Failure of confined granular media due to pullout of an intruder: from force networks to a system wide response†

Srujal Shah,†a Chao Cheng,b Payman Jalali a and Lou Kondic b*

We investigate computationally the pullout of a spherical intruder initially buried at the bottom of a granular column. The intruder starts to move out of the granular bed once the pulling force reaches a critical value, leading to material failure. The failure point is found to depend on the diameter of the granular column, pointing out the importance of particle–wall interactions in determining the material response. Discrete element simulations show that prior to failure, the contact network is essentially static, with only minor rearrangements of the particles. However, the force network, which includes not only the contact information, but also the information about the interaction strength, undergoes nontrivial evolution. An initial insight is obtained by considering the relative magnitudes of normal and tangential forces between the particles, and in particular the proportion of contacts that reach Coulomb threshold. More detailed understanding of the processes leading to failure is reached by the analysis of both spatial and temporal properties of the force network using the tools of persistent homology. We find that the forces between the particles undergo intermittent temporal variations ahead of the failure. In addition to this temporal intermittency, the response of the force network is found to be spatially dependent and influenced by proximity to the intruder. Furthermore, the response is modified significantly by the interaction strength, with the relevant measures describing the response showing differing behaviors for the contacts characterized by large interaction forces.

1 Introduction

The processes related to failure in soft solids have been explored for a long time, and in particular during the last couple of decades significant progress has been achieved; excellent review articles are available, discussing soft solids in general,1 failure in the context of fracture and avalanching,2 and related issues in the context of glass transition of amorphous materials,3 among other research directions. In the context of granular matter, the concept of failure is closely related to jamming, another topic that has produced significant interest, see ref. 4–7 for reviews. In particular, a close connection between particle scale information, including local contact networks, and macroscale rheology of sheared or compressed granular materials, has been established. In addition, a point was made years ago8,9 that not only contact networks per sé are important in governing the system response, but also their strength; this point will be of particular relevance in the present work.

In this paper, we focus on a system in which the connection between contact and force networks, and material failure, can be analyzed in detail. We consider a spherical intruder, large compared to the particle size, that is initially buried in a granular column. The intruder is exposed to an upward pullout force which increases with time until the material fails, similarly as considered recently in two dimensions (2D) in experiments with photoelastic particles,10 and even more recently in 3D experiments.11 To some degree, this pull-out setup may be considered as a reverse of the impact of an object on the surface of the granular material,12,13 although one may wonder to which degree slowing down a moving intruder is similar to the failure due to the applied force on an initially static object. Another related setup of relevance is the one of a solid rod that is pulled out of a granular column. This setup was analyzed both computationally and experimentally, suggesting that, once the rod starts to move, shear occurring in a cylindrical shear zone surrounding the rod may lead to local jamming that increases the frictional resistance.14

After discussing in general, the system-wide response to the applied pull-out force, we will focus in particular on the
question of particle-scale responses, both from static and dynamic points of view. As pointed out above, even if the intruder and the granular particles are stationary, there could still be changes in the network describing mutual interactions between the granular particles, particles and the intruder, as well as particles and the walls. In the present context, such a network is weighted by the strength of the force between the particles. This strength can be quantified by either normal, tangential, or some combination of these force components. By now it has been established that the properties of such a force network are crucial for the purpose of developing better understanding of granular systems in the context of analysis of static packs, shear, compression, wave propagation, or impact; see also ref. 7 for a recent review. Reaching this understanding is however complicated by the complexity of the force networks due to a large amount of time-dependent data. Obviously, some type of simplification is needed; in addition, one would like to use measures that are precisely defined and that allow for a meaningful comparison of the force networks at different time instances, since we will be also interested in a dynamic setting.

In recent years, significant progress has been made towards developing better understanding of force networks using a variety of tools, including force network ensemble analysis, statistics-based methods, and application of topological methods, more precisely persistent homology; see ref. 7 and 42 for recent reviews. While different methods provide a complementary insight, we will focus here on the persistent homology based approach since it allows for significant data reduction, for the formulation of objective measures describing the force network, as well as for precise comparison of different networks in a dynamic setting. Such an approach was used with success to discuss force networks at different time instances, since we will be also interested in a dynamic setting.

