Binding of host immunoglobulin is a common immune evasion mechanism demonstrated by microbial pathogens. Previous work showed that the malaria parasite *Plasmodium falciparum* binds the Fc-region of human IgM molecules, resulting in a coating of IgM on the surface of infected erythrocytes. IgM binding is a property of *P. falciparum* strains showing virulence-related phenotypes such as erythrocyte rosetting. The parasite ligands for IgM binding are members of the diverse *P. falciparum* Erythrocyte Membrane Protein One (PfEMP1) family. However, little is known about the amino acid sequence requirements for IgM binding. Here we studied an IgM binding domain from a rosette-mediating PfEMP1 variant, DBL4ε of TM284var1, and found that the minimal IgM binding region mapped to the central region of the DBL domain, comprising all of subdomain 2 and adjoining parts of subdomains 1 and 3. Site-directed mutagenesis of charged amino acids within subdomain 2, predicted by molecular modelling to form the IgM binding site, showed no marked effect on IgM binding properties. Overall, this study identifies the minimal IgM binding region of a PfEMP1 domain, and indicates that the existing homology model of PfEMP1-IgM interaction is incorrect. Further work is needed to identify the specific interaction site for IgM within the minimal binding region of PfEMP1.

1. Introduction

Many pathogens have evolved to bind to a common site on the Fc portion of immunoglobulin, however, the consequences of such interactions are largely unexplored [1]. *Plasmodium falciparum*, the major cause of severe malaria, is an example of such a pathogen that has been shown to bind to the Fc region of human IgM [2]. Binding occurs during the asexual stage of the parasite life cycle on the surface of infected Red Blood Cells (iRBCs) to a parasite-derived ligand called *P. falciparum* Erythrocyte Membrane Protein 1 (PfEMP1) [2], which is a variant surface antigen encoded by the var gene family. Each parasite has approximately 60 var genes in its genome, with only one transcribed at a time per iRBC [3]. Switching of var gene transcription leads to a change in the PfEMP1 variant expressed on the surface of the iRBC and is responsible for antigenic variation of malaria parasites [3]. PfEMP1 molecules are made up of cysteine-rich adhesion domains called Duffy Binding Like (DBL) and Cysteine-rich Inter-Domain Regions (CIDR) that bind to a range of host receptors including CD36, Chondroitin Sulphate A (CSA), InterCellular Adhesion Molecule-1 and Endothelial Protein C Receptor [4]. The adhesion domains are further classified into subtypes, DBL (α, β, γ, δ, ε, ζ and ξ) and CIDR (α, β, γ, δ and PAM), based on sequence similarity [5,6]. Only a minority of PfEMP1 variants show IgM binding activity, but IgM binding is linked to several virulence-associated *P. falciparum* phenotypes such as rosetting with uninfected RBC in severe childhood malaria [7] and binding to CSA in placental malaria [8]. The molecular basis of IgM binding by PfEMP1 is not fully understood, but current data suggest that most IgM binding sites lie within specific DBLe and DBLζ domains [2,9–11].

Previously we studied an IgM binding rosetting *P. falciparum* line TM284R+, which is a culture-adapted parasite derived from a Thai patient with cerebral malaria [12]. Rosetting is the binding of iRBC to two or more uninfected RBC, and is a PfEMP1-mediated parasite virulence phenotype that is implicated in severe malaria [13]. Many rosetting PfEMP1 variants bind IgM [14], and the IgM is thought
Fig. 1. Identification of the minimal IgM binding region of the TM284var1 DBL4ζ domain.

(A) Diagram showing the domain composition of the TM284var1 PIEMP1 variant, with the IgM binding DBL4ζ domain underlined in red. (B) Diagram showing the amino acid domain boundaries and IgM binding properties of each DBL4ζ deletion construct. The full length DBL4ζ domain (top bar) contains 16 cysteines as visualized by the dashed lines (construct used in previous work [2]). Seven deletion constructs were made spanning various regions of DBL4ζ. Proteins that bind human IgM are shown as black bars, and non-binding proteins are shown as white bars. (C) The minimal binding region of DBL4ζ (red). Subdomain (SD) 1 (yellow), 2 (blue) and 3 (grey) are shown, and cysteine residues are highlighted by arrowheads. The five charged residues within subdomain 2 predicted to be involved in IgM binding are shown in bold.

In our previous work, we localised the PIEMP1-IgM binding interaction site to the Cμ3-Cμ4 region of IgM Fc, and showed that the same site on IgM is used by multiple different *P. falciparum* genotypes [2,16]. Although, a common site on the host IgM molecule has been identified, the IgM binding site within a parasite DBL domain has not yet been investigated further. The aim of this study was to determine the minimal region within TM284var1 DBL4ζ required for IgM binding, and to use site-directed mutagene-
sis to investigate the role of specific amino acids within TM284var1 DBL4\text{c} identified as possible IgM-interaction sites from homology modelling.

