(Dated: March 22, 2022)

We determine the capillary attraction and equilibrium configurations of particles trapped at a liquid-fluid interface due to the pinning of their contact-line. We calculate analytically the asymptotic interaction energy between two particles and, numerically, the multi-body energy landscape for up to four contacting particles. Our results are consistent with recent experiments. We show that a system composed of a large number of such particles behaves as a jammed system.

PACS numbers: 68.03.Cd, 82.70.Dd, 83.80.Hj

Capillary interactions arise whenever particles that are floating between a liquid and a fluid distort the interface. These interactions originate from the dependence of the energy stored in the interface on the distance between the particles. More generally, interactions mediated by the elasticity of the medium in which particles are embedded occur in, e.g., phase-separating binary mixtures [1], critical fluids [2], bilayer membranes [3, 4], and liquid crystals [5, 6]. Capillary interactions play significant roles in several important technologies [7], including ore flotation [8], foam stabilization [9], and solid surface nanostructuring by deposition of two dimensional colloidal crystal or aggregates [10, 11, 12].

The interaction between floating objects is well understood only when the contact-lines can freely adjust their shape at the particles’ surfaces: the weight of the particles induces an interfacial distortion that relaxes by capillarity, thereby mediating the interaction. Exact numerical results are only available, however, for the simplest case of two parallel cylinders [13]. Various approximations, e.g., Nicolson’s superposition approximation [14], have been devised for spheres and cylinders [13, 15, 16].

Recently, strong capillary aggregations of floating colloidal spheres have been reported in a regime where the above gravity-induced interaction is negligible, due to the smallness of the particles [18]. This effect has been attributed to a pinning of the contact-line at the particles’ surface. The corresponding long-range interfacial distortion has a quadrupolar shape, which mediates an interaction very strong in units of $k_B T$. Similar behaviors were recently observed in experiments involving photolithography-fabricated curved discs having an hydrophobic and an hydrophilic side. It is then the edge of the curved disc that effectively pins the contact-line [19].

In this paper, we model both experiments in an unified way and we produce exact results for the interaction between such “trapped” particles. We obtain the asymptotic interaction analytically without using uncontrolled superposition approximations. We then compute numerically the exact interaction between two particles, and the many-body interaction between three and four particles, in order to understand collective behaviors. We finally attempt to connect our results with the jammed–fluidized transition for attractive particles under external stress [20, 21], thereby proposing these systems as models for micro-rheological studies.

For definiteness, we consider floating particles that posses a fixed, non-planar line that pins the fluid’s interface (as in the above examples [15, 16]). When such particles interact, their contact-lines rise, tilt and rotate rigidly with the particles; however, each line remains fixed in the local frame attached to its particle. For simplicity, and in agreement with Ref. [19], we assume that the contact-lines depart weakly from a circle, thus excluding elongated particles. We also assume weak distortions of the interface height $h(x, y)$ relative to the plane $(x, y)$. This implies that the projection of each contact-line onto this plane can be approximated by a circle, even when the particle is tilted. We describe the $i$-th particle’s contact-line by the height function $\zeta_i(\phi_i)$ (see Fig. 1), that we expand in Fourier harmonics: $\zeta_i(\phi_i) = C_{0i} + \sum_n [C_{ni} \cos(n\phi_i) + S_{ni} \sin(n\phi_i)]$. Due to the fixed shape of the contact-line in the particle’s frame, some of the above coefficients are constrained while others are free. $C_{0i}$, which describes how the particle rises, is free (Fig. 1). The dipolar coefficients $C_{1i}$ and $S_{1i}$, which parametrize the tilts of the contact-line relative to the $z$-axis, are also free. The lowest-order multipole bearing the information concerning the shape of the contact-line is therefore the quadrupole [19]. We assume explicitly

$$\zeta_i(\phi_i) = C_{0i} + C_{1i} \cos \phi_i + S_{1i} \sin \phi_i + H_{2i} \cos [2(\phi_i - \beta_i)] + H_{4i} \cos [4(\phi_i - \beta_i)].$$ (1)
The quadrupolar coefficient \( H_{2i} \) is a constant, associated with the shape of the contact-line, and \( \beta_i \) is the free variable that represents the rotation of the particle about its normal \( n \) (Fig. 1). For the sake of completeness we have added the lowest-order multipole that does not break mirror-symmetry, \( H_{4i} \cos[4(\phi_i - \beta_i)] \). The octupolar coefficient \( H_{4i} \) is a constant that describes how the contact-lines departs from a purely quadrupolar shape. The two points where the height modulation of the contact-line relative to its average plane is the largest define an axis, evidenced by the dashed line in the figures.

