Systems of particles in a confining potential exhibit a spatially dependent density which fundamentally alters the nature of phase transitions that occur. A specific instance of this situation, which is being extensively explored currently, concerns the properties of ultracold optically trapped atoms. Of interest are how the superfluid-insulator transition is modified by the inhomogeneity, and, indeed, the extent to which a sharp transition survives at all. This paper explores a classical analog of these systems, the Blume-Capel model with a spatially varying single-ion anisotropy and/or temperature gradient. We present results both for the nature of the critical properties and for the validity of the “local density approximation” which is often used to model the inhomogeneous case. We compare situations when the underlying uniform transition is first and second orders.

DOI: 10.1103/PhysRevB.78.214208 PACS number(s): 64.60.De, 71.15.Mb, 37.10.Jk, 64.60.fd

I. INTRODUCTION

The realization of superfluid and Mott insulator transitions in optically trapped atoms has led to an examination of the nature of phase transitions in the presence of a spatially varying potential. For example, it was found that when a confining potential is added to the Bose-Hubbard Hamiltonian, the variation in density across the sample results in a coexistence of superfluid and Mott insulator regions. As a consequence, critical phenomena which occur in the uniform case, when the entire system collectively makes a transition from one phase to another, are smeared. The density no longer exhibits a singularity as a function of chemical potential, as what occurs in the translationally invariant case. Measures of “local quantum criticality” can be defined to help draw out residual signals of the global phase transition.

These conclusions have been drawn from direct examination of the inhomogeneous model but have also been inferred from studies of the translationally invariant model combined with the local density approximation (LDA). Specifically, the LDA assumes that the properties of the confined system at a particular spatial location are identical to those of the unconfined system with a uniform potential taking the same value as the local potential at that location. Various checks have been made, for example, by comparing the LDA results using quantum Monte Carlo (QMC) of a collection of uniform systems, with QMC simulations of a lattice with a real trap.

This LDA approximation is of course in direct analogy with that commonly used in density-functional theory, where the exact exchange-correlation potential present at a particular position \(r\), in a system where the electron density varies spatially, is replaced by the exchange-correlation energy of the uniform electron gas at the same constant density as that present at \(r\). It is known that this approximation yields very good results in a number of contexts, especially when the electron-electron interactions are of weak to intermediate strength. On the other hand, when the coupling is stronger, and phenomena such as magnetism and Mott transitions occur, the LDA is less accurate.

In this paper, we examine the nature of phase transitions in spatially inhomogeneous systems, and the validity of the LDA, within a simpler classical context. We will not explore here the effects of inhomogeneities in the quantum Hamiltonians (such as the Bose-Hubbard model) believed to be appropriate for optical lattices. Indeed, it is likely that classical analogs can provide only rough qualitative insights into the much more complex quantum phase transitions being explored in the cold atom community. Previous work in the area of the effect of inhomogeneities on classical phase transitions includes studies of Ising transitions in systems with a temperature gradient where the nature of the interface between ferromagnetic regions adjacent to the “cold side” \(T < T_c\) of a sample and paramagnetic regions next to the “hot side” \(T > T_c\) has been explored. Spatial gradients arising from confinement (“Casimir effects”) have also been explored in models of \(^3\)He-\(^4\)He mixtures within the context of vectorized analogs of the Blume-Emery-Griffiths (BEG) model.

II. MODEL AND CALCULATIONAL APPROACH

A classical model which can be constructed to have a spatially varying density similar to that in optically trapped atom systems is the Blume-Capel model with a site dependent single-ion anisotropy is

\[
E = -J \sum_{\langle ij \rangle} S_i S_j + \sum_i \Delta_i S_i^2.
\]