The simulation geometry consists of a vertical column of diameter $D_c$ filled with monodisperse spherical particles and a spherical intruder. The intruder is initially at contact with the center of the bottom of the column. Two column sizes are used, motivated by the ongoing experimental efforts. The columns are filled with glass beads to a specified height, $H$, by pouring them randomly from the top at a certain mass flow rate. The initial configuration of the particles and intruder is shown in Fig. 1.

After filling to a desired height, the granular material is relaxed until the particle velocities are near zero. Once the particles come to rest, the intruder is pulled vertically upward by a force, $F_p$, which is specified as a linear function of time with a slope of 1 N/s. At a certain force, namely the pullout force at failure $F_{\text{pull}}(H,D_c)$, the granular material fails and the intruder leaves the granular bed in a fraction of a second. Fig. 1(b) shows the snapshot of the assembly where the intruder is halfway out of the granular bed; see also ESI, showing an animation of the pull out process. For further illustration, Fig. 2 shows the forces between granular particles just prior to the failure. The normal and tangential forces between the particles are displayed in this figure as a function of radial and vertical coordinates, and averaged over the angular direction. We note a significant modification of the inter-particle forces in the process of failure. Section 4 is devoted to the conclusions of the present study and to the discussion of possible future research directions.

2 Methodology

2.1 General setup

The simulation geometry consists of a vertical column of diameter $D_c$ filled with monodisperse spherical particles and a spherical intruder. The intruder is initially at contact with the center of the bottom of the column. Two column sizes are used, motivated by the ongoing experimental efforts. The columns are filled with glass beads to a specified height, $H$, by pouring them randomly from the top at a certain mass flow rate. The initial configuration of the particles and intruder is shown in Fig. 1.

After filling to a desired height, the granular material is relaxed until the particle velocities are near zero. Once the particles come to rest, the intruder is pulled vertically upward by a force, $F_p$, which is specified as a linear function of time with a slope of 1 N/s. At a certain force, namely the pullout force at failure $F_{\text{pull}}(H,D_c)$, the granular material fails and the intruder leaves the granular bed in a fraction of a second. Fig. 1(b) shows the snapshot of the assembly where the intruder is halfway out of the granular bed; see also ESI, showing an animation of the pull out process. For further illustration, Fig. 2 shows the forces between granular particles just prior to the failure. The normal and tangential forces between the particles are displayed in this figure as a function of radial and vertical coordinates, and averaged over the angular direction. We note a significant modification of the inter-particle forces in the process of failure. Section 4 is devoted to the conclusions of the present study and to the discussion of possible future research directions.
can be computed from the modified Hertz–Mindlin model as below:

\[
\mathbf{F}_{n,jk} = -\frac{4}{3}Y^* \sqrt{R^* \delta_n^{1/2}} + 2 \sqrt{\frac{5}{6}} b \sqrt{S_n \mu \mathbf{v}_{n,j,k}}, \\
\mathbf{F}_{t,jk} = -8G^* \sqrt{R^* \delta_t^{1/2}} + 2 \sqrt{\frac{5}{6}} b \sqrt{S_t \mu \mathbf{v}_{t,j,k}},
\]

where \( S_n = 2Y^* \delta_n \) and \( S_t = 8G^* \delta_t \). Here, \( \delta_n \) is the normal overlap distance between the particles, \( \mathbf{n}_{jk} \) is the normal unit vector directed from the center of particle \( j \) to that of particle \( k \), \( \mathbf{v}_{n,j,k} \) is the tangential displacement vector calculated by integrating the relative tangential velocity at the contact over time, \( \mathbf{v}_{t,j,k} \) are the normal and tangential components of the relative velocity of particles \( j \) and \( k \). The expression for the torque is given as \( \mathbf{T}_{jk} = R \mathbf{n}_{jk} \times \mathbf{F}_{t,jk} \). The magnitude of the tangential force is truncated by the Coulomb friction criterion: \( \mathbf{F}_{t,jk} \leq \mu \mathbf{F}_{n,jk} \), where \( \mu \) is the friction coefficient. In the above eqn (1) and (2), the coefficient \( \beta \), expressed as a function of restitution coefficient \( \epsilon \), is given by \( \beta = \ln \epsilon / \sqrt{\ln^2(\epsilon) + \pi^2} \). The other quantities used in eqn (1) and (2) are given as follows

