We calculate the neutral pion (π⁰) to off-shell two photon (γ∗γ∗) transition form factor in lattice QCD. The transition form factor can be extracted from the three-point function of the form (axial-vector)-(vector)-(vector) as a function of off-shell two-photon momentum. Since the axial-anomaly plays an important role in the π⁰ → γγ decay process, we employ the overlap fermion, which preserves the exact chiral symmetry on the lattice. After extrapolating to the chiral and the vanishing photon momentum limit with a fit function based on vector meson dominance (VMD) model, we find that the Adler-Bell-Jackiw anomaly is correctly reproduced.

The XXVII International Symposium on Lattice Field Theory

1. Introduction

In this report we present our lattice study of the $\pi^0 \to \gamma\gamma$ transition form factor. The photons could be either on-shell or off-shell. The goal of this study is two-fold. The first is to reproduce the contribution of the Adler-Bell-Jackiw (ABJ) anomaly [1] to the form factor, which validates the following application. The second is the application to the estimate of the hadronic light-by-light (L-by-L) scattering amplitude, which is significantly important to the calculation of the muon transition form factor, $a^{\mu-\mu}_{L-by-L}$ [2]. Since, in contrast to the vacuum polarization diagram, no experimental result gives useful information to the estimate of the L-by-L diagram, purely theoretical estimate is required. However, the L-by-L diagram is the four-loop one containing nonperturbative pieces, and hence it is not easy to estimate it from the first principles [3]. One of the well motivated phenomenological estimates is based on the assumption that the L-by-L scattering amplitude is dominated by the effective diagram containing $a^{\gamma\gamma\gamma\gamma}_{\gamma\gamma\gamma\gamma}$ transition form factors connected by a pion propagator. Then various model dependent calculations of this supposed dominant contribution are desirable in the lattice calculation. We therefore apply the overlap fermion formulation. Since the axial-anomaly plays a key role, the exact chiral symmetry and flavor SU(2) symmetry are desirable in the lattice calculation. We therefore apply the overlap fermion formulation. We use the $N_f = 2$ dynamical overlap fermion configurations generated on a $16^3 \times 32$ lattice at $\beta = 2.3$ [12], which corresponds to the inverse lattice spacing $a^{-1} = 1.67$ GeV. Topological charge is fixed to $Q = 0$, which induces an improvable finite size effect [13]. For chiral extrapolation, we take four values of quark mass, $m_q = 0.015, 0.025, 0.035, 0.05$, approximately covering the range of $m_s/6$ to $m_s/2$ with $m_s$ the physical strange quark mass.

2. $\pi^0 \to \gamma\gamma$ transition form factor

In the continuum theory the $\pi^0 \to \gamma\gamma$ transition form factor, $f^{\pi\gamma\gamma}(p_1, p_2)$, is defined through a matrix element of two electromagnetic (EM) currents $V_{\mu\nu}^{EM}$ between the pion state and the vacuum,

$$\int d^4 x e^{i p_2 x} \langle \pi^0(q) | V_{\mu\nu}^{EM}(x) V_{\bar{\mu}\bar{\nu}}^{EM}(0) | 0 \rangle = \epsilon_{\mu\nu\alpha\beta} p_1^{\alpha} p_2^{\beta} f^{\pi\gamma\gamma}(p_1, p_2),$$  \hspace{1cm} (2.1)

where $p_1, p_2$ are Minkowski photon four-momenta and $q = -p_1 - p_2$ is the pion four-momentum. $f^{\pi\gamma\gamma}(p_1, p_2)$ can be extracted from the three point function of an axial-vector current and two EM currents via

$$\int d^4 x \int d^4 y e^{-i(qx + py)} \langle 0 | T \{ \partial A^3(x) V_{\mu}^{EM}(y) V_{\bar{\mu}}^{EM}(0) \} | 0 \rangle$$

$$= -\frac{f_\pi m_\pi^2}{-q^2 + m_\pi^2} \epsilon_{\mu\nu\alpha\beta} p_1^{\alpha} p_2^{\beta} f^{\pi\gamma\gamma}(p_1, p_2) + \cdots,$$  \hspace{1cm} (2.2)

with the pion decay constant $f_\pi = 131$ MeV. The ellipsis represents excited state contributions which have the same quantum number with a pion. In the Euclidean lattice calculation, we only
have a direct access to the negative $q^2$ region, and we mainly focus on the small negative $q^2$. Thus, in the following preliminary analysis, we assume that the first term of (2.2) gives the dominant contribution, and the excited state contributions are ignored.