2. Materials and methods

2.1. Deletion constructs and COS cell immunofluorescence assays

Deletion constructs based on TM284var1 (Genbank accession number JQ684046) DBL4c were amplified and cloned into the pRE4 vector as described previously [9,17]. The amino acid boundaries and primers used are described in Table S1. Immunofluorescence assays (IFAs) were carried out as described previously [9]. Briefly, COS-7 cells were seeded in wells containing 12 mm coverslips and transfected with constructs using FuGene (Roche) according to the manufacturer’s protocol. IFAs were carried out forty-eight hours after transfection on cells that were washed with Phosphate Buffered Saline (PBS) and fixed for 10 min in PBS/2% formaldehyde. Cells were blocked for 1 h with PBS/5% Bovine Serum Albumin (BSA) and incubated with PBS containing 10% pooled human serum as a source of IgM for 1 h. Cells were washed in PBS/0.1% BSA and incubated for 1 h with either a mouse anti-human IgM monoclonal antibody (mAb) (AbD Serotec MCA 1662) or mouse mAb D6L (Santa Cruz Biotechnology sc-21719) diluted 1:1000 in PBS/0.1% BSA. D6L detects the HSV-1 glycoprotein D tag at the C-terminal end of the cloned DBL domain [17]. Cells were washed in PBS/0.1% BSA and incubated with 1:6000 of Alexa Fluor 488–labelled goat anti-mouse IgG (Molecular Probes, A-11029) diluted in PBS/0.1% BSA for 45 min. Cells were washed for 10 min with PBS/0.1% BSA, mounted on a slide using Fluoromount-G (Southern Biotech) and viewed using a Leica DM LB2 fluorescence microscope. The transfection efficiency and/or IgM binding was assessed by counting the percentage of COS-7 cells showing positive surface fluorescence with D6L or anti-IgM mAb in 10 fields with a 40x objective. The total number of COS-7 cells per field was counted using the auto-fluorescence of the cell nuclei to identify individual cells. The precise number of cells counted differed in experiments with varying cell confluence (80–100% confluent), but at least 500 COS-7 cells per slide were counted in all cases. Positive cells were defined as those showing fluorescence over the whole COS-7 cell surface as indicated in Fig. S1 and in our previously published work [2,9].

2.2. Molecular modelling

The homology model of TM284var1 DBL4\text{c} was constructed with the automated homology modelling tools in DeepView v.3.7 [18] using the structure of 3D7var2CSA DBL6\text{e} (PDB accession code 2WAU) as the template, as described previously [16].

2.3. Expression and purification of mutant DBL4\text{c} protein

Site-directed mutagenesis of TM284var1 DBL4c was carried out by two-step PCRs using mutagenic primers and Pfx Platinum polymerase according to the manufacturer’s protocol (Invitrogen). The primers used for the E1663R mutant were 5’-caagggaaacacagaaagacagacaaaaa-3’ and 5’-ttttttgcctattttggtttctttccagct-3’. The primers used for R1764E mutant were 5’-ttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttttt
Table 1
Summary of transfection efficiency and IgM binding of TM284var1 DBLζ deletion constructs expressed in COS-7 cells.

| Construct | Cysteines | Transfection efficiency (%) | IgM binding (%) |
|-----------|-----------|-----------------------------|-----------------|
| 1: E1481-T1952 | C1-C16 | 10-15 | 8-12 |
| 2: K1595-H1839 | C4-C11 | 15-20 | 10-15 |

a Transfection efficiency was determined by counting the percentage of COS-7 cells showing surface fluorescence by IFA with mAb DL6.
b IgM binding was determined by counting the percentage of COS-7 cells showing surface fluorescence by IFA using a mouse anti-human IgM mAb. Data from at least 2 experiments for each construct is shown.
c Used in previous study [2].
d Some faint positive cells (1–2%) were seen with these constructs in some but not all experiments (n = at least 3).

3. Results

3.1. Identification of the minimal IgM binding region of DBLζ (TM284var1)

We previously showed that recombinant TM284var1 DBLζ (amino acids Glu1481-Thr1952) containing 16 cysteine residues (construct 1) binds to human IgM [2]. We made deletion constructs based on this domain, which we expressed on the surface of COS-7 cells, to identify the minimal region that could bind IgM. Construct 2, containing 8 cysteine residues (C4-C11), and construct 3 containing 7 cysteine residues (C4-C10) bound IgM similarly to construct 1 (Fig. 1B and Table 1). Deleting cysteine 10 resulted in a loss of IgM binding (construct 4, C4-C9). The smaller constructs 5–8 also failed to bind IgM. Therefore, the minimal IgM binding region is C4-C10 (construct 3, Lys1595 to Glu1814).

