**Abstract**—Data from software repositories have become an important foundation for the empirical study of software engineering processes. A recurring theme in the repository mining literature is the inference of developer networks capturing e.g., collaboration, coordination, or communication from the commit history of projects. Most of the studied networks are based on the co-authorship of software artefacts defined at the level of files, modules, or packages. While this approach has led to insights into the social aspects of software development, it neglects detailed information on code changes and code ownership, e.g. which exact lines of code have been authored by which developers, that is contained in the commit log of software projects.

Addressing this issue, we introduce *git2net*, a scalable python software that facilitates the extraction of fine-grained co-editing networks in large git repositories. It uses text mining techniques to analyse the detailed history of textual modifications within files. This information allows us to construct directed, weighted, and time-stamped networks, where a link signifies that one developer has edited a block of source code originally written by another developer. Our tool is applied in case studies of an Open Source and a commercial software project. We argue that it opens up a massive new source of high-resolution data on human collaboration patterns.

## I. INTRODUCTION

Software repositories are a rich source of data facilitating empirical studies of software engineering processes. Methods to use meta-data from these repositories have become a common theme in the repository mining literature. Thanks to the availability of massive databases, already simple means allow to query meta-data on the commits of developers [1, 2]. Apart from the evolution of software artefacts, they also contain a wealth of fine-grained information on the human and social aspects of software development teams. Specifically, the commit history of developers allows to construct social networks that proxy collaboration, coordination, or communication structures in software teams. These databases have therefore facilitated data-driven studies of social systems not only in empirical software engineering, but also in areas like computational social science, social network analysis, organisational theory, or management science [3, 4].

The detailed record of file modifications contained in the commit log of, e.g. git repositories also enables more advanced network reconstruction techniques. In particular, from the micro-level analysis of textual modifications between subsequent versions of code we can infer *time-stamped, weighted, and directed co-editing relationships*. Such a relationship \((A,B,t,w)\) indicates that at time \(t\) developer \(A\) modified \(w\) characters of code originally written by another developer \(B\). Recent research has shown that such a fine-grained analysis of co-editing networks in large software projects can provide insights that go beyond more coarse-grained definitions [5, 6]. However, a tool to conveniently extract such rich, time-stamped collaboration networks for the large corpus of git repositories available, e.g. via public platforms like github, is currently missing.

Addressing this gap, we present such a tool that facilitates the scalable extraction of time-stamped co-editing relationships between developers in large software repositories. The contributions of our work are as follows:

- We introduce *git2net*, a python tool that can be used to mine time-stamped co-editing relations between developers from the sequence of file modifications contained in git repositories. Building on the repository mining framework *pyDriller* [7], *git2net* can operate both on local and remote repositories. Providing a command-line interface as well as an API, *git2net* can be used as stand-alone tool for standard analysis tasks as well as a framework for the implementation of advanced data mining scripts. Our tool is available as an Open Source project\(^1\).

- Analysing all file modifications contained in the commit log, *git2net* generates a database that captures fine-grained information on co-edited code either at the level of lines or contiguous code regions. Building on text mining techniques, it further analyses the overlap between co-edited code regions using (i) the Levenshtein edit distance [8] and (ii) a text-based entropy measure [9]. These measures facilitate (i) a character-based proxy estimating the effort behind code modifications, and (ii) an entropy-based correction for binary file changes that can have a considerable impact on text-based effort estimation techniques.

- We develop an approach to generate time-stamped collaboration networks based on multiple projections: (i) time-stamped co-editing networks, (ii) time-stamped bipartite networks linking developers to edited files, and (iii) directed networks linking files to files.

\(^1\)https://github.com/gotec/git2net
acyclic graphs of code edits that allow to infer “paths” of consecutive edits building upon each other. All network projections are implemented in git2net and can be directly exported as HTML visualisations as well as formats readable by common network analysis tools.

- Thanks to a parallel processing model that utilises modern multi-core architectures, git2net supports the analysis of massive software repositories with hundreds of thousands of commits and millions of lines of code. A scalability analysis proves that our parallel implementation yields a linear speed-up compared to a single-threaded implementation, thus facilitating the fine-grained textual analysis even in massive projects with a long history.

- Utilizing git2net in a case study on two software projects, we show that the fine-grained textual analysis of file modifications yields considerably different network structures compared to coarse-grained methods that analyse code co-authorship at the level of files or modules. We further demonstrate how our tool can be used to breakdown developer effort into (a) the revision of code authored by the developer him or herself vs. (b) the revision of code written by other team members.

Providing a novel method to mine fine-grained collaboration networks at high temporal resolution from any git repository, our work opens new perspective for empirical studies of development processes. It further contributes a simple method to generate data on temporal social networks that are of interest for researchers in computational social science, (social) network analysis and organisational theory.