Here \(S_i\) is a discrete classical variable which can take on three values: \(S_i = 0, \pm 1\). A coupling \(J\) is present between nearest-neighbor spins which we choose to be positive (ferromagnetic). We consider a square lattice of linear size \(L\). That is, \(i = (i_x, i_y)\) with \(1 \leq i_x, i_y \leq L\). The value \(S_i = 0\) can be thought of as corresponding to a vacancy, while \(S_i = \pm 1\) is an Ising spin, a collection of which can order ferromagnetically if the ratio of \(J\) to temperature \(T\) is sufficiently large. \(\Delta\) is the single-ion anisotropy parameter and controls the density of \(S_i = 0\) spins.
The Blume-Capel model was originally introduced by Blume and Capel, separately, to study first-order magnetic transitions. It was later generalized to the BEG model, which incorporates an additional biquadratic interaction $K \Sigma_{ij} S_i^z S_j^z$ and odd perturbations $H \Sigma_{ij} \delta S_i^z S_j^z$. Since their initial formulation, the Blume-Capel and BEG models have been extensively used to study the phase separation of He$^3$-He$^4$ mixtures and semiconductor alloys. Recent works have used the Blume-Capel model to study ferromagnetic thin films using an alternating single-ion anisotropy and the dynamics of rough surfaces. A spatially dependent $\Delta_i$ has been studied in a vector generalization of the Blume-Capel model to describe wetting in He$^3$-He$^4$ mixtures. Here $\Delta_i$ takes on separate values in the surface and bulk, and as a consequence the helium concentration and superfluid order parameter have a nontrivial spatial dependence as one moves away from the boundaries.

Our computational method is standard Metropolis Monte Carlo. Each spin of the lattice is visited and a change from the current spin value to one of the two other possibilities is suggested. This change is accepted or rejected with the Metropolis prescription. To ensure equilibrium, a large number of sweeps of all the spins in the lattice is performed prior to making measurements. Unless otherwise noted, the statistical errors in our results are smaller than the symbol size. The lattices studied in the paper are small enough that it is not necessary to employ more powerful cluster algorithms such as those developed by Swendsen and Wang.

For uniform systems, an accurate determination of the critical point can be obtained from computing the second moment of the magnetization:

$$\langle M^2 \rangle(T,L) = \frac{1}{L^2} \left( \sum_i S_i \right)^2. \quad (2)$$

Near the critical temperature $T_c$ the following finite-size scaling expression holds:

$$\langle M^2 \rangle(T,L) = L^{-2\beta/\nu} f[L^{1/\nu}(T_c - T)]. \quad (3)$$

Here $\beta/\nu$ are the critical exponents governing how the magnetization correlation length vanishes (diverges) as $T \to T_c$ in the thermodynamic limit. Equation (3) implies that plots of $L^{2\beta/\nu} \langle M^2 \rangle$ for different lattice sizes $L$ cross at $T = T_c$, providing a method to locate the critical temperature.

The physics of the Blume-Capel model with uniform $\Delta_i = \Delta$ is well understood. When $\Delta \to -\infty$, vacancies ($S_i = 0$) are energetically very unfavorable. The system reduces to the Ising model and there is, on a square lattice, a second-order magnetic phase transition at $T = 2.269 J$. We can also deduce the critical coupling at zero temperature. The energy of the fully polarized ferromagnetic state (all $S_i = +1$) is $E_{\text{ferro}} = -(2J + \Delta) L^2$. The energy of the empty state (all $S_i = 0$) is $E_{\text{vac}} = 0$. The ferromagnetic phase is favored up until $\Delta > 2J$. Thus the phase diagram in the $(T/J, \Delta/J)$ plane consists of a ferromagnetic region at low $T/J$ and low $\Delta/J$ bounded by the lines $T/J = 2.269$ and $\Delta/J = 2$. As $\Delta$ increases from $\Delta = -\infty$ the extra entropy of vacancies reduces $T_c$ until the Ising limit boundary bends over to contact the $T = 0$ critical point.

