end{equation}

\begin{equation}
1 = AA^T + BB^T. \tag{A.2}
\end{equation}

Then, we can reformulate the problem as an optimization problem using Lagrange multipliers. The Lagrangian is given by

\begin{equation}
\mathcal{L}_E = \sum_{ij} T_{ij}(AB^T - BA^T)_{ij} - 3 \sum_{ijkl} U_{ijkl}(AB^T - BA^T)_{ij}(AB^T - BA^T)_{kl}
\end{equation}

\begin{equation}
+ \sum_{i,k,l} \lambda_{ikl}(A_{ki}A_{li} + B_{ki}B_{li} - \delta_{kl}), \tag{A.3}
\end{equation}

where $\lambda^T = \lambda$ is the matrix of the Lagrange multipliers. The necessary conditions for a local minimum are given by

\begin{equation}
\frac{\partial \mathcal{L}_E}{\partial A_{\alpha\beta}} = 2(\bar{\hbar} B + \lambda A)_{\alpha\beta} = 0, \tag{A.4}
\end{equation}

\begin{equation}
\frac{\partial \mathcal{L}_E}{\partial B_{\alpha\beta}} = 2(-\bar{\hbar} A + \lambda B)_{\alpha\beta} = 0. \tag{A.5}
\end{equation}

From this we can obtain equations for the CM if we use equations (A.1) and (A.2),

\begin{equation}
-\bar{\hbar} \Gamma + \lambda 1 = 0, \tag{A.6}
\end{equation}

\begin{equation}
\bar{\hbar} + \lambda \Gamma = 0. \tag{A.7}
\end{equation}

Because $\Gamma^2 = -1$ and $\lambda^T = \lambda$, the condition $[\bar{\hbar}, \Gamma] = 0$ follows immediately.

**Appendix B. Imaginary time evolution of the covariance matrix (CM)**

In this section, we provide some details that lead to equation (19). To this end, we will show that either an evolution with the quadratic, state-dependent Hamiltonian $H_Q$ or an evolution with the interaction Hamiltonian $H(T, U)$ followed by an application of Wick’s theorem lead to the desired equation.

**B.1. Imaginary time evolution with the quadratic, state-dependent Hamiltonian**

In the following, we will show how the CM evolves under an evolution in imaginary time with the quadratic, state-dependent Hamiltonian $H_Q = i \sum_{ij} \bar{\hbar}_{ij} c_i c_j$, i.e. we have to calculate (cf equation (18))

\begin{equation}
\dot{\Gamma}_{kl} = -\text{itr}([H_Q, c_k c_l]) + 2\text{tr}[H_Q \rho] \Gamma_{kl}.
\end{equation}
First, note that $\text{tr}[H \rho] = -\text{tr}[\Gamma H]$. Next, we want to calculate $-\text{itr}[\{H_Q, c_k c_l\}]$ using Wick's theorem,

$$-\text{itr}[\rho(t)\{H_Q, c_k c_l\}] = \sum_{i,j} \hat{h}_{ij} \langle c_i c_j c_k c_l + c_k c_l c_i c_j \rangle$$

$$= 2 \sum_{i,j \neq k,l} \hat{h}_{ij} (-\Gamma_{ij} \Gamma_{kl} + 2 \Gamma_{ik} \Gamma_{jl}) - 4\hat{h}_{kl}$$

(B.1)

and we obtain $\Gamma = -4(\Gamma \tilde{h} \Gamma + \tilde{h})$.

**B.2. Evolution with the interaction Hamiltonian**

In the following, we will show how the CM evolves under an evolution in imaginary time with the interaction Hamiltonian $H(T, U) = i \sum_{ij} T_{ij} c_i c_j + \sum_{ijkl} U_{ijkl} c_i c_j c_k c_l$, i.e. we have to evaluate (cf equation (18))

$$\dot{\Gamma}_{kl} = -\text{itr} \{\{H(T, U), c_k c_l\}\} + 2\text{tr}[H(T, U) \rho] \Gamma_{kl}.$$  

We split the Hamiltonian $H(T, U)$ into two terms, $H_q = i \sum_{kl} T_{kl} c_k c_l$ and $H_I = \sum_{klmn} \times U_{klmn} c_k c_l c_m c_n$, and perform the calculation for both terms independently. First, the calculation for $H_q$ is the same as for $H_Q$, so that we can deduce from equation (B.1)

$$-\text{itr}[\rho(t)\{H_q, c_k c_l\}] = 2\text{tr}[T \Gamma] \Gamma_{kl} - 4(\Gamma T \Gamma + T)_{kl}.$$  

(B.2)

Next, we calculate the contribution of the interaction term. First,

$$-\text{itr}[\{H_I, c_k c_l\}\rho(t)] = -2i \sum_{i,j,m,n \neq k,l} U_{ijmn} \langle c_i c_j c_m c_n c_k c_l \rangle - 24\text{tr}_B[U \Gamma]_{kl}.$$  

Next, using Wick's theorem, we find

$$-2i \sum_{i,j,m,n \neq k,l} U_{ijmn} \langle c_i c_j c_m c_n c_k c_l \rangle = \sum_{i,j,m,n \neq k,l} U_{ijmn} \left(6 \Gamma_{ij} \Gamma_{mn} \Gamma_{kl} - 24 \Gamma_{ik} \Gamma_{jm} \Gamma_{nl}\right).$$  

We treat the two terms independently, starting with $\sum_{i,j,m,n \neq k,l} U_{ijmn} \Gamma_{ij} \Gamma_{mn}$

$$\sum_{i,j,m,n \neq k,l} U_{ijmn} \Gamma_{ij} \Gamma_{mn} = \text{tr}[\Gamma \text{tr}_B[U \Gamma]] - 4(\text{tr}_B[U \Gamma] \Gamma)_{kk} - 24(\text{tr}_B[U \Gamma])_{kl}$$

$$- 8 \sum_{i,j} U_{ijkl} \Gamma_{ik} \Gamma_{jl} - 4\text{tr}_B[U \Gamma]_{kl} \Gamma_{kl}.$$  