The remainder of this paper is structured as follows: Section II provides an overview of works addressing the construction of social networks from software repository data. Section III introduces our proposed methodology to extract time-resolved and directed links between developers who subsequently edit each others’ code. Section IV presents a case study, in which we apply our tool to git repositories from (i) an Open Source Software project, and (ii) a commercial, closed-source project. In section V we draw conclusions from our work and highlight the next steps in our research.

II. RELATED WORK

Given the large body of work using network analysis to study software development processes, we restrict our overview to related works that address the reconstruction of social networks from software repositories. A broader view on applications of graph-based data analysis and modelling techniques in empirical software engineering—including works on (technical) dependency networks that are outside the scope of our work—is, e.g., available in [10, 11, 12].

A number of studies use operational data on software projects to construct graphs or networks where nodes capture developers while links capture social interactions and/or work dependencies between developers. To this end, a first line of works has used data that directly capture communication [13], e.g. via IRC channels [14], E-Mail exchanges [15, 16, 17, 18, 19], mailing lists [20], or communication via issue trackers [21, 22, 23, 24, 25].

While data on direct developer communication facilitate the construction of meaningful social networks, they are often not available, e.g. due to privacy concerns. To address such settings, researchers have developed methods to infer or reconstruct collaboration networks based on developer actions recorded in code repositories like CVS, SVN, or git. A common approach starts from code authorship or code ownership networks, which map the relation between a developer and the artefacts (i.e. files, modules, binaries, etc.) that he or she contributed to [26, 27, 28, 29]. The resulting directed bipartite developer-artefact networks [30] can then be projected onto co-authorship networks, where undirected links between two developers A and B indicate that A and B have modified at least one common artefact. The authors of [31, 32] have studied co-change based on a large corpus of CVS repositories of Open Source Software projects.

The majority of works mining social networks from software repositories build on this general idea. In [29, 33, 34, 35, 36] a file-based notion of co-authorship is used to construct co-commit networks, where a link between two developers signifies that they have committed the same file at least once. The authors of [37] adopt a module-based definition, assuming that two developers are linked in the co-authorship network if they have contributed to at least one common module. Taking a similar approach, Huang and Liu [38] use information on modified file paths in SourceForge repositories to infer relations between authors editing the same part of a project. Incorporating the time stamps of commits, Pohl and Diehl [39] used a file-based co-authorship definition to construct dynamic developer networks that can be analysed and visualised using methods from dynamic network analysis [40]. The authors of [41] recently developed a similar approach to study the ecosystem of software projects on GitHub. To this end, they define project-level co-commit networks, i.e. a projection of commits where two developers are linked if they committed to the same Open Source project. Schweitzer et al. [42] provided a related study, analysing ten years of data from the Open Source project hosting platform SourceForge.

These works have typically constructed undirected co-authorship networks based on joint contributions to files, modules, or projects. Such coarse-grained definitions of co-authorship networks introduce a potential issue: They do not distinguish between (i) links between developers that are due to independent contributions to the same artefact, and (ii) links that are due to commit sequences where one developer builds upon and/or redacts the particular lines of source code previously authored by another developer. Networks defined based on the latter type of time-ordered co-editing of code regions are likely associated with a stronger need for coordination and communication than the mere fact that developers edited the same file or module [43]. So far, few studies have adopted such fine-grained approaches to create developer collaboration networks. Notable exceptions include the function-level co-editing networks constructed by Joblin et al. [5]. The authors
further argue that, using file-based definitions of collaboration networks, network analytic methods fail to identify meaningful communities. The authors of [6] constructed line-based co-editing networks, showing that such an analysis (i) yields insights into the coordination structures of software teams, and (ii) provides new ways to test long-standing hypotheses about cooperative work from social psychology.

While such a fine-grained analysis of the co-editing behaviour of developers has its advantages, it also introduces challenges that have so far limited its adoption. First and foremost, it requires a detailed analysis of file modifications and makes it necessary to identify the original author for every modified line of code affected in each commit. Requiring a potentially large number of git operations for every commit being analysed, such an analysis is both complicated to implement as well as time-consuming to perform. Compared to other approaches, which often merely require a suitable query in structured databases like ghTorrent [1, 2], a tool that facilitates this task for very large repositories is still missing.

Closing this gap, our work introduces a practical and scalable solution for the construction of fine-grained and time-stamped co-editing networks from git repositories. Our work extends the state-of-the-art and facilitates analyses of developer collaboration and coordination in software projects. Providing a new method to construct large, dynamic networks at high temporal resolution we further expect our work to be of interest for the community of researchers developing methods to analyse dynamic (social) networks [40, 44, 45].