To evaluate the three-point function on the lattice, we use a combination of the conserved axial-vector current ($A^v_p$) and the non-conserved local EM currents ($V^\mu_{EM}loc$). With the overlap fermion formulation the conserved current takes a non-local form $A^v_\mu(x) = \sum_{x,y} \bar{q}(y) \gamma^\nu K^A_\mu(y, z; x) q(z)$ where $K^A_\mu(y, z; x)$ is a kernel derived from the flavor non-singlet axial transformation [14]. $\tau^a$ is the generator of flavor SU(2) Lie group normalized by $\text{tr}\tau^a \tau^b = \delta^{ab}$. The local EM current is defined as $V^\mu_{EM}loc(x) = Z \langle \bar{q}(x) Q \gamma_\mu q(x) \rangle$ with a quark charge matrix $Q_e = \text{diag}(2/3, -1/3)$. The renormalization factor $Z = 1.3842(3)$ is obtained non-perturbatively [15]. This local current does not satisfy the charge conservation and thus unphysical contamination (lattice artifacts) can appear in the result as will be discussed later. Since the EM current consists of the flavor triplet and singlet parts, the evaluation of the three point function $\langle A^v_p V^\mu_{EM}loc V^\nu_{EM}loc \rangle$ requires to calculate both connected and disconnected quark diagrams. Since we do not calculate disconnected ones, we simply ignore it in the following analysis.

We define two three-point functions of type (axial-vector)-(EM vector)-(EM vector) and (pseudo-scalar)-(EM vector)-(EM vector) by

\[
G^\mu_{VV}(P_2, Q) = \sum_{x,y} e^{-iQx-ipy} \left\langle \nabla A^v_\mu(x) V^\nu_{EM}loc(y) V^\sigma_{EM}loc(0) \right\rangle_c \tag{2.3}
\]

\[
= \text{tr} \tau^3 \langle x \rangle \left\langle \sum_{x,y,z} e^{-iQx-ipy} 2 \text{Re} \text{Tr} \left[ S_q(0, y') \partial^x K^A(y', z|x) S_q(z', y) \gamma_\nu S_q(y, 0) \gamma_\mu \right] \right\rangle_c, \tag{2.4}
\]

\[
G^\mu_{PV}(P_2, Q) = \sum_{x,y} e^{-iQx-ipy} \left\langle 2 m_q p^{\text{tot}3}(x) V^\nu_{EM}loc(y) V^\sigma_{EM}loc(0) \right\rangle_c \tag{2.5}
\]

\[
= 2 \text{m}_q \text{tr} \tau^3 \langle x \rangle \left\langle \sum_{x,y,z} e^{-iQx-ipy} 2 \text{Re} \text{Tr} \left[ S_q(0, y') \Gamma_\nu(y', x) S_q(x, y) \gamma_\nu S_q(y, 0) \gamma_\mu \right] \right\rangle_c, \tag{2.6}
\]

where $\langle \rangle_c$ denotes the connected contraction, $\langle \rangle$ denotes the statistical average, $S_q(x, y)$ denotes the quark propagator and $\Gamma_\mu(x, y) = (1 - D_{mn}/M_0) \gamma_\mu(x, y)$. “tr” represents the trace for flavor indices and “Tr” represents the trace for color and spinor indices. The $P_{1,2}, Q$ are Euclidean momenta of two photons and a pion, respectively. On the lattice they are dicretized as $2P_{1,2}/(L_{x,y,z})$, with the lattice spacing $a$ and the lattice size $L_{x,y,z} = 16, L_z = 32$. The pseudo-scalar density operator $p^{\text{tot}3}(x) = \bar{q}(x) \tau^3 \gamma_\mu (1 - D_{mn}/M_0) q(x)$ forms the axial-Ward-Takahashi identity with $A^v_\mu$. The reason for considering (2.6) will become clear soon. In the above equation $\nabla A^v_\mu$ denotes the forward derivative $\nabla A^v_\mu(x) \equiv \sum_p [A^v_\mu(x + \vec{p}) - A^v_\mu(x)]$. We apply the source method for spatial integral over $y$ with $P_2 = (0, 0, 0, P_{21})$ and $v = 1$. After making Fourier transformation for $t_3$ and $x$, we obtain $G^\mu_{VV}(P_2, Q)$ and $G^\mu_{PV}(P_2, Q)$ for each $\mu = 1 \sim 4$ and $P_{21}$. The remaining momentum $P_1$ is determined by the momentum conservation, $P_1 = -Q - P_2$.

