Abstract

We propose MASKER, an unsupervised text-editing method for style transfer. To tackle cases when no parallel source–target pairs are available, we train masked language models (MLMs) for both the source and the target domain. Then we find the text spans where the two models disagree the most in terms of likelihood. This allows us to identify the source tokens to delete to transform the source text to match the style of the target domain. The deleted tokens are replaced with the target MLM, and by using a padded MLM variant, we avoid having to predetermine the number of inserted tokens. Our experiments on sentence fusion and sentiment transfer demonstrate that MASKER performs competitively in a fully unsupervised setting. Moreover, in low-resource settings, it improves supervised methods’ accuracy by over 10 percentage points when pre-training them on silver training data generated by MASKER.

1 Introduction

Text-editing methods (Dong et al., 2019; Malmi et al., 2019; Awasthi et al., 2019; Mallinson et al., 2020), that target monolingual sequence transduction tasks like sentence fusion, grammar correction, and text simplification, are typically more data-efficient than the traditional sequence-to-sequence methods, but they still require substantial amounts of parallel training examples to work well. When parallel source–target training pairs are difficult to obtain, it is often still possible to collect non-parallel examples for the source and the target domain separately. For instance, negative and positive reviews can easily be collected based on the numerical review scores associated with them, which has led to a large body of work on unsupervised text style transfer, e.g., (Yang et al., 2018; Shen et al., 2017; Wu et al., 2019; Li et al., 2018).

The existing unsupervised style transfer methods aim at transforming a source text so that its style matches the target domain but its content stays otherwise unaltered. This is commonly achieved via text-editing performed in two steps: using one model to identify the tokens to delete and another model to infill the deleted text slots (Li et al., 2018; Xu et al., 2018; Wu et al., 2019). In contrast, we propose a more unified approach, showing that both of these steps can be completed using a single model, namely a masked language model (MLM) (Devlin et al., 2019). MLM is a natural choice for infilling the deleted text spans, but we can also use it to identify the tokens to delete by finding the spans where MLMs trained on the source and the target domain disagree in terms of likelihood. This is inspired by the recent observation that MLMs are effective at estimating (pseudo) likelihoods of texts (Wang and Cho, 2019; Salazar et al., 2020).

Moreover, by using a padded variant of MLM (Mallinson et al., 2020), we avoid having to separately model the length of the infilled text span.

To evaluate the proposed approach, MASKER, we apply it to two tasks: sentence fusion, which requires syntactic modifications, and sentiment transfer, which requires semantic modifications. In the former case, MASKER improves the accuracy of state-of-the-art text-editing models by more than 10 percentage points in low-resource settings by providing silver data for pretraining, while in the latter, it yields a competitive performance compared to existing unsupervised style-transfer methods.

2 Method

Our approach to unsupervised style transfer is to modify source texts to match the style of the target domain. To achieve this, we can typically keep most of the source tokens and only modify a fraction of them. To determine which tokens to edit and how to edit them, we propose the following three-step approach:

1) Train padded MLMs on source domain data ($\Theta_{\text{source}}$) and on target domain data ($\Theta_{\text{target}}$). (§2.1)
(2) Find the text spans where the models disagree the most to determine the tokens to delete. (§2.2)
(3) Use \( \Theta_{\text{target}} \) to replace the deleted spans with text that fits the target domain.

2.1 Padded Masked Language Models

The original MLM objective in BERT (Devlin et al., 2019) does not model the length of infilled token spans since each \([\text{MASK}]\) token corresponds to one wordpiece token that needs to be predicted at a given position. To model the length, it is possible to use an autoregressive decoder or a separate model (Mansimov et al., 2019). Instead, we use an efficient non-autoregressive padded MLM approach by Mallinson et al. (2020) which enables BERT to predict \([\text{PAD}]\) symbols when infilling a fixed-length spans of \( n_p \) \([\text{MASK}]\) tokens.

When creating training data for this model, spans of zero to \( n_p \) tokens, corresponding to whole word(s), are masked out after which the mask sequences are padded to always have \( n_p \) \([\text{MASK}]\) tokens. For example, if \( n_p = 4 \) and we have randomly decided to mask out tokens from \( i \) to \( j = i + 2 \) (inclusive) from text \( W \), the corresponding input sequence is:

\[
W_{\backslash i:j} = (w_1, \ldots, w_{i-1}, [\text{MASK}], [\text{MASK}], [\text{MASK}], [\text{MASK}], w_{i+3}, \ldots, w_{|W|}).
\]

The targets for the first three \([\text{MASK}]\) tokens are the original masked out tokens, i.e. \( w_i, w_{i+1}, w_{i+2} \), while for the remaining token the model is trained to output a special \([\text{PAD}]\) token.