III. MINING CO-EDITING RELATIONS FROM GIT REPOSITORIES

A. From Commit Logs to Co-Edits

We first outline our proposed method to extract co-editing relationships from git commits. An overview of the mining procedure, which we will explain in the following, is presented in Algorithm 1.

git projects generally consist of multiple files that can be edited by a large number of developers. Sets of changes made by a developer to potentially multiple files are recorded as commits, where each commit is identified by a unique hash. Building on the package pydriller [7], we first extract the history of all commits in a repository and record the meta-data (author, time of commit, branch, etc.) for each commit. As the person committing the changes is not necessarily the author of these changes (a different developer can commit code on behalf of the original author), both the committer and author of the changes are considered. Subsequently we analyse the changes made with the commit.

As each commit can contain modifications of multiple files, we analyse each file modification individually to associate every changed text region with its original author. In a first step, select the modifications relevant for the current analysis. To this end, we have implemented a filter allowing to exclude specific files, file types as well as entire directories or sub-directories from the analysis. For all selected modifications, the associated diff is analysed, determining which lines have been added or deleted. In addition, we identify the original author of every edited line of code by executing git blame on the version of the analysed file before the current commit. By matching the author $A$ of a modification contained in the current commit with time stamp $t$ to all original authors $B_i$ of an edited line $i$, we obtain time-stamped and directed co-editing relations $(A, B_i, t)$.

For each extracted relation, we record hashes of the original and modifying author as well as meta-data capturing the location (file name, line number) of the associated co-edit. Naturally, such co-edits can be linked to vastly different development effort, ranging from a change of whitespaces to the complete rewriting of code. To capture to what extent developers edit each others’ code, we use a text mining approach to address these differences. We specifically use the Levenshtein edit distance [8], which can be thought of as the minimum number of keystrokes required to transform the prior source code version into the version after the edit. This measure proxies the development effort associated with an edit, where single character changes, line deletions, or the commenting/uncommenting of lines are associated with a minimum effort while the writing of a new line of code is associated with maximum effort. This approach allows us to construct time-stamped and weighted co-edit relations $(A, B_i, t, w)$, where the weight $w$ captures the Levenshtein distance of the associated edit.

An issue that we have encountered during the testing of our method in real-world repositories is associated with the embedding of text-encoded binary objects in source code, e.g. due to the inclusion of base64-encoded images in HTML or JavaScript. Notably, the modification of a single pixel in a text-encoded image, can result in a completely different text encoding. Considering our approach to associate the weight of a co-edit relation with the Levenshtein edit distance this can considerably distort our analysis, potentially leading to the issue that binary file modifications dominate the recorded weights. We take an information-theoretic approach to enable the detection (and potential exclusion) of such modifications. In particular, we compute the entropy $S$ of code before and after the change, defined as:

$$S = - \sum_k p_k \log_2(p_k)$$

(1)

This computation is based on the utf-8 encoding space with 256 possible symbols. Entries of the vector $p$ represent a
symbol’s normalised frequency in a given string. Given this definition, the entropy $S$ can take values between 0 and 8 bits. Some examples for this measure are given in Figure 1. The resulting distribution of entropy for all co-edits can be used for a Bayesian classification distinguishing, e.g., binary encoded images or hashes from natural language or source code changes.

In the discussion above, we have considered a purely line-based approach, which treats every modified line of code as a separate entity. However, it is common that developers edit contiguous regions of code, consisting of multiple adjacent lines, with a single modification. As illustrated in Figure 2, git2net therefore provides an option to analyse co-edits at the granularity of such contiguous code regions rather than lines. Compared to previous approaches, which have used programming language constructs like functions to identify co-edits at a granularity smaller than files [5], this approach has the advantage that it is agnostic of the programming language. It further allows to analyse co-edit relations in files that do not represent source code, e.g., in text documents.

To explain our approach of identifying edited blocks of code, we distinguished between different cases contained in Figure 2: For deleted lines (e.g. line 2 in Fig. 2) a normal co-editing relationship is recorded. As the effort required for deletions can vary both between projects and the type of analysis performed, we mark these cases in the database but do not specify a Levenshtein edit distance. Edits exclusively consisting of added lines are recorded in the database but not considered as co-edits (neither by a line-based nor by a block-based approach) as no previous author exists. The Levenshtein edit distance for pure additions matches the number of characters that were added. For cases where a set $D$ of deleted lines is replaced by a set $A$ of added lines, the line-based approach matches each line $d_i \in D$ with a line $a_i \in A$ for $i \leq \min(|D|, |A|)$. If $|D| < |A|$, a line-based approach would thus treat the excess lines in $A$ as added lines, thus not considering them as a co-edit. This is the case in line 4-5 in Fig. 2. With our block-based approach, we instead identify that a block of lines (lines 4-5) in the original file is replaced by a new block (lines 3-5) in the new file. If $|D| > |A|$, a line-based approach identifies the excess lines in $D$ as deleted lines (see line 7-8 in Fig. 2). Through a block-based analysis we are instead able to identify that a block of lines (lines 7-8) in the original file is replaced by a new block of lines (line 7) in the new file.