For small deformations, the excess free-energy associated with the interface’s surface tension \( \gamma \) is given by

\[
F = \frac{\gamma}{2} \int d^2r \left( \nabla h \right)^2 ,
\]

where \( r = (x, y) \). For micron-sized particles as we consider here, gravity is negligible \[18\]. At equilibrium the first variation of \( F \) vanishes, which yields (see Fig. 1)

\[
\int d^2r \left( \nabla^2 h \right) \delta h + \sum_i \oint_{D_i} ds_i \frac{\partial h}{\partial r_i} \delta \zeta_i = 0 ,
\]

where \( ds_i = a_i d\phi_i \). Thus \( \nabla^2 h = 0 \). For fixed projected positions and rotations \( \beta_i \) of the particles, \( \delta \zeta_i \) reduces to \( \delta C_{0i} + \delta C_{1i} \cos \phi_i + \delta S_{1i} \sin \phi_i \), since the \( \beta_i \)'s and the coefficients \( H_{2i} \) and \( H_{4i} \) in Eq. (2) are constant. Hence the boundary equilibrium (freedom of the particles to rise and tilt) is expressed by the vanishing of the zeroth and first-order Fourier harmonics of \( \partial h/\partial r_i \) on \( D_i \), which implies that the expansion of \( \partial h/\partial r_i \) starts at \( n = 2 \):

\[
\frac{\partial h}{\partial r_i} (r_i = a_i, \phi_i) = \sum_{n=2}^\infty c_{ni} \cos (n\phi_i) + s_{ni} \sin (n\phi_i) .
\]

The condition \( \nabla^2 h = 0 \) implies the integral equation:

\[
h(r') = \sum_i \oint_{D_i} \left[ \frac{\partial h(r)}{\partial r_i} G(r, r') - h(r) \frac{\partial G(r, r')}{\partial r_i} \right] ds_i ,
\]

known as the second Green identity \[22\], where \( G(r, r') = \log |r - r'|/2\pi \) is \( \nabla^2 \)'s Green function. Evaluating Eq. (3) for \( r' \) on the \( D_i \)'s with the Fourier series (2) and (4), and with the multipolar expansion:

\[
G(r, r') = \frac{1}{2\pi} \left[ \log r' - \sum_{n=1}^\infty \frac{r^n}{n!r^n} \cos [n(\phi - \phi')] \right] ,
\]

we obtain a linear set of equations for the unknown variables \( C_{0i}, C_{1i}, S_{1i}, \) and \( c_{ni}, s_{ni} \) for \( n \geq 2 \). Given \( \beta_i, H_{2i} \) and \( H_{4i} \), these variables determine completely both \( h \) and \( \partial h/\partial r_i \) on the \( D_i \)'s. Finally, Eq. (5) determines \( h(r) \) everywhere. The corresponding free-energy is obtained by integrating Eq. (5) by parts and using \( \nabla^2 h = 0 \):

\[
F = \frac{\gamma}{2} \int d^2r \nabla \cdot (h \nabla h) = -\frac{\gamma}{2} \sum_i \int_0^{2\pi} d\phi_i \zeta_i \frac{\partial h}{\partial r_i}
= -\frac{\pi \gamma}{2} \sum_{i, k} a_i [H_{ki} (c_{ki} \cos(k\beta_i) + s_{ki} \sin(k\beta_i))].
\]

Two particles.—Consider two particles \( (i = \ell, r) \) separated by a distance \( d \) (Fig. 2). Solving analytically the linear system determining the unknown profile coefficients for \( d \to \infty \) yields \( F(d) = F_0 + F_4(d) + O(d^{-6}) \), where the leading-order interaction is

\[
F_4 = -12\pi^2 \frac{a_\ell^2 a_r^2}{d^4} H_{2\ell} H_{2r} \cos (\beta_\ell + \beta_r) .
\]

It coincides with the result found in Ref. \[18\] from a superposition approximation in the spirit of Nicolson \[14\].
Note that it does not depend on the $H_{4i}$'s. At fixed $d$, the particles interaction is minimized when the particles' axes are symmetrically rotated with respect to the line joining them ($\beta_t = -\beta_r$), as if the particles were geared. Then, the force acting between them is attractive, asymptotically given by

$$f_\infty(d) = -48\pi\gamma a_2^2 a_r^2 H_{2t} H_{2r} d^5.$$  \hspace{1cm} (9)

The exact interaction energy $\Delta F(d, \beta_t, \beta_r)$ can be obtained for any distance by solving numerically the set of equations for the profile coefficients after truncating the Fourier expansions at a large but finite order, and checking for convergence. $f_\infty$ turns to be a very good approximation for a wide range of separations, as evidenced in Fig. 2 for two identical particles with $H_{4i} = 0$. The corresponding force at contact is however $\approx 65\%$ weaker than $f_\infty$. The associated interaction energy is $-2.0\gamma H_t^2$, $\approx 20\%$ weaker than the approximation given by $F_4$. For $\gamma \approx 70$ erg/cm$^2$ (water), $a \approx 1$ $\mu$m, and $H_2/a\approx 0.1$, this gives $\approx -1.4 \times 10^{-8}$ erg ($\approx -3 \times 10^3$ $k_B T$). Note that the contact force actually depends on the details of the higher Fourier components.