The flavor non-singlet axial Ward-Takahashi (AWT) identity for the three point functions can be expressed as

\[
G^\mu_{VV}(P_2, Q) = G^\mu_{PV}(P_2, Q) + \langle (\delta^3_{VEM} V^\mu_{VEM})_c(P_2) \delta^4(Q) \rangle_c + \langle V^\mu_{VEM} (\delta^3_{VEM})_c(P_2) \delta^4(Q) \rangle_c + \cdots \tag{2.7}
\]
where the second and third terms are contact terms coming from lattice axial transformation, 
\[ \tilde{A}^{\mu V} = \bar{q} \gamma_\mu \tau^a q + \bar{q} \gamma_\mu \tau^a (1 - D_{\text{ov}}/M_0) q \] 
for \( V^\text{locEM}_\mu V^\text{locEM}_{\mu} \). These terms do not contribute to \( f^{\pi^0 \gamma \gamma}(P_1, P_2) \) as \( Q = 0 \) implies \( P_1 = -P_2 \), for which the three point function (2.2) vanishes due to its Lorentz structure. Since we ignore the disconnected diagram, there may be some contributions denoted by ellipsis. Thus, we calculate the both sides independently to estimate the potential size of disconnected diagrams.

The \( \pi^0 \to \gamma \gamma \) transition form factor is extracted from the three-point function with the following momentum assignments:

\[ P_1 = (0, P_1, 0, 0) \text{ at } \mu = 3, \text{ or } P_1 = (0, 0, P_1, 0) \text{ at } \mu = 2. \tag{2.8} \]

Then the only nonzero term is the one proportional to \( P_{1a} P_{2b} \epsilon_{\mu \nu \alpha \beta} \). Furthermore, these momentum assignments suppress a class of lattice artifact due to the violation of Lorentz symmetry and EM charge conservation. Since \( P_1 \) and \( P_2 \) are orthogonal to each other and have only one nonzero component, Lorentz violating terms such as \( (P_{1a}^2 + P_{2a}^2)P_{1a} P_{2b} \epsilon_{\mu \nu \alpha \beta} \) vanish. Therefore we obtain

\[ F^{\text{lat}}(P_1, P_2) = G^{V V}_{\mu \nu}(P_2, Q) / \left( \sum_{\alpha \beta} P_{1a} P_{2b} \epsilon_{\mu \nu \alpha \beta} \right) = -\frac{f_\pi m_\pi^2}{Q^2 + m_\pi^2} f^{\pi^0 \gamma \gamma}(P_1, P_2). \tag{2.9} \]

up to contributions from excited states and disconnected diagrams. Since \( P_{1,2} \) are defined in the Euclidean space-time, the on-shell condition is realized only at zero momentum \( P_1 = P_2 = 0 \). Note that we numerically check the consistency of \( F^{\text{lat}} \) obtained from \( G^{V V}_{\mu \nu} \) and \( G^{V V}_{\mu \nu} \) within the statistical error. \( F^{\text{lat}}(P_1, P_2) \) from (2.9) are averaged over the two physically equivalent momentum assignments in (2.8).

### 3. Results

First we test if the ABJ anomaly \[1\]

\[ f^{\pi^0 \gamma \gamma}(0, 0) = \frac{1}{4 \pi^2} f_\pi, \tag{3.1} \]

is reproduced in the chiral and the photon’s on-shell limit. The data are extrapolated to the zero momentum and zero quark mass limit assuming a fit function. Here we consider the vector meson dominance (VMD) model as an ansatz. Since we neglected disconnected diagrams, the EM vector current only couples to \( \rho \) meson. The functional form is

\[ F^{\text{VMD}}(P_1, P_2; X_a) = -\frac{m_\pi^2}{Q^2 + m_\pi^2} X_a G_v(P_1, m_v) G_v(P_2, m_v), \tag{3.2} \]

with a free parameter \( X_a \), which is supposed to correspond to the axial-anomaly, \( X_a = f_\pi f^{\pi^0 \gamma \gamma}(0, 0) \).

The vector meson propagator is

\[ G_v(P, m_v) = \frac{m_v^2}{P^2 + m_v^2}, \tag{3.3} \]

where \( m_v \) denotes a vector meson mass. The vector meson mass is determined independently from an exponential fit of a smear-local vector current correlator. Performing chiral extrapolation
π0 to two-photon decay in lattice QCD

E. Shintani

Figure 1: Lattice results for $F_{\text{lat}}(P_1, P_2)$ at a fixed $(aP_1^2) \simeq 0.154$ as a function of $(aP_2^2)$ and fit function of $F^{\text{VMD}}(P_1, P_2; X_a)$ (solid curve) and $F^{\text{VMD}+}(P_1, P_2; X_a, c_3, c_4)$ (dashed curve) for each quark mass. Thin lines denote the VMD (dashed-dotted) and VMD+(solid) in physical point.