\[
\frac{1}{Y^*} = 1 - \nu_j^2 + 1 - \nu_k^2, \\
\frac{1}{R} = \frac{1}{R_j} + \frac{1}{m_j} + \frac{1}{m_k}, \\
\frac{1}{G} = \frac{2(2 - \nu_j)(1 + \nu_j)}{Y_j} + \frac{2(2 - \nu_k)(1 + \nu_k)}{Y_k}.
\]

where \( Y^* \) is the effective Young’s modulus, \( G^* \) is the effective shear modulus, \( \nu \) is the Poisson’s ratio, \( R^* \) is the effective radius and \( m^* \) is the effective mass. Similar equations as the above-mentioned ones are used to compute particle-wall contact forces, in which particle \( k \) is assumed to be a particle with an infinite radius and mass.

2.2.2 Simulation details. Table 1 specifies the mechanical properties of materials and simulation parameters. The mechanical properties of materials as given in Table 1 represent glass.
beads as the granular material, the sidewall of the column has properties close to PVC, and the intruder and bottom wall of the column have properties close to steel, motivated by recent experiments.\textsuperscript{14} The Young’s modulus and the Poisson’s ratio were obtained from the literature.\textsuperscript{48–50}

The value of the restitution coefficient between glass beads is taken as 0.9.\textsuperscript{50} The restitution coefficient of steel is typically in the range of about 0.6–0.9, and a value of 0.8 is assigned here for steel and glass bead contacts. The restitution coefficient between glass beads and sidewall is assigned as 0.85. The relevance of all above-mentioned values of the coefficient of restitution is found to be insignificant in present simulations as the granular material remains essentially in the static state prior to failure.

2.3 Normalization of relevant quantities

To obtain a better insight into the physics of the studied system, and for simplicity, we normalize the relevant quantities using the intruder diameter, \( D_i \) and the reference force, \( F_0 \). The choice of \( F_0 \) is based on the weight of a reference volume, which is taken as a cylinder of diameter \( D_i \) and height \( H \), filled with granular matter. Since the volume fraction changes (very slightly) with the filling height, \( H \), due to gravitational compaction, we choose the average value obtained in simulations (that use different \( H \)), giving the value of \( F_0 = 0.425 \) N. We will see later in Section 3.1 that the force scale chosen as specified is natural for the considered problem. From this point, all the results are given using \( D_i \) and \( F_0 \) as the scales for the length and force, except if specified differently. At a couple of places in the present paper, we will also need a time scale, which for simplicity we take as \( \sqrt{D_i/g} \).

We note that the pullout force, \( F_p \), does not include the weight of the intruder. Therefore, the value of \( F_p = 0 \) corresponds to the time at which the applied force on the intruder is exactly equal to its weight.

2.4 Persistent homology

For the present purposes, persistent homology could be thought of a tool for describing a complicated weighted network (such as the one describing interaction forces between the particles) in the form of diagrams, so called persistent diagrams (PDs). These diagrams are obtained by filtering, or thresholding, the strength of the interactions between the particles. As an example, let us assume that this strength is quantified by the normal interaction force between the particles in the system. Then, the simplest persistence diagrams, which we refer to as \( \beta_0 \) PD for the reasons that will become clear shortly, essentially trace how ‘structures’ (could be thought of as ‘force chains’, without attempting to define them) appear as the filtration level is decreased or disappear as two structures merge. Such a PD contains rather complete information about how connectivity between the contacts depends on their strength. Fig. 3 shows examples of the PDs computed at a given time for the system considered in the present paper (both for \( \beta_0 \) discussed above, and for \( \beta_1 \), that describes loops or cycles, and discussed further below). Each point (generator) in this diagram has two coordinates, ‘birth’ – specifying when (at which filtration level) it appeared, and ‘death’ – specifying when it disappeared, due to merging with another structure. Note that the term ‘persistence’ in this context refers to the force range over which a certain structure ‘persists’, or survives, as the considered filtration level is changed. The interested reader could find rather detailed description on how these diagrams can be (properly) defined and computed in ref. 39, and a simplified description including toy examples and insightful animations in ref. 19. For the purposes of the present paper, we list here few key features of PDs that are important for understanding their meaning, relevance, and use:

- Persistent diagrams live in a metric space and therefore can be compared in a meaningful manner. This means that one can compare the weighted force network at different points in time, which is a crucial feature if one wants to understand an evolving system.
- Since the description of a weighted force network in terms of persistence diagrams provides a significant data reduction, there is an associated loss of information, and therefore PDs do not provide full information about the underlying network. However, the information contained in PDs still provides for all practical purposes a reasonably precise insight not only regarding the number of structures, but about how their connectivity changes as one considers different thresholding (filtering) levels.
- The number of PDs for a given weighted network is equal to the number of spatial dimensions: i.e., for a 3D system considered here, in principle there are three PDs that can be associated: \( \beta_0 \) PD describing clusters, \( \beta_1 \) PD describing loops (cycles), and \( \beta_2 \) PD describing three dimensional holes. In the present work, we do not find \( \beta_2 \)'s, and therefore focus on \( \beta_0 \) and \( \beta_1 \) PDs. Fig. 3 shows that the \( \beta_0 \) generators appear at a higher

\[ D_i = \sqrt{g H} \]

\[ F_p = \frac{F_0}{\sqrt{D_i}} \]
force level than $\beta_1$ ones, since $\beta_0$ structures need to merge to form loops, and this happens at lower force levels. The points at the death level $D = 0$ in Fig. 3(b) show all the loops that formed, but never died: a loop dies at the threshold level $D$ when it is filled up with contacts with the force of at least $D$, and for many loops this does not happen; see ref. 39 for more details. On the other hand, all $\beta_0$ components disappear at nonzero $D$, since for low values of force, all separate clusters merge.

- A PD provides information about a weighted network that is threshold independent: there is no need to specify a threshold level to describe the considered network. A PD provides information about all threshold levels at once. This is a major difference compared to other measures describing force networks, which often require separation of a force network into a ‘strong’ or a ‘weak’ network. With this being said, one can in principle consider only a subset of points in a PD and focus on a particular range of interest. For example, for the diagram shown in Fig. 3, one could consider only the points found for large thresholds, describing a strong part of the force network, or the points for small thresholds, describing a weak part of the network.

- The number of ‘force chains’ or ‘clusters’ of connected contacts (or the number of loops (cycles)) characterized by a force larger than the specified threshold can be easily extracted from the PDs, providing therefore information about Betti numbers, $\beta_n$, that essentially measure a number of features of a given type. Note however that the number itself does not provide any information about connectivity. Furthermore, one can show that Betti numbers are susceptible to noise, meaning that a small change in the input data could lead to a large change of the Betti numbers. Finally, the $\beta_n$’s are threshold dependent, and therefore provide less complete information about the underlying weighted network.

- The PDs are essentially point clouds, and an appropriate measure for their quantification needs to be developed. One possibility is based on the idea that both the number of points in a diagram and for how long (that is, for how many thresholds levels) a point persists are appropriate measures describing the force network between particles. Using landscape as an analogy, the number of points in $\beta_0$ PD specifies the number of (mountain) peaks, and their lifespan (see below) describes how well developed these peaks are, or, to push the landscape analogy further, how high they are compared to the ‘valleys’ that surround them. The concept of lifespan, $\mathcal{L}$, is illustrated in Fig. 3, as essentially the difference between birth ($B$) and death, $D$, coordinates, so $\mathcal{L} = B - D$. Both measures could be combined into one by defining total persistence, TP, as a sum of all lifespans. We will be using TP in discussing some properties of the force networks in the considered system.

- The reader should note the enormity of the data reduction described so far: first a weighted force network is reduced to a point cloud (PD) and then this point cloud is reduced to a single number (TP). Such a reduction clearly leads to huge data loss, but as we will see, it still provides insightful information about the underlying weighted network.