When the $H_{4i}$'s are zero (purely quadrupolar particles), the numerically determined interaction turns out to be proportional to $\cos[2(\beta_t + \beta_r)]$ at any separation: the energy minimum is degenerate, corresponding to $\beta_t = -\beta_r$. Physically, this “gearing” condition is favored because it allows the heights $\zeta_i$ of the particles’ contact-lines to match, thereby preventing a strong local interfacial distortion [19]. Our exact calculations further showed that the presence of nonzero octupolar corrections $H_{4i}$ actually lifts this degeneracy: the minimum energy is attained when $\beta_t = \beta_r = 0$ (particles’ axes parallel to the separation vector), as intuited in Ref. [19].

Indeed, it is best to match the heights where the contact-lines have a sharper distortion, i.e., at the tips of the axes.

**Three particles.**—Owing to the strength of the above attraction ($\approx 10^5$ $k_B T$), we study the equilibrium states of three particles by assuming: i) that each particle contacts at least another particle, ii) that the particles can rotate around each other, in agreement with the experiments of Ref. [19]. We consider generic particles, i.e., $H_{4i} \neq 0$. Without loss of generality, we fix two particles at contact, and we explore the energy landscape as a function of the position of the third particle, described by the angle $\psi$ (Fig. 3). For each $\psi$ we minimize the energy with respect to the rotations $\beta_i$ of the three particles.

We obtain two distinct branches exhibiting three metastable minima (see Fig. 3). The latter almost perfectly satisfy the above-mentioned “gearing” rule. The curved-line configuration A suggests a three-body effect, since the particle’s axes are not parallel to one-another, contrary to the pairwise case. Indeed, repeating the calculation with pairwise interactions instead of the exact many-body interaction yields a straight line. The most stable, packed configuration is the triangle C with a radial orientation of the particles. One might argue that it best relaxes the strong interfacial distortion located at the facing tips of the particles’ axes. The orthoradial triangle B is also very stable.

**Four particles.**—To determine the equilibrium states of four contacting particles, we explore the energy landscape by fixing the positions of three particles through the angle $\psi_r$, and minimizing with respect to both the position $\psi_t$ of the fourth one and all the rotation angles $\beta_i$ (see Fig. 3). We obtain three branches and six equilibrium states.

As a new indication of a many-body effect, the “gearing” rule is strongly violated in configuration D and slightly violated in C. Contrary to the three-particle case, the orthoradial square B is more stable than the radial
square E. One might suspect that since the gap between the particles is larger than in the triangular case, it is more important to relax the distortion stored at the axes’ tips on the sides of the square rather than in its center. Note however that such reasonings become more and more delicate as the number of particles increases. The fact that B and E are the most stable configurations suggests, as proposed in Ref. [19], that the ground state for many particles should be a square lattice with B, or equivalently E, as unit cell. We find again the curved line A and different triangular arrangements with a fourth attached particle (C, D, F). Our results do successfully reproduce the various structures that can be locally seen in the experimental pictures of Ref. [19].

Such floating particles can be considered as a model system to study jamming phenomena in complex fluids. Jamming occurs in the presence of either repulsive or attractive forces [21], when a disordered system gets trapped in phase space, for kinetic or energetic reasons, and thus exhibits a yield stress [20]. Aggregates of a large number of the “trapped” particles discussed in this paper should form by accretion of individual particles or small clusters. In the absence of irreversible sticking, at each accretion the particles will rearrange until they fall in one of the many metastable configurations. They will thereby form a disordered structure with a yield stress. Such colloidal aggregates are therefore more akin to a foam [23] than to a collection of sticky spheres [24].

To test the relevance of this description in terms of jamming, we estimate the dependence of the yield stress \( \sigma_y \) on the volume fraction \( \phi \), from the energetical landscape for four particles (Fig. 4). For each metastable state, we set \( \phi \propto 1/L^2 \), where \( L \) is the distance between the farthest particles, and we estimate \( \sigma_y \approx E_b/aL \), where \( E_b \) is the energy barrier towards the nearest minimum, and \( \approx E_b/a \) the force required to rearrange a given state. This yields the diagram of Fig. 5, which is quite reminiscent of the phase diagram for attractive athermal systems proposed in Ref. [21], with a characteristic power-law \( \sigma_y \sim \phi^\mu \).

It should thus be very interesting to experimentally study the micro-rheological behavior of such particles’ aggregates. Indeed, direct observations would be possible because the system is two-dimensional; furthermore, as we have shown, this is one of the few systems where exact many-body calculations are possible.

We thank D. Johannsmann, A. Ajdari, E. Raphaël, D. T. Wu, and P. Flaud for interesting discussions and comments.

---

**FIG. 5:** Tentative jamming phase diagram extrapolated from the results for four particles. The dashed line is the power-law \( \sigma_y \sim \phi^{2.5} \).