with a linear function, $m_v = m_0^v + c_m m_\pi^2$, we obtain $m_0^v = 0.798(19)$ GeV, which reasonably agrees with the physical $\rho$ meson mass 0.775 GeV. Since we encoded the quark mass dependence of $F^{\text{VMD}}(P_1, P_2; X_a)$ into $m_\pi$ and $m_v$, only one free parameter $X_a$ is left for the fit of the lattice data. In Fig. 1, we plot $F_{\text{lat}}(P_1, P_2)$ at $(aP_1^2) = 0.154$, which is the minimum non-zero value, as a function of $(aP_2^2)$. The fit results at different quark masses are also shown by solid curves, where the fit point is taken to be $(aQ^2) = 0.039$. From this plot we can see that lattice data and $F^{\text{VMD}}(P_1, P_2; X_a)$ are in good agreement at the lowest momentum. We obtain

$$X_a = 0.0260(6), \quad (3.4)$$

which is fully consistent with the expectation $X_a = 1/(4\pi^2) = 0.02533$ despite of various crude approximations. The main reason is the exact chiral symmetry; the existence of the conserved axial-vector current significantly reduces lattice artifact.

Going beyond the minimum value of the momenta, the fit curves deviate from the data point. To accommodate this deviation, we modify the fit form by incorporating an excited vector meson state as

$$F^{\text{VMD}+}(P_1, P_2; X_a, c_{3,4}) = -\frac{m_\pi^2}{Q^2 + m_\pi^2} X_a \left[ c_3 G_v(P_1, m_v) G_v(P_2, m_v) + \frac{c_4 - c_3}{2} (G_v(P_1, m_v) + G_v(P_2, m_v)) + 1 - c_4 \right], \quad (3.5)$$

with mass dependent couplings, $c_3 = 2 - c_4^0 + c_4^0 m_\pi^2$ and $c_4 = c_4^0 + c_4^0 m_\pi^2$. In this fit form, the propagator of the excited vector meson is approximated by a constant $G_v(P, m_v) \sim 1$ (see Fig. 2). We have four free parameters. This parametrization [16] satisfies the anomaly relation (3.1). We impose a constraint $\lim_{m_\pi^2 \to 0} (c_3 + c_4) = 2$, so that the transition form factor in the high $Q^2$ limit
scales as $1/Q^2$ as suggested by perturbative QCD [17]. We note that a phenomenological estimate leads to $(c_3 + c_4)/2|_{\text{phenom}} = 1.06(13)$ [16]. Setting the fit range to $0.039 \leq (aP_2)^2 \leq 0.347$, we obtain the dashed curves in Fig. 1. Compared with the naive VMD fit (3.2), the agreement of the fit with the data in momentum range of $(aP_2)^2 > 0.039$ is improved especially at larger quark mass region. Fit parameters obtained using (3.5) are $c_4^0 = 1.20(21)$, $c_3^0 = -8.4(8.6)$, $c_4^m = -1.3(5.8)$ and $X_A = 0.0243(29)$. Again $X_A$ is consistent with the expectation. Furthermore $c_4^0$ is consistent with unity, which implies that the VMD approximation is reasonable and the coupling with the excited vector meson state gives a sub-leading contribution. In Fig. 1 we also show the comparison with VMD and VMD+ curves in the physical pion and $\rho$ meson mass. The difference between the two lines are almost negligible.

The construction of reasonable fit function for $f_{\pi^0 \gamma \gamma}$ over higher momentum region is important when estimating the hadronic L-by-L diagram, because it is necessary to integrate $f_{\pi^0 \gamma \gamma}(P_1, P_2)$ from zero to infinity in both $P_1^2$ and $P_2^2$. This study provides suggestive information that the VMD model describes the data of $f_{\pi^0 \gamma \gamma}(P_1, P_2)$ reasonably well, and inclusion of its excited state significantly extends the safe usage to larger momentum region.

4. Summary

We studied the $\pi^0 \to \gamma \gamma$ transition form factor by calculating the three point function, $\langle AVV \rangle$, on the $N_f = 2$ dynamical overlap fermion configurations. The data of $f_{\pi^0 \gamma \gamma}$ is fitted to the VMD motivated functions, and in the chiral and the on-shell photon limits the ABJ anomaly, $f_{\pi^0 \gamma \gamma}(0, 0) = 1/(4\pi^2 f_\pi)$, is reproduced. It is also found that the fit function based on the VMD model well describes the behavior of mass dependence at the lowest momentum in which the higher resonance contribution is small. Although the present work is feasible study and there are many things which have to be understood, our result encourages us to apply to the non-perturbative estimate of the hadronic L-by-L scattering amplitude.