Similar to (Wang and Cho, 2019; Salazar et al., 2020), we can compute the pseudo-likelihood (\( \mathcal{L} \)) of the original tokens \( W_{i:j} \) according to:

\[
\mathcal{L}(W_{i:j} | W_{\backslash i:j}; \Theta) = \prod_{t=i+1}^{j} P_{\text{MLM}}(w_t | W_{\backslash i:j}; \Theta) \\
	imes \prod_{t=j+1}^{i+n_p-1} P_{\text{MLM}}([\text{PAD}]_t | W_{\backslash i:j}; \Theta),
\]

where \( P_{\text{MLM}}(w_t | W_{\backslash i:j}; \Theta) \) denotes the probability of the random variable corresponding to the \( t \)-th token in \( W_{\backslash i:j} \) taking value \( w_t \) or \([\text{PAD}]\). Furthermore, we can compute the maximum pseudo-likelihood infilled tokens \( \hat{W}_{i:j} = \arg \max_{W_{i:j}} \mathcal{L}(W_{i:j} | W_{\backslash i:j}; \Theta) \) by taking the most likely insertion for each \([\text{MASK}]\) independently, as done by the regular BERT. These maximum likelihood estimates are used both when deciding which spans to edit (as described in §2.2) as well as when replacing the edited spans.

In practice, instead of training two separate models for the source and target domain, we train a single conditional model. Conditioning on a domain is achieved by prepending a special token ([SOURCE] or [TARGET]) to each token sequence fed to the model.\(^1\) At inference time, padded MLM can decide to insert zero tokens (by predicting \([\text{PAD}]\) for each mask) or up to \( n_p \) tokens based on the bidirectional context it observes. In our experiments, we set \( n_p = 4.\(^2\)

2.2 Where to edit?

Our approach to using MLMs to determine where to delete and insert tokens is to find text spans where the source and target model disagree the most. Here we introduce a scoring function to quantify the level of disagreement.

First, we note that any span of source tokens that has a low likelihood in the target domain is a candidate span to be replaced or deleted. That is, source tokens from index \( i \) to \( j \) should be more likely to be deleted the lower the likelihood \( \mathcal{L}(W_{i:j} | W_{\backslash i:j}; \Theta_{\text{target}}) \) is. Moreover, if two spans have equally low likelihoods under the target model, but one of them has a higher maximum likelihood replacement \( \hat{W}_{i:j}^{\text{target}} \), then it is safer to replace the latter. For example, if a sentiment transfer model encounters a polarized word of the wrong sentiment and an arbitrary phone number, it might evaluate both of them as unlikely. However, the model will be more confident about how to replace the polarized word, so it should try to replace that rather than the phone number. Thus the first component of our scoring function is:

\[
\text{TargetScore}(i, j) = \mathcal{L}(\hat{W}_{i:j}^{\text{target}} | W_{\backslash i:j}; \Theta_{\text{target}}) - \mathcal{L}(W_{i:j} | W_{\backslash i:j}; \Theta_{\text{target}}).
\]

This function can be used on its own without having access to a source domain corpus, but in some cases

\(^1\)The motivation for using a joint model instead of two separate models is to share model weights to give more consistent likelihood estimates. An alternative way of conditioning the model would be to add a domain embedding to each token embedding as proposed by Wu et al. (2019).

\(^2\)In early experiments, we also tested \( n_p = 8 \), but this resulted in fewer grammatical predictions since each token is predicted independently. To improve the predictions, we could use SpanBERT (Joshi et al., 2020), which is designed to infill spans, or an autoregressive model like T5 (Raffel et al., 2019).
cases, this leads to undesired replacements. The target model can be very confident that, e.g., a rarely mentioned entity should be replaced with a more common entity, although this type of edit does not help with transferring the style of the source text toward the target domain. To address this issue, we introduce a second scoring component leveraging the source domain MLM:

\[
\text{SourceScore}(i, j) = - \max \left[ 0, \mathcal{L}(\hat{W}_{i:j} \mid W_{i:j}, \Theta_{\text{source}}) \right] - \mathcal{L}(W_{i:j} \mid W_{i:j}, \Theta_{\text{source}})
\]

By adding this component to TargetScore\((i, j)\), we can counter for edits that only increase the likelihood of a span under \(\Theta_{\text{target}}\) but do not push the style closer to the target domain.\(^3\)

Our overall scoring function is given by:

\[
\text{Score}(i, j) = \text{TargetScore}(i, j) + \text{SourceScore}(i, j)
\]

To determine the span to edit, we compute \(\arg \max_{i, j} \text{Score}(i, j)\), where \(1 \leq i \leq |W| + 1\) and \(i - 1 \leq j \leq i + n_p - 1\). The case \(j = i - 1\) denotes an empty source span, meaning that the model does not delete any source tokens but only adds text before the \(i\)-th source token.