While for the line-based approach, all editing statistics such as the Levenshtein edit distance or the entropy are computed on pairs of lines $(d_i, a_i)$, the block based approach considers the set of lines in $A$ as a replacement of the lines contained in $D$. Consequently all statistics are computed for the pair of code blocks $(D, A)$.

After evaluating each commit, results are written to an sqlite database. This allows to pause and resume an analysis at any point in time and helps to prevent data loss from system crashes. The resulting database scheme is shown in Figure 3.

| code          | entropy |
|---------------|---------|
| a for x in 'hello world': print(x) | 3.94    |
| b for c in 'hello world': print(c) | 3.94    |
| c d = [x[0]:x[1]] for x in df['d']] | 3.80    |
| d Uatsffm+BC+s7KwKvPMLrMvEWK7hTFK1 | 4.41    |

Fig. 1. Entropy of equal length strings based on discrete utf-8 (256 possible symbols) probability space. The entropy can take values between 0 and 8 bits. The entropy of base64 encoded image (d) is considerably higher than of typical lines of (python) code (a-c). In practice the effect is amplified as strings of binary encoded images are longer. Small changes within a line have a small or no effect on entropy as can be seen in the entropy difference between a and b.

![Fig. 2. Identification of replacements using line- and block-based analysis.](image)

![Fig. 3. Relations in the co-editing database. Elements marked † only occur for line based analysis, whereas entries marked ‡ are specific to block based analysis.](image)
B. From Co-Edits to Networks

Given the database of co-editing relationships generated by the approach described above, git2net provides procedures to generate three different types of network projections: (i) co-editing networks, (ii) directed acyclic graphs of edit sequences for a given file, and (iii) bipartite networks linking developers to edited files.

The process of generating co-editing networks is illustrated in an example shown in Figure 4. The left column shows three developers (A, B, and C) editing three colour-coded files. Modified lines are shown in red. Edges between files represent the number of overlapping lines, which for illustrative purposes we show instead of the more granular Levenshtein edit distance. Given these edges, we generate a temporal network connecting the developers (cf. Fig. 4, centre for a time-unfolded representation). A link \( \langle A, B; t, w \rangle \) in this network represents a commit by developer A at time \( t \) in which \( w \) lines originally authored by developer B are modified. By the aggregation of time-stamped links over a (moving) time window we obtain co-editing networks as shown in the right column of Figure 4.

Apart from co-editing networks, git2net supports the construction of file-based directed acyclic graphs (DAGs) of commits based on co-editing relationships. Each path in this DAG represent a sequence of consecutive co-editing relationships of developers editing the given file, i.e. a sequence of commits containing file modifications that built upon each other. The nodes in this graph represent commits and edges represent co-editing relationships between the authors of the commits. An example for the construction of such a DAG from a set of five commits containing file modifications is shown in Figure 5. Individual connected components of the DAG represent proxies of knowledge flow for this file. This has been highly valuable in our own research as it immediately allows the extraction of paths from the co-editing relationships. Analysing these paths with the methods provided by the software package pathpy [46] allows to trace knowledge flow within specific areas of the development—a topic we identified as highly relevant in discussions with practitioners from software development companies.

To additionally facilitate coarse-grained analyses at the level of file-based coauthorship relations, git2net finally supports the construction of bipartite file-developer networks, where directed links \( (d, f) \in D \times F \) indicate that a developer \( d \in D \) has modified a file \( f \in F \).

C. Usage of git2net

git2net comes as a python package that can be installed via the python package manager pip. During the installation all dependencies, which consist of the python packages pandas, python-Levenshtein, pyDriller, progressbar2, and pathpy, will be installed automatically. git2net runs on all major operating systems and has been tested under Windows, Mac OS X, and Linux. Assuming that the git repository that shall be examined has been cloned to a directory repo, our tool can be launched by the command

```bash
./git2net.py mine repo coedits.db
```

where coedits.db indicates the sqlite database file where the results will be stored. An optional parameter --exclude can be used to pass a text file that contains paths of files or directories in the repository tree that shall be excluded from the analysis. In our own analyses of a large commercial software project, this function has proven crucial to exclude directories containing large binary files or external Open Source software dependencies that would considerably distort the analysis. While the analysis of co-edited code uses the line-based approach described above by default, an optional command line switch --use-blocks can be used to use the block-based extraction of co-editing relations instead.