The phase boundary for uniform $J$, $\Delta$, has been obtained by a number of methods, including Monte Carlo simulations, finite-size scaling, renormalization-group methods, and series expansions. From these studies it is known that there is a tricritical point along the phase boundary at $(T/J, \Delta/J) = (0.609(4), 1.965(5))$. At low temperatures in the vicinity of the $T = 0$ critical point $(T/J, \Delta/J) = (0, 2)$ the magnetization jumps discontinuously upon leaving the ferromagnetic phase. Beyond the tricritical point, the transition becomes continuous (second order). The phase boundary for this model is shown in Fig. 1 (top), where the values for $T_c$ were obtained through the analysis of Eqs. (2) and (3) using our code and from Refs. 33 and 38. Figure 1 (bottom) shows a representative finite-size scaling crossing for $\Delta/J = 0$. Table I provides the locations of $T_c$ for various values of $\Delta$.

Having reviewed and reproduced some of the features of the transitionally invariant Blume-Capel model, we now turn to the subject of this paper, the inhomogeneous case. We choose three models of spatial inhomogeneity. In the first two we introduce a linear variation in either the single-ion anisotropy or the temperature, keeping the other parameters fixed.
TABLE I. Table of the critical temperatures for various values of $\Delta/J$ that were found using our code and finite-size scaling technique in comparison with those from Refs. 33 and 34. The value at $\Delta/J = -8$, where vacancies are strongly suppressed, is close to the $T_c/J = 2.269$ of the two-dimensional Ising model, as expected.

| $\Delta/J$ | $k_BT_c/J^a$ | $k_BT_c/J^b$ | $k_BT_c/J^c$ |
|------------|--------------|--------------|--------------|

$^a$This work. $^b$Reference 33. $^c$Reference 34.

with vastly different single-ion anisotropies: $\Delta_x$ and $\Delta_1$. To avoid this problem, the simulations were run on lattices with linear size $2L_x + 1$ in the $x$ direction with $\Delta_1$ symmetric across the center of the lattice. In effect, a second copy of the lattice is connected to the $x = 1$ boundary of the first, and the values of $\Delta_1$ increase linearly back up to $\Delta_1$ at which point the PBC connection is established. A final point about the geometry is that when we explore finite-size effects we will fix $L_y = 50$ and increase $L_x$ at constant $(\Delta_1 - \Delta_0)$. This is done because the $x$ direction is the one along which the gradient is established and so increasing $L_x$ allows us to explore the limit where the anisotropy gradient becomes weaker and weaker. Each of the cases will be used in regions where the respective gradient is approximately perpendicular to the phase boundary, as shown in Fig. 1 (top). This ensures that the critical region will be localized to a small area of the lattice.

We present results for the “linear structure factor,” which we define as

$$S(i_x) = \frac{1}{L_y^2} \left( \sum_{i_y} S_{i_x,i_y} \right)^2 = \frac{1}{L_y} \sum_{i_y} \langle S_{i_x,i_y} S_{i_x,1+i_y} \rangle. \quad (6)$$

$S(i_x)$ sums up the spin-spin correlations for all separations $i_y = 1, 2, \ldots, L_y$ with a given $i_x$. The pairs of sites in $S(i_x)$ therefore all have the same value of $\Delta_1$. This is a convenient (indeed essential) choice in order to make meaningful comparisons with the LDA which employs lattices of constant $\Delta$. In this way, $S(i_x)$ is the natural generalization of the mean-square magnetization [Eq. (2)] used in the translationally invariant case.

We will also compare the energy for an inhomogeneous lattice with that obtained by the LDA. Similar considerations apply here as with the linear structure factor; we would like to compare observables for sets of sites with the same value of $\Delta_1$. However, the energy involves links (in the $x$ direction) which connect sites with different $\Delta_1$. For this reason we will present results for the energy associated with bonds only in the $y$ direction,

$$E_y(i_x) = -\frac{J}{L_y} \sum_{i_y} S_{i_x,i_y} S_{i_x,1+i_y} + \frac{1}{L_y} \sum_{i_y} \Delta_{i_x,i_y} S_{i_x,i_y}^2. \quad (7)$$