The process for selecting the span to edit is illustrated in Figure 1, where the source text corresponds to two sentences to be fused. The source MLM has been trained on unfused sentences and the target MLM on fused sentences from the DiscoFuse corpus (Geva et al., 2019). In this example, the target model is confident that either the boundary between the two sentences or the grammatical mistake “in the France” should be edited. However, also the source model is confident that the grammatical mistake should be edited, so the model correctly ends up editing the words “. She” at the sentence boundary. The resulting fused sentence is: Marie Curie was born in Poland and died in the France.

**Efficiency.** The above method is computationally expensive since producing a single edit requires \(\mathcal{O}(|W| \times n_p)\) BERT inference steps – although these can be run in parallel. The model can be distilled into a much more efficient supervised student model without losing – and even gaining – accuracy as shown in our experiments. This is done by applying MASKER to the unaligned source and target examples to generate aligned silver data for training the student model.

### 3 Experiments

We evaluate MASKER on two different types of tasks: *sentence fusion* and *sentiment transfer*. For both experiments, we only apply MASKER once to edit a single span of at most four tokens, since the required edits are often local.\(^4\)

#### 3.1 Sentence Fusion

Sentence fusion is the task of fusing two (or more) incoherent input sentences into a single coherent sentence or paragraph, and DiscoFuse (Geva et al., 2019) is a recent parallel dataset for sentence fusion. We study both a fully unsupervised setting as well as a low-resource setting.

**Unsupervised.** First, we remove the alignment between unfused and fused examples in the training set of 4.5 million examples and finetune MASKER on the resulting, non-parallel source and target corpora. This model yields an Exact match accuracy (which is a standard metric for sentence fusion (Geva et al., 2019; Rothe et al., 2020)) of 12.65

\(^3\)SourceScore\((i, j)\) is capped at zero to prevent it from dominating the overall score. Otherwise, we might obtain low-quality edits in cases where the likelihood of the source span \(W_{i:j}\) is high under the source model and low under the target model but no good replacements exist according to the target model. Given the lack of good replacements, \(\hat{W}_{i:j}\) may end up being ungrammatical, pushing SourceScore\((i, j)\) close to 1 and thus making it a likely edit, although TargetScore\((i, j)\) remains low.

\(^4\)We tried running multiple iterations of MASKER, but this somewhat decreased the accuracy of the method. When parallel development data is available, it could potentially be used to optimize a threshold of Score\((i, j)\) so that the model could be called repeatedly until the Score\((i, j)\) falls below the threshold. Alternatively, we could be interesting to explore methods for simultaneously identifying multiple, not necessarily adjacent, spans to edit.
on the development set. This is already on par with the Exact score of 12.32 obtained by a supervised LASERTAGGER model (Malmi et al., 2019) trained on 450 examples. We also test ablating SourceScore, which results in a decreased Exact score of 2.14, attesting to the importance of using the source model. Finally, we test our model on the reverse direction of going from a fused text to unfused sentences. Here, MASKER yields a significantly higher Exact score of 23.18. This direction is typically easier since it does not involve predicting discourse markers, which would require modeling the semantic relation between two sentences. The predictions of the reverse model are used in the low-resource experiments. The unsupervised results are summarized in Table 1.

### 3.2 Sentiment Transfer

In sentiment transfer, the task is to change a text’s sentiment from negative to positive or vice versa. We use a dataset of Yelp reviews (Li et al., 2018), containing 450K training, 4K development, and 1K test examples. Half of the test reviews are positive and half negative, and human annotators have written a reference review of the opposite sentiment for each test review. We use the same automatic evaluation metrics used in previous work: BLEU score and accuracy that a classifier trained to distinguish negative and positive reviews assigns to the modified reviews being of the target sentiment.

We finetune the MLMs on the training set and apply the resulting MASKER model to the test set. Additionally, we apply the MASKER model to the non-parallel training set to create parallel silver data and train a LASERTAGGER model. Interestingly, the latter setup outperforms MASKER alone (15.3 vs. 14.5 BLEU score; 49.6 vs. 40.9 sentiment accuracy). We think this happens because LASERTAGGER employs a restricted vocabulary of 500 most frequently inserted phrases, which prevents the model from reproducing every spurious infilling that the padded MLM may have produced, effectively regularizing MASKER. In Table 3, we report these results along with baseline methods developed specifically for the sentiment transfer task by Li et al. (2018) and Wu et al. (2019). Overall, MASKER yields a competitive performance although AC-MLM w/ attention-based (Wu et al., 2019) slightly outperforms it.