DBL domains are composed of a core scaffold of alpha-helical bundles stabilised by disulphide bonds, and consist of three subdomains [21]. The minimal IgM binding region comprises all of subdomain 2 of TM284var1 DBLζ, with flanking parts of subdomain 1 and 3 (Fig. 1C). The minimal binding region is shown in orange in a homology model of the TM284var1 DBLζ domain (Fig. 2).

3.2. Production of TM284var1 DBLζ mutants to investigate the IgM binding site

We previously used homology modelling of the TM284var1 DBLζ domain [16] and human IgM [22] to construct a model of the DBLζ-IgM complex. The DBL-IgM docking model was generated under constraints that took into account the narrowness of the IgM Cµ3-Cµ4 interdomain region and the position and limited solvent accessibility of the DBL domain in the context of the entire PIEMP1 molecule [16]. In this model, the predicted interaction site included five charged amino acid residues in subdomain 2 of DBLζ (Fig. 2) that were immediately adjacent to oppositely charged residues in IgM, suggesting that these residues might be important for the interaction. The deletion mutant experiments in Fig. 1 confirmed that subdomain 2 is essential for IgM binding, consistent with a role for the five charged residues.

Therefore, to test the role in IgM binding of the charged residues predicted by the model, we expressed mutant recombinant proteins in E. coli and tested the ability of each mutant to bind human IgM. In each mutant the key residue(s) were mutated to residues showing the opposite charge. The proteins tested were single amino acid mutants E1663R and R1764E, double mutant E1663R, R1764E and quadruple mutant E1663R, E1665R, R1764E, E1779K. All proteins were expressed as soluble his-tagged proteins in E. coli and were purified using nickel affinity chromatography followed by size exclusion chromatography. The proteins were assessed by SDS-PAGE and in each case showed a major band about 56 kDa under non-reducing conditions, with a shift upon reduction consistent with the presence of disulphide bonds in the recombinant proteins (Fig. 3A). All proteins showed complex size exclusion chromatograms (an example is shown in Fig. S2) and contained some smaller fragments in addition to the major species (Fig. 3A), possibly due to proteolytic degradation [23]. Western blotting with an anti-his mAb showed that all the proteins of approx. 50 kDa and larger retained the N-terminal his-tag. However, the 27 and 23 kDa fragments were not recognised by the anti-his mAb, and therefore could be bacterial impurities or DBL fragments cleaved at the N-terminus (Fig. S3).

We assessed the quality of the expressed proteins by circular dichroism to test whether the recombinant DBLζ mutants and
wild type are comparable and show the characteristic secondary structure seen with other DBL proteins. All four mutants showed a characteristic α-helical signature at 208 and 222 nm, similar to the wild type protein (Fig. 3B). Deconvolution of the CD spectra using CDNN software (Applied Photophysics) showed similar distribution of secondary structure components for each recombinant DBL4ζ protein (Table 2), suggesting that the mutants show similar overall DBL folds to the wild type. Furthermore, the CD spectra and secondary structure predictions are highly similar to those reported previously for other DBL recombinant proteins [24,25].

### 3.3. Binding of recombinant TM284var1DBL4ζ mutants to human IgM

Surface Plasmon Resonance (SPR) was used to assess the binding of single (E1663R and R1764E), double (E1663R, R1764E) and quadruple (E1663R, E1665R, R1764E, E1779K) mutants to immobilized IgM. All mutants bound IgM similarly to the wild type (Fig. 4), with binding affinities (K_D) in the nanomolar range for all proteins (Table 3). There were minor differences in K_D between some of the proteins, but further investigation with completely pure protein preparations would be required to determine the significance of these minor changes. All mutants containing R1764E showed biphasic association and dissociation curves (Fig. 4). Fitting the data to a model with two independent binding sites gave a K_D similar to the value obtained for the single-site model, together with a much tighter complex with no detectable dissociation over the time course of the experiment (koff < 10^{-6} s^{-1}, the lower limit of the SPR machine). This suggests that a fraction of the R1764E protein preparation bound irreversibly to the chip, probably due to small amounts of aggregates. Critically, however, the rest of the protein bound with similar kinetics to the wild type protein. Overall, the SPR data show that the mutated residues do not play a major role in binding human IgM, although further work would be needed to exclude minor effects.