Fig. 4. Process of generating a co-editing network from git commits. To enhance readability, each commits only modifies a single file. Three different colour coded files are considered. Edited lines are shown in red. For all edits, edges to the commit containing the original line are shown on the left hand side. Link weights are determined based on the number of lines changed. A time stamped link between the authors of the modified lines is recorded once the edit takes place (cf. centre figure). The resulting set of time stamped edges can either be analysed itself or aggregated into co-editing networks via a sliding window analysis as shown on the right. Unless indicated otherwise, all edge weights are 1.

Fig. 5. Process of creating file based directed acyclic co-editing graphs. The left hand side shows a set of commits modifying three colour coded files. For each file a directed acyclic graph is generated linking consecutive commits with overlapping changes.
In addition to the command line interface outlined above, git2net provides an API that can be used for the development of custom repository mining scripts. In particular, the API provides methods that allow to extract co-edit relations from individual commits that can be passed as PyDrilller objects. It can further be used to augment the analysis of edited code blocks by advanced text mining and code analysis techniques. In order to generate network projections based on a database of co-edits, git2net can be launched with the command

```
./git2net.py graph [type] coedits.db graph.csv
```

where type can be --coedit, --bipartite, or --dag. Depending on the choice, git2net generates a projection of the co-editing database in terms of a temporal co-editing network (cf. Fig. 4), a bipartite network linking authors to files, or a directed acyclic co-editing graph (cf. Fig. 5) respectively.

All networks can be exported in a csv-based format that can be read by popular network analysis packages like igraph [47], graphtool\(^2\), Gephi [48], and NetworkX [49]. Time-stamped co-editing networks can further be exported in a format that can be read by the dynamic network analysis and visualisation packages ORA [45] and pathpy [46] via the provided API. Moreover, all networks can be exported in terms of dynamic and interactive d3js visualisations, which directly run in any HTML5-compliant browser.

D. Experimental Evaluation of Scalability

We conclude this section by an experimental evaluation of the scalability of git2net. In particular, our tool facilitates the analysis of large repositories thanks to the automatic utilisation of multiple processing cores. By default, git2net uses all available processing core, creating multiple child processes that extract co-edits from independent commits in parallel. Through an optional command line switch --no-parallel, multi-core processing can be deactivated. An optional command line parameter --numprocesses further allows to limit multi-core processing to at most \(N\) processing cores. Similarly, the API exposed by git2net provides parameters that can be used to control multi-core processing.

In order to evaluate the scalability gains provided by the parallel processing model, we performed an experiment using real-world data. We specifically cloned the git repository of the Open Source software igraph [50] and used git2net to extract line-based co-editing relationships. We then measured the time needed to analyse the full git history with close to 6,000 commits and approximately 35,000 file edits over a period of 14 years. We repeated this experiment multiple times, using different numbers of processing cores on a recent 16 core desktop processor\(^3\).

Figure 6 shows the time required to extract all co-editing relationships from the repository of igraph (y-axis) plotted against the number of processing threads (x-axis). Up to the number of physical processing cores of the machine (16) we observe an almost perfect linear scaling of processing time, cutting down processing time from close to one hour (single-threaded) to less than 5 minutes. Starting from 16 processing cores we observe deviations from the linear scaling that are likely due to the synchronised writing to the sqlite database. This deviation from the linear scaling is naturally intensified as we exceed the number of physical processing cores, additionally utilising logical cores exposed through Intel's implementation of HW-based multi-threading.

IV. EXEMPLARY CO-EDITING ANALYSIS OF AN OPEN SOURCE AND COMMERCIAL PROJECT

Having discussed the implementation, usage, and scalability of our tool, we now demonstrate its usefulness through four short exemplary studies of real-world software projects. We apply git2net to (i) the git hub repository of the Open Source network analysis software igraph [47], and (ii) a large git repository of a commercial software project obtained via an industry collaboration with the software company GENUA. We specifically demonstrate (A) the construction of different static network projections capturing co-editing, co-authorship, and code-ownership relations, (B) a comparative study of fine-grained co-editing networks vs. coarse-grained co-authorship networks generated at the level of files, (C) the analysis of dynamic co-editing networks by means of temporal network analysis techniques, and (D) a comparison of temporal co-editing patterns between an Open Source and a commercial software project. These case studies should be seen as seeds for future work that demonstrate the usefulness of our approach rather than as conclusive analyses. To support such future studies, the co-editing relationships extracted from the Open Source project igraph are available on zenodo.org [51].

A. Static Network Projections

To demonstrate our tool, we illustrate the three different network projections introduced in III, using the co-edit information extracted from the public git repository of the network analysis package igraph [50]. The resulting networks are shown in Figure 7.