III. RESULTS

Figure 2(a) shows, for fixed $T/J = 1.25$, the linear structure factor $S$ as a function of $\Delta/J$. More precisely, $S(i_x)$ is computed at different values of $i_x$ for a system with a gradient $\Delta x = (\Delta_1 - \Delta_0)/L_x$ with $\Delta_0/J = -8.00$ and $\Delta_1/J = 4.00$. The value of $S(i_x)$ is plotted against the corresponding value of $\Delta_{i_x,i_{x+1}}$ on the horizontal axis. Since the relation between $\Delta_{i_x,i_{x+1}}$ and $i_x$ is linear [Eq. (4)], the horizontal axis can equivalently be viewed as labeling the spatial position as one sweeps across the inhomogeneous lattice. At the same time, the LDA values are obtained by simulating uniform systems at a range of $\Delta$ values corresponding to the vertical trajectory marked “Fig. 2” in the phase diagram of the uniform system [Fig. 1 (top)]. This trajectory crosses the ferromagnetic to paramagnetic phase boundary at $\Delta = 1.305(5)$ in a second-order transition. We see that the LDA predicts the behavior...
and dependence on PITTMAN, BATROUNI, AND SCALETTAR PHYSICAL REVIEW B 78 is when not change much over a correlation length; in other words, it thus confirming the scaling argument. In Fig. 2

We expect the LDA and the nonuniform system to agree except in the transition region. As expected, the accuracy of the LDA improves as the gradient of the inhomogeneity decreases (see text). Inset: the width of the critical region $\Delta J$ exhibits linear dependence on $\delta \Delta / L$ (see text). (b) Same as (a) except that the vertical axis is scaled by $S / \Delta J$ at $\Delta J = 1.326$ giving the critical value in the thermodynamic limit.

of $S$ in a qualitatively correct fashion over the entire range of $\Delta$ and is quantitatively accurate except in the vicinity of the critical region where the lattice inhomogeneity blurs the transition. This is the same basic result as found for optically trapped atom systems. However, we are able in this simple classical model to compare more precisely the LDA with the inhomogeneous case. In particular, Fig. 2 shows the improved accuracy of the LDA as the gradient of the inhomogeneity becomes smaller, something which has not yet been done in the quantum case.

We expect the LDA and the nonuniform system to agree well when the gradient $\delta \Delta$ is small enough, so that $\Delta$ does not change much over a correlation length; in other words, it is when $\xi \Delta$ is small compared to the width of the critical region for the LDA. It is well known $\delta \Delta$ to be very small. In this case, however, we have a first-order transition and $\xi$ remains small as the transition is approached. It does not scale with $\Delta \Delta$. Consequently, $\xi \Delta \sim \Delta \Delta$ decreases linearly with the gradient compared with $(\Delta \Delta)^{1/2}$ in the previous case. It is notable that curves of the linear structure factor for different values of the gradient cross at roughly a single point.

Our final two results for the linear structure factor are given in Figs. 4 and 5 and show cuts across the phase boundary in which both temperature and the single-ion anisotropy are simultaneously evolving. The trajectories are labeled “Fig. 4” and “Fig. 5” in Fig. 1. The physics of our model does not depend independently on $T$, $\Delta \Delta$, and $J$ but only on the ratios $\Delta / T$ and $J / T$. In Fig. 2 only the first of these ratios is changing, while in Figs. 4 and 5 both ratios are evolving as we traverse the lattice. Since both of these cuts traverse the phase boundary in the second-order region, the results for the LDA resemble those of Fig. 2. This emphasizes that the question of the accuracy of the LDA does not appear cru-

$$ S = S_0 + (\Delta_0 + \Delta_0 / L) \Delta \Delta / L \Delta \Delta $$

$$ T(\Delta) = m \Delta + (\Delta_0 + \Delta_0 / L) \Delta \Delta / L \Delta \Delta $$

FIG. 3. (Color online) $S$ versus $\Delta(i)$ at $T/J=0.56$, a temperature below the tricritical point. Data are shown for several different values of the single-ion potential gradient.