---

**Fig. 3.** Characterization of recombinant DBL4ζ mutant proteins.

(A) SDS-PAGE of purified wild type DBL4ζ and mutant proteins on 4–12% bis-Tris polyacrylamide gels. Five micrograms of proteins were used per lane and the broad range pre-stained protein marker (NEB) was used as a reference. Predominant bands at approximately 56kDa were observed under non-reducing conditions, which shifted upon reduction, which is typical of DBL domains and characteristic of folded proteins with disulphide bonds. Lanes were as follows: (1) Wild type DBL4ζ, (2) E1663R, (3) R1764E, (4) E1663R, R1764E and (5) E1663R, E1665R, R1784E, E1779K. (B) CD spectra of purified recombinant wild type and mutant DBL4ζ proteins. Minima near 208 and 222 nm and maximum near 190 nm indicate the presence of significant α-helical content.

**Table 2**

Secondary structure elements in wild type and mutant proteins predicted from circular dichroism.

| Protein                  | α-Helices (%) | α-Parallel β-sheets (%) | Parallel β-sheets (%) | β-Turns (%) | Random-coils (%) | Total secondary elements (%) |
|--------------------------|---------------|------------------------|-----------------------|-------------|------------------|-----------------------------|
| DBL4ζ wild type          | 52            | 3.0                    | 4.5                   | 14.8        | 15.3             | 89.6                        |
| E1663R                   | 58.2          | 2.6                    | 3.4                   | 14.4        | 9.8              | 88.4                        |

| E1663R, E1665R, R1764E, E1779K | 59.3          | 2.2                    | 4.6                   | 14.2        | 16.1             | 91.0                        |
flowed to non-specifically SPR amino acids be involved in binding IgM. We used deletion mutants to identify the minimal IgM binding region comprising all of subdomain 2 of DBL4ζ, along with adjoining regions of subdomains 1 and 3, containing seven cysteine residues in total. However, testing of charged amino acids within subdomain 2 that were predicted from homology modelling to form part of the interaction site with IgM, showed no large effect on IgM binding when the specific amino acids were mutated to ones bearing the opposite charge. Therefore the existing model is not supported by experimental data, and needs to be revised.

Recent structural studies of DBL-receptor complexes have shown that although the DBL core scaffold composed of alpha helices is very similar between different DBL structures, there is extensive variation in the surface exposed loops linking the helices [21,26–28]. Many of the known receptor binding sites map to such variable loops [21,26–28]. This diversity may limit the use of homology models to predict binding residues that are present in variable loops. X-ray crystallography provides the gold standard for identifying contact residues between receptors and ligands. However, this approach is currently problematic for the study of DBL-IgM interactions, due to the large size of IgM.

One of the limitations of the current study was the difficulty in preparing completely pure recombinant protein. Even after size exclusion chromatography, multiple protein species were seen on SDS-PAGE. Despite this, the DBL4ζ proteins showed the character-
istic secondary structure of DBL domains by CD, and all proteins bound human IgM at nanomolar concentrations by SPR. Western blotting indicated that the >50 kDa proteins were his-tagged, likely representing the full-length protein and fragments with limited proteolytic degradation at the C-terminus. The experiments shown in Fig. 1 indicate that up to 138 amino acids (17 kDa) can be removed from the C-terminus of the construct without loss of IgM binding, therefore it is likely that all of the DBL4C fragments in the 50–65 kDa range contributed to the IgM binding interactions determined by SPR. Smaller fragments at ≈25 kDa protein were also present, which were not his-tagged, and could either represent bacterial impurities or DBL4C fragments that were degraded at the N-terminus. In either case, it is unlikely that these small fragments contributed to the IgM binding measure by SPR. This could lead to a slight underestimation of the binding affinity measured here, because the true concentration of the DBL4C protein in the assay is less than the apparent concentration used to calculate the K_D values. Despite the uncertainty introduced by the lack of completely pure protein, it is clear from the SPR data that all the mutant proteins retained the ability to bind human IgM at similar concentrations as the wild type. Repeated experiments with more highly purified protein preparations would be needed to determine whether there are any minor differences in binding affinity between the mutants and the wild type.

Recent work has provided some insights into the function of PFEPM1–IgM interactions. The binding of IgM to the VAR2CSA PFEPM1 variant, that plays a key role in sequestration of IRBC in the placenta in pregnancy malaria, has been shown to be an immune evasion mechanism that masks the IRBC from being targeted by parasite-specific IgG antibodies [29]. Other studies have shown that IgM binding enhances cell–cell adhesion in the context of rosette formation [10,15]. Whether IgM binding by P. falciparum proteins also results in effects on host Fcγ receptors or B cell receptors remains unknown [16]. Further work is needed to gain an accurate understanding of the molecular basis of DBL-IgM binding interactions and their influence on Plasmodium host-parasite interactions and severe malaria.