PDs provide information about the state of the system at a given time and do not include any information about the dynamics. As pointed out, however, PDs can be compared, and in particular the concept of distance between PDs is well defined. The distance between two PDs could be thought as a minimum (Euclidian) distance by which the points in one diagram need to be adjusted to map them exactly to the other one; if the number of points in two PDs is different, then extra points are mapped to the diagonal. Stated formally

$$d_{W_q}(\text{PD, PD'}) = \inf_{\gamma: \text{PD} \to \text{PD'}} \left( \sum_{p \in \text{PD}} \| p - \gamma(p) \|_q^q \right)^{1/q}.$$  

Here, $d_{W_q}$ stands for the degree $q$ Wasserstein distance, and PD, and PD’ are the two considered PDs. Computing the distance is a computationally expensive process in particular for complex diagrams with many points. In the present work, we focus on $q = 2$ for simplicity, and perform calculations using the method discussed in ref. 52 and 53.

3 Results and discussion

We discuss the main findings in this section, focusing first in Section 3.1 on the system-scale response, including the force at the failure point, the influence of system boundaries, geometry, and material parameters. These results set a stage for Section 3.2, where more in-depth analysis of the failure process itself is discussed by considering the weighted force networks that form spontaneously between granular particles.

3.1 Failure: macro-scale picture

3.1.1 Failure force. We start by discussing the magnitude of the pulling force applied to the intruder that causes failure. Fig. 4(a) shows how the pullout force at failure, $F_{pf}$, depends on the filling height, $H$, for the two granular columns; at first we focus on the $\Delta$ symbols (connected by the solid lines) which show the results obtained using the friction parameters given in Table 1.

We see that $F_{pf}$ increases with $H$, as expected, since larger $H$ leads to a larger pressure on the intruder. Fig. 4(a) (inset) also shows the force scaling: with the choice of $F_0$ specified in Section 2.3, $F_{pf}$ extrapolates to $F_{pf} \approx 1$ as $H \to 1$ (note that all quantities are dimensionless). Furthermore, we observe that $F_{pf}$ is larger for a smaller diameter column, showing the relevance of particle-wall interactions. This finding can be understood based on the increased forces on the side walls (Janssen effect, see ref. 54 for recent discussion), which are considered in more detail in Section 3.1.2. Note that the effect of the sidewall on $F_{pf}$ diminishes as $H$ decreases, since for small $H$ we enter the hydrostatic regime where the column size is not relevant. Fig. 4(b), which also plots the results obtained using smaller particles (diameter 3 mm, in contrast to 5 mm particles used in Fig. 4a while keeping $D_1$ the same) leads to a consistent conclusion: the influence of the sidewall decreases as the number of particles increases, since for smaller particle sizes there are more particles between the intruder and the sidewall.

One important question involves the influence of friction coefficient on the pullout failure force. In the present DEM
Fig. 4 (a) The pullout force at failure, \( F_{\text{pf}} \), for different filling heights, \( H \), and for two different column diameters, (red) \( D_c = 1.49 \), and (blue) \( D_c = 1.75 \). ▲ and ▼ corresponding to the higher (given in Table 1) and lower (discussed in the text) values of the friction coefficients, respectively. The circled data point shows the reference case that is analyzed in detail later in the paper. The inset expands the region for small \( H \), showing that \( F_{\text{pf}} \rightarrow 1 \) as \( H \rightarrow 1 \) (purple dashed line). (b) The pullout force at failure, \( F_{\text{pf}} \), as the size of particles is modified, and the tube diameter is kept fixed at \( D_c = 1.49 \). (red) 5 mm particles (the same data as shown in (a), and (green) 3 mm particles. Note that all quantities in this and the following figures are dimensionless.