### 4 Related Work

Section 1 provides a high-level overview of the related work. Closest to this work is the AC-MLM sentiment transfer method by Wu et al. (2019). This method first identifies the tokens to edit based on n-gram frequencies in the source vs. target domain (as proposed by Li et al. (2018)) and based

Table 3: Yelp review sentiment transfer results.
We have introduced a novel way of using masked language models for text-editing tasks where no parallel data is available. The method is based on training an MLM for source and target domains, identifying the tokens to delete by finding the spans where the two models disagree in terms of likelihood, and infilling more appropriate text with the target MLM. This approach yields a competitive performance in fully unsupervised settings and substantially improves over previous works in low-resource settings.

5 Conclusions

We have introduced a novel way of using masked language models for text-editing tasks where no parallel data is available. The method is based on training an MLM for source and target domains, identifying the tokens to delete by finding the spans where the two models disagree in terms of likelihood, and infilling more appropriate text with the target MLM. This approach yields a competitive performance in fully unsupervised settings and substantially improves over previous works in low-resource settings.

A Examples of Model Outputs

To further illustrate how MASKER works, Table 7 shows all the input sequences and the output scores that go into computing Figure 1 in the main paper. Furthermore, Tables 5 and 6 present random samples of correct and incorrect outputs by MASKER for the DiscoFuse and Yelp datasets.

B Hyperparameter Settings

We did not perform any hyperparameter tuning, but used a fixed learning rate of 3e-5 and a batch size roughly proportionate to the training set size (see Table 4 for the chosen values). The number of training steps was determined by running the training until convergence and choosing the checkpoint with the highest validation score, shown in Table 4.

C Other Experimental Details

Code. The padded MLM implementation is based on: https://github.com/google-research/bert. LASERTAGGER code is available at: https://github.com/google-research/lasertagger

Datasets. The DiscoFuse dataset (Geva et al., 2019) is available at: https://github.com/google-research-datasets/discofuse. The Yelp review dataset (Li et al., 2018) is available at: https://github.com/lijuncen/Sentiment-and-Style-Transfer.

Evaluation. To compute BLEU scores, we used the implementation of Wu et al. (2019): https://github.com/IIEKES/MLM_transfer. The ACDMLM baseline predictions after 10 training epochs are taken from the directory. For the sentiment classification accuracy score, we trained a BERT
| Method         | Dataset                        | Learning rate | Batch size | Exact score (validation) |

| Padded MLM     | Yelp                           | 3e-5          | 2048       | 49.15                    |
| LASERTAGGER    | Yelp, MASKER silver data (neg to pos) | 3e-5    | 512        | 31.79                    |
| LASERTAGGER    | Yelp, MASKER silver data (pos to neg) | 3e-5   | 512        | 31.15                    |

Table 4: Hyperparameter settings for the proposed method in Table 1 and 2, along with the Exact scores on validation set. For Padded MLM, the validation score refers to the accuracy of predicting all four masked tokens correctly.

model, which yields an accuracy of 98.4% on the development set (slightly higher than the CNN classifier used by Shen et al. (2020) which has an accuracy of 97.7%). The Exact scores reported in the paper were computed after lowercasing the predictions and the targets.

**Padded MLM pretraining.** The padded masked language model used in our experiments uses the uncased BERT-base architecture (Devlin et al., 2019) with 110M parameters. It is pretrained with the maximum pad length of $n_p = 4$ on the Wikipedia and books corpora that the original BERT was also trained on. When creating MLM finetuning data for the source and the target domain, we always mask out only a single span of zero to four input tokens so that the masked span corresponds to whole word(s). The accuracy of the MLM at filling the masked span correctly is 44% for sentence fusion and 49% for sentiment transfer as shown in Table 4.

**Computing infrastructure.** The models were trained using Tensor Processing Units (TPUs). Inference was distributed to multiple CPUs using Apache Beam and Google Cloud.

**Runtime.** Inference time increases with the sequence length. For the example in Figure 1 of the main paper, prediction takes 52 seconds when running BERT inference on CPU. Using GPUs or TPUs can significantly reduce the runtime, but we chose to use CPUs to be able to distribute the computation more effectively. Moreover, after distilling the model into a LASERTAGGER model (the autoregressive variant) as done in our experiments, inference takes only 535 milliseconds on GPU (Malmi et al., 2019).