\(^2\)https://graph-tool.skewed.de/

\(^3\)Intel® Core™ i9 7960X, 16C/32T, 2.80GHz base, 4.2GHz boost
Figure 7 shows a static co-editing network where nodes represent developers. For this initial demonstration we employ a time-aggregated projection, i.e. we use time-stamped co-editing relations \((v,w; t)\) capturing that at time \(t\) a developer \(v\) edited code originally written by developer \(w\) to construct a time-aggregated graph \(G(V, E)\) where \((v,w) \in E\) iff \(\exists \tau : (v,w; \tau)\). The directionality of links in this projection allows us to distinguish between team members with different roles: Nodes with zero in-degree, i.e. developers with no incoming co-edit relations, have never contributed code that was subsequently revised by other developers. Nodes with zero out-degree, i.e. developers with no outgoing co-edit relations, have never revised code that was originally authored by other developers. Such a maximally simple static projection can thus give a first “birds-eye” view of the collaboration and coordination structures in a software developing team. It highlights pairs of developers who exhibit strong mutual co-editing relations as well as pairs of developers working independently. This analysis can be refined by taking into account the time stamps of co-editing events, which we will do in section IV-C. In section IV-B we further discuss the difference between file-based coauthorship networks considered in prior works and the static projection of a fine-grained line-based definition.

Apart from co-editing relations between developers, in section III we have argued that git2net also provides a new perspective on the history of commits modifying a given file in the repository. In particular, this information can be used to construct a directed acyclic graph of commits, where a link \((v,w)\) in the graph indicates that commit \(w\) edited a region of source code originally contributed in commit \(v\). Hence, each path from a root node \(r\) to a leaf node \(l\) in the resulting directed acyclic graph can be interpreted as a time-ordered sequence of commits that transforms code originally introduced in commit \(r\) into the “final” version contained in \(l\). We highlight that this projection is different from commonly studied commit graphs, which link each commit to their parent commit independent of whether there is an overlap in the edited code. Fig. 7b illustrates this idea. It shows the directed acyclic graph of commits for the source code file \(flow.c\) in igraph [50]. Root nodes (with in-degree zero) in which the original version of a region of source code was committed are shown in red, while the commits containing the “final” version of code regions (out-degree zero) are highlighted in green. Intermediary nodes (yellow) represent commits that have both (a) edited code originally contributed in a previous commit and (b) contributed new code that is being revised in a subsequent commit. The analysis of such directed acyclic graphs can give insights into the complexity of code edits and their distribution across the team or across time. They further provide a novel abstraction that can be useful for the comparison of software artefacts, development processes, or projects.

In order to make it easy to reproduce file-based definitions of co-authorships used in the literature, git2net finally supports the construction of networks linking developers with the files that they have edited. The time-aggregated bipartite network resulting from the file edits made in the year 2016 for the project igraph is shown in Fig. 7c. Apart from being a basis for the construction of file-based coauthorship networks, this simple representation can give a coarse-grained view of code ownership and the distribution of contributions across the development team.

B. Co-editing vs. co-authorship networks

As outlined in section II, the analysis of co-authorship networks that capture which developers have contributed to the same files has received significant attention. At the same time, recent works have argued for more fine-grained definitions of collaboration networks, using e.g. function points or code lines [5, 6]. We contribute to this discussion and investigate the differences between a line- and a file-based approach to con-
struct developer collaboration networks. Our results show that (i) this choice of granularity has considerable influence on the resulting network topologies, (ii) that the resulting differences are project-dependent, and (iii) that the differences between the resulting networks exhibit temporal inhomogeneities.

For our analysis, we first use git2net to extract (a) a file-based co-editing network $G_f$ (which for simplicity we call co-authorship network), and (b) a line-based co-editing network $G_l$ for the Open Source project igraph as well as for a large commercial software project. For both networks, we compare the time-aggregated projections (constructed as described in IV-A) and the sequence of networks obtained via a rolling window analysis. For each time window (as well as for the time-aggregated network), we then quantitatively assess the difference between $G_l$ and $G_f$. We first observe that the set of nodes in both networks is necessarily the same. As a maximally simple approach to assess the difference between the two networks, we can thus calculate $\delta := \frac{m_f}{m_l}$, where $m_f$ and $m_l$ are the number of links in the file-based co-authorship network and the line-based co-editing networks, respectively.

Figure 8 shows the result of this analysis. Fig. 8a confirms that the file-based co-authorship network does not resolve where in the file edits take place, leading to a significantly higher number of links compared to the co-editing network in both projects. We expect many of these additional links to be false positives, in the sense that despite two developers having made edits to the same file no actual collaboration on the same code actually occurred.