$\sim (\Delta \Delta)^{-\nu(1+\nu)}$. All curves intersect at $\Delta/J=1.326$ thus determining the critical value of $\Delta$ for $T=1.25 J$.

Figure 3 shows a similar set of data but for $T/J=0.56$ which corresponds to the trajectory labeled “Fig. 3” in Fig. 1 (top) and crosses the ferromagnetic-paramagnetic phase boundary in a first-order transition at $\Delta/J=1.986(5)$. Again, the LDA is qualitatively correct. To examine the agreement between LDA and the nonuniform system, we apply the same argument as before: $\xi \Delta \Delta$ must be very small. In this case, however, we have a first-order transition and $\xi$ is not small as the transition is approached. It does not scale with $\Delta \Delta$. Consequently, $\xi \Delta \sim \Delta \Delta$ decreases linearly with the gradient compared with $(\Delta \Delta)^{1/2}$ in the previous case. It is notable that curves of the linear structure factor for different values of the gradient cross at roughly a single point.

FIG. 4. (Color online) The linear structure factor $S$ versus $T(\Delta(i))$ for the inhomogeneous case with both a spatially varying single-ion potential and temperature gradient. The choice $m = 0.1458$ in Eq. (5) makes this trajectory cross perpendicular to the phase boundary.
The result might be expected since it is the long-range pieces of $S$ whose behavior is crucial to the occurrence of a second-order transition. Finally, Fig. 7 shows the same cut at constant $T/J=0.56$ as in Fig. 3. Here, when the underlying homogeneous transition is first order, we see that even the energy is badly estimated by the LDA. The local energy has a universal crossing, corresponding to the transition value of $\Delta/J$ similar to that of the linear structure factor $S$.

IV. CONCLUSIONS

The local density approximation is a commonly employed method to understand the phase transitions of ultracold optically trapped atoms which experience a spatially varying confining potential. In this paper we have explored the validity of the LDA in the simpler classical Blume-Capel model to which we have applied a gradient in the temperature and/or the single-ion anisotropy. Our basic conclusion is that the LDA performs well quantitatively in regions that are not close to where the state of the system is making a transition between the allowed phases, in our case ferromagnetic and paramagnetic. That is, the values of the local structure factor and energy predicted by the LDA match those of a direct simulation of the inhomogeneous system except in the transition zone. This is similar to the conclusions drawn in the optical lattice case. However, because our model is classical as opposed to quantum mechanical, we can explore the validity of the LDA in greater detail, including the systematic improvement in the accuracy of the LDA with inhomogeneous systems which have smaller gradients.

An especially interesting feature of the Blume-Capel model is the presence of a tricritical point on the phase boundary. This allows us to compare the validity of the LDA for first- and second-order transitions in the same model. Our conclusion is that a quantity such as the linear structure factor which samples long-range correlations is more badly estimated by the LDA in the transition region of a first-order phase change but that the width of the region over which the
LDA is inaccurate is more narrow. Overall, the accuracy of the LDA in the two cases is not so dramatically different. On the other hand, the predictive accuracy of the LDA for the energy, which samples just short-range correlations, is very different for the first- and second-order situations. In the second-order case, the LDA energy is quantitatively correct different for the first- and second-order situations. In the first-order case, the LDA energy is quantitatively correct even through the transition region, while in the first-order case the energy is rather badly misestimated. In optical lattice experiments, it is known (for example, for spinor condensates\textsuperscript{40,41}) that both first- and second-order transitions can occur, depending on the sign of the interaction and the Mott lobe which is being entered. While we do not expect our results for the Blume-Capel model to have a generic character that would allow them to be taken over to the boson Hubbard model, studies of such classical models might nevertheless provide qualitative insight into how the order of the transition affects the accuracy of methods such as the LDA.