Next, we calculate $\sum_{i,j,m,n \neq k,l} U_{ijmn} \Gamma_{ik} \Gamma_{jm} \Gamma_{nl}$,

$$\sum_{i,j,m,n \neq k,l} U_{ijmn} \Gamma_{ik} \Gamma_{jm} \Gamma_{nl} = (\text{tr}_B[U \Gamma] \Gamma)_{kl} - (\text{tr}_B[U \Gamma] \Gamma)_{kl} \Gamma_{kl} - (\text{tr}_B[U \Gamma])_{kl} \Gamma_{kl}$$

$$- \text{tr}_B[U \Gamma]_{kl} \Gamma_{kl}^2 - 2 \sum_{i,n} U_{klmn} \Gamma_{ik} \Gamma_{nl} \Gamma_{kl}.$$  

Thus, we obtain

$$-\text{itr}[\rho\{H_I, c_k c_l\}] = -24 \text{tr}[U \Gamma]_{kl} - 24(\Gamma \text{tr}[U \Gamma] \Gamma)_{kl} + 6 \text{tr}[\Gamma \text{tr}[U \Gamma]] \Gamma_{kl}.$$  

Hence, $-\text{itr}[\rho\{H, c_k c_l\}] = -2\text{tr}[H \rho] \Gamma_{kl} - 4(\Gamma \tilde{h} \Gamma + \tilde{h})$, which leads to equation (19).
Appendix C. Minimization of the free energy

We want to minimize

$$\min_{\rho \text{ Gaussian}} F(\rho) = \min_{\rho \text{ Gaussian}} \left\{ E(\rho) - \beta^{-1} S(\rho) \right\}$$

with the help of Lagrange multipliers. An expression for the energy has already been given in equation (14). The entropy $S = -\text{tr}[\rho \ln \rho]$ is given by $S = M \ln 2 - \frac{1}{2} \text{tr}[(\mathbb{1} + i\Gamma) \times \ln(\mathbb{1} + i\Gamma)]$ [43], so that we have to solve the following optimization problem,

$$\min_{\rho \text{ Gaussian}} F(\rho) = \min_{i \Gamma \leq 1} \left\{ -\text{tr}[(T + 3\text{tr}_B[U \Gamma])\Gamma] - \beta^{-1}(M \ln 2 - \frac{1}{2} \text{tr}[(\mathbb{1} + i\Gamma) \ln(\mathbb{1} + i\Gamma)]) \right\}.$$ 

As already stated in appendix A, the condition $i \Gamma \leq 1$ is fulfilled if $\mathbb{1} - i\Gamma = (A + iB)(A + iB)^*$, where $A$ and $B$ are real matrices [42], from which we derive

$$\Gamma = AB^T - BA^T, \quad (C.1)$$

$$\mathbb{1} = AA^T + BB^T. \quad (C.2)$$

Thus, we can reformulate the minimization of the free energy as an optimization problem with Lagrange multipliers. The Lagrangian is of the form

$$L_S = F(A, B) + \sum_{i, k, l} \lambda_{kl}(A_{ki}A_{li} + B_{ki}B_{li} - \delta_{kl}), \quad (C.3)$$

where $\lambda = \lambda^T$ is the matrix of Lagrange multipliers. Now, $\frac{\partial L_S}{\partial A_{mn}} = \frac{\partial L_S}{\partial A_{kl}}$, $\frac{\partial L_S}{\partial B_{mn}}$ (resp. $B$), and we calculate first $\frac{\partial F}{\partial \Gamma_{kl}}$. To this end, we consider the entropy term $\text{tr}[(\mathbb{1} + i\Gamma) \ln(\mathbb{1} + i\Gamma)]$: we use

$$\ln(\mathbb{1} - X) = -\sum_{k=1}^{\infty} \frac{1}{k} X^k \quad \text{see e.g. [44]},$$

leading to

$$\text{tr}[(\mathbb{1} + i\Gamma) \ln(\mathbb{1} + i\Gamma)] = -\sum_{k, l} \frac{1}{k} (-i)^k (\Gamma^k + i\Gamma^{k+1})_{kl}.$$ 

Then

$$\frac{\partial}{\partial \Gamma_{kl}} \text{tr}[(\mathbb{1} + i\Gamma) \ln(\mathbb{1} + i\Gamma)] = i [\mathbb{1} + \ln(\mathbb{1} - i\Gamma)]_{kl}, \quad (C.4)$$

where we have made use of the formula $(\mathbb{1} - X)^{-1} = \sum_{k=0}^{\infty} X^k$ [44] because $[\ln(\mathbb{1} - i\Gamma)]^T = \ln(\mathbb{1} + i\Gamma)$, we arrive at

$$\frac{\partial L_S}{\partial A_{mn}} = 2(h_F B + \lambda A) = 0,$$

$$\frac{\partial L_S}{\partial B_{mn}} = 2(-h_F A + \lambda B) = 0,$$

$$h_F(\Gamma) = \bar{h} - \frac{i}{4\beta} \ln \frac{\mathbb{1} + i\Gamma}{\mathbb{1} - i\Gamma}. \quad (C.5)$$

Then, using equations (C.1) and (C.2), we obtain the following necessary conditions for minimal entropy,

$$[h_F(\Gamma), \Gamma] = 0, \quad (C.5)$$

$$h_F(\Gamma)(\mathbb{1} + \Gamma^2) = 0. \quad (C.6)$$