Fig. 8b highlights the temporal dimension of these differences. It shows the time-evolving difference between the two network abstractions, using a 90 day moving window. For each window, the difference $\delta$ between the two networks is reported. Importantly, we observe time windows where $\delta < 1$, which indicates that the line-based co-editing networks feature additional links over the file-based co-authorship network. This is due to the fact that a file-based (temporal) co-authorship network does not consider commits to files made outside the time window currently analysed. However, our detailed analysis of co-edit relations can nevertheless identify that at time $t$ within the time window developer $A$ has edited code originally authored by developer $B$ in a commit outside the time window. We argue that neglecting this relation introduces the risk of false negatives, in the sense that we would omit the need of collaboration or coordination associated with a commit occurring at time $t$. This subtle but important difference highlights the limitations of a simple file-based extraction of collaboration networks and showcases the advantage of our approach.

C. Analysis of Temporal Co-Editing Networks

A major advantage of git2net is its support for the extraction of dynamic co-editing networks with high temporal resolution. To showcase the benefits of such a temporal analysis for the two projects mentioned above, we have used git2net’s python API to extract a time-stamped co-editing network from the repositories of the two projects mentioned above. We then used the temporal network analysis package pathpy [46] to apply a rolling window analysis, which provided us with a time series of network analytic measures. Figure 9 shows the resulting time series for four measures both for the Open Source project igraph as well as the commercial software project. The first row gives the number of developers working on the projects in a 365-day sliding window. The number of unique co-editing relations between these developers, shown in the second row, can be used to proxy the amount of collaboration on joint code regions taking place in a project in a given time window. We observe that the number of such collaborations relative to the number of developers is considerably higher for the commercial software project compared to the Open Source project. This finding is further corroborated by the mean out-degree of nodes shown in the third row. This suggests that on average developers in igraph edit the code of one to two other developers, while for the commercial software project each developer has to coordinate his or her changes with four to eight other team members. It is a remarkable finding for the commercial software project that both the number of unique directed edges and the mean out-degree decline from 2013 onwards, despite the growing number of developers. This
could mark a change in the software development processes and/or the social organisation of teams. While a first feedback from the project managers suggests that this could be related to a change in the adoption of an agile development model, testing this hypothesis requires a separate in-depth study. Finally, in the fourth row in Figure 9 we report the evolution of normalised (total) degree centralisation over time [52]. A minimum value of zero indicates that all nodes in the network have the same degree, while a maximum value of one corresponds to a perfect star network where all nodes except a hub node have degree one. We find that igraph exhibits considerably larger degree centralisation than the commercial software project, which is likely related to previous findings of highly skewed distributions of code contributions in Open Source projects [6, 53, 54].

D. Editing of Own vs. Foreign Code

In a final experiment, we showcase how git2net can be used to analyse temporal co-editing patterns in software development teams. To this end, we extend our analysis of the mere topological dimension of co-editing relations performed in previous sections, to use additional information on the Levenshtein distance associated with these relations. The Levenshtein distance between two source code versions captures the number of characters one has to type to transform one string into another string. It has been used as a proxy for development effort associated with commits [6]. Extending this approach, an interesting aspect of our methodology is that it allows us to distinguish between (i) the cumulative Levenshtein distance of code edits made in a developer’s own code and (ii) the cumulative Levenshtein distance of edits made in foreign code, i.e. code originally written by other developers. This enables us to calculate, for each time window in the commit history of a project, the relative proportion of development effort falling into these two categories.

Figure 10 shows the result of this analysis for the two projects introduced above, where the top-part of the figure reports the total number of (unweighted) co-edit relations, while the bottom part shows the relative proportion of the total Levenshtein distance of own code changes vs. foreign code changes. This analysis highlights considerable project- and time-dependent differences. For the Open Source project igraph, during a first phase from 2006 to 2015, the majority of code edits take place in code previously written by the same developer. This indicates a strict notion of code “ownership”, where developers rarely touch code written by others. For the commercial software project we observe a completely different dynamics, where for the majority of time windows development effort is dominated by foreign code edits. We hypothesise that this finding is likely related to code changes triggered by the specific implementation of the code review process in the commercial software project [55]. While an in-depth study of this claim goes beyond the scope of this tool paper, this finding highlights a specific research question that can be addressed with our tool in future work.

V. CONCLUSION AND OUTLOOK

Over the past two decades, the analysis of co-authorship, co-commit, or co-editing networks in software development teams has experienced huge interest from the empirical software engineering and repository mining community. Exemplary studies have shown that the analysis of such collaboration
networks helps to assess the time-evolving social structure of
teams [6, 33], predict software defects [34], categorise devel-
oper roles [39], identify communities [5], or study knowledge
spillover across individuals, teams, and projects [4, 36, 38, 41].
Most of these studies have employed definitions of co-
authorship networks which assume that developers are linked
if they edited a common file, module, or binary. However,
such coarse-grained definitions have been shown to neglect
information on the microscopic patterns of collaborations
contained in the time-ordered sequence of lines of code edited
by developers [5, 6].

To facilitate data-driven studies of developer networks that
take advantage of this detailed information, we have intro-
duced git2net, a python package for the mining of fine-
grained and time-stamped collaboration networks from large
git repositories. Going beyond previous works, we adopt
text mining techniques to assess (a) the development effort
of an edit in terms of the Levenshtein distance between the
version before and after the commit, and (b) the entropy of file
modifications, which can be used to filter out changes in text-
encoded binary data. Thanks to a parallel processing model
our tool exhibits a linear speed up for an increasing number
of processing cores. This makes git2net suitable to analyse
git repositories with hundreds of thousands of commits and
millions of lines of code.

Apart from a description of our tool, we have reported
results of a case study using the repositories of an Open
Source and a commercial software project. While the results
are rather anecdotal and should thus not be generalised to
other projects, this case study is meant to demonstrate that
the presented tool simplifies the construction and analysis
of dynamic developer collaboration networks and co-editing
behaviour. It further showcases scenarios where our tool can
be useful and highlights interesting research questions that we
will address in future works.

Extending the analysis presented in [5], in section IV-B we
report on a small comparative study of a file- vs. line-based
construction of co-editing networks. A future systematic study
of the differences of these approaches would be import-
ant. This should highlight in which case we need fine-grained
methods and in which other cases coarse-grained notions of
collaboration may be sufficient. Given the large number of
studies using coarse-grained definitions of collaboration net-
works, such a study could make a substantial methodological
contribution to the repository mining literature.

The results presented in section IV-C indicate topological
differences between co-editing networks that are potentially
linked to (a) the difference between Open Source and com-
mercial software projects, and (b) the adoption of an ag-
ile development process in the commercial software project.
These hypotheses must be tested in a larger corpus of projects
that differ in these two dimensions. To support such a study,
we recently mined co-editing relationships from the full git
commit history of Linux\(^4\), comprising more than 800,000
commits over a period of 18 years. Running git2net on a
machine with 16 processing cores, we were able to complete
the extraction of more than 60 million time-stamped co-editing
relations in four days.

In section IV-D we further demonstrate that the information
extracted by our tool can be used to generate a time-resolved
breakdown of developer effort into (a) the revision of code
authored by the developer him or herself vs. (b) the revision
of code written by other team members. We currently work
on a more systematic analysis of this interesting aspect of
collaboration in development teams. Specifically, we study
how collaboration is related to team size, project types, release
schedules, code review processes, or the difference between
Open Source and industrial projects.

Finally, a key advantage of our tool is that it provides a
simple method to extract fine-grained collaboration networks
at high temporal resolution from any git repository. Publicly
available repositories cover a variety of different collaborative

\(^4\)https://github.com/torvalds/linux
tasks, like software development, manuscript editing, web content management, etc. [56]. Our tool efficiently utilises the large number of such repositories and thus opens up a massive new source of high-resolution data on human collaboration patterns.

The fact that the resulting dynamic collaboration networks can be cross-referenced with project-related information (project success, organisational structures and project culture, developer roles, etc.) is likely to be of value for researchers in computational social science and organisational theory. We further expect the resulting corpus of data to be of considerable interest for the network science and social network analysis community, which have recently moved beyond moving window analyses, developing techniques that incorporate the chronological ordering of interactions in high-resolution time series data [30, 40, 57]. We thus hope that the tool and analyses presented in our work will serve the growing community of interdisciplinary researchers working at the intersection of data science, (social) network analysis, computational social science and empirical software engineering.

ACKNOWLEDGMENT

Ingo Scholtes acknowledges financial support by the Swiss National Science Foundation through grant 176938. We thank Alexander von Gernler as well as all other members of the software company GENUA for allowing us to validate our tool in a large commercial software project. All authors express their thanks to the anonymous reviewers of the manuscript.

TOOL AVAILABILITY, ARCHIVAL, AND REPRODUCIBILITY

The tool presented in this work is available as Open Source software package on gitHub.\(^1\) git2net is further available via the python package index pypi, enabling users to simply install and update it via the package management tool pip. To support the reproducibility of our work, we have permanently archived the version of our tool that was used to obtain the results presented in this paper on the open-access repositoryzenodo.org [51].

git2net comes with unit tests and a comprehensive inline documentation. To support users in developing their first analysis, we further provide access to interactive jupyter notebooks, which allow to reproduce our approach.

Since the submission of this paper, the following additional features have been added to the release version of git2net:

- Extraction of line-editing networks, where nodes represent states of content lines of files, while edges link consecutive versions.
- Detection of copying and moving lines both within and between files for the file-based approach via the git blame -C option.
- Extraction of edits rather than co-edits in the sqlite database. With this also pure additions are listed in the database allowing users of git2net to implement own co-editing measures, e.g. based on the distance (in line numbers) of an addition to other lines.