Simulations, there are three relevant friction coefficients: intruder – glass beads, \( \mu_{\text{ig}} \), glass beads – sidewall, \( \mu_{\text{gw}} \), and glass beads – glass beads, \( \mu_{\text{gg}} \). Fig. 4 shows the influence of friction: ▲ were obtained using the values of friction coefficients given in Table 1, and the values shown by ▼ were obtained for lower values of friction coefficients (\( \mu_{\text{ig}} = 0.4 \), \( \mu_{\text{gg}} = 0.35 \), and \( \mu_{\text{gw}} = 0.25 \)). One could wonder which of the three friction coefficients is the most/least relevant; to answer this question, we discuss the reference case (circled data point in Fig. 4) in more detail. The \( F_{\text{pf}} \) for the reference case is 30.8. When only \( \mu_{\text{ig}} \) is reduced, we find \( F_{\text{pf}} = 50.1 \); when \( \mu_{\text{gg}} \) is reduced, \( F_{\text{pf}} = 46.6 \), and when \( \mu_{\text{gw}} \) is reduced, \( F_{\text{pf}} = 43.8 \). Thus, the effect caused by the change in the particle-wall friction coefficient is the most dominant, although all friction coefficients influence \( F_{\text{pf}} \). We note that these variations are considerably larger than the ones found between different realizations of nominally the same simulation, when the initial particle configurations were modified. This variability is less than 1%.

The relevance of particle-wall friction discussed above also suggests a possible explanation for a slightly weaker influence of friction for a larger column diameter, \( D_c \). Furthermore, the influence of friction disappears for small values of \( H \). This finding shows that in the hydrostatic regime frictional effects do not influence the failure process; it should be noted however that frictional effects may be important once the system fails and the intruder starts to move, as discussed for the case of a rod pulled out of granular matter.\(^{14} \)

3.1.2 Parameter study. Here we compare the results obtained using the smaller column diameter, and varying the height of the granular material, \( H \). Fig. 5(a) shows the (vertical) \( z \)-component of the force exerted by particles on the sidewall, \( F_w \), versus the pullout force, \( F_p \), as \( H \) is varied. The reported values of \( F_w \) are obtained by averaging the instantaneous values over a short time window (of duration \( t \approx 0.13 \)).

We focus at first on the results obtained for large filling heights in Fig. 5(a).Clearly \( F_w \) grows with \( F_p \), showing that the pullout force is transferred via particles to the sidewall. This growth is non-trivial however: as \( F_p \) increases, the difference \( F_p-F_w \), shown in the inset of Fig. 5(a), reaches a plateau whose height depends on \( H \). Therefore, for small \( F_p \), the coupling of \( F_p \) and \( F_w \) is not complete, with \( F_p \) increasing faster than \( F_w \). However, for larger values of \( F_p \), the coupling becomes stronger, with essentially all the applied force transferred to the sidewall. The fact that the height of the plateau is \( H \)-dependent suggests that the forces between the particles (that may depend on both \( H \) and \( F_p \)) play a role. We defer further discussion of this effect until considering these forces in Section 3.2.

Fig. 5 (a) The sidewall force, \( F_w \), in the (vertical) \( z \) direction exerted by the particles. (a) \( D_c = 1.49 \) with variation of the filling height; \( H = 4.18 \) (solid blue line), \( H = 3.78 \) (dashed orange line), \( H = 2.89 \) (dash-dot green line), \( H = 2.21 \) (dotted red line), and \( H = 1.78 \) (loosely dashed purple line). (b) \( H = 4.18 \) with variation of the column diameter; \( D_c = 1.49 \) (solid blue line) and \( D_c = 1.75 \) (dashed red line).
For small filling heights ($H = 1.78$ and $H = 2.21$ in Fig. 5(a)) the results are less clear, with non-monotonous growth of $F_p$ and $F_p/F_w$ as $H$ is increased; possibly in this regime the inverse Janssen effect discussed recently\textsuperscript{54} becomes relevant. We leave detailed discussion of this regime for future work.

Next, we focus on comparing the results of simulations carried out using different column diameters, $D_c$, with the height, $H$, kept fixed. Fig. 5(b) shows the results: we observe that $F_w$ depends on $D_c$ with a larger magnitude of $F_w$ at the failure for smaller $D_c$. The inset in Fig. 5(b), which plots the difference $F_p-F_w$, shows that the height of the plateau at which this difference saturates increases as $D_c$ increases, and the plateau itself becomes less clearly defined. This again shows that for larger column diameters, the wall forces become less important in helping the granular material to avoid failure. This motivates us to analyse further the response of the force networks prior to the failure. This is discussed in the next section.

3.2 Road to failure

In this section we discuss the failure process itself, focusing on a single choice of parameters, represented by the reference case (circled data point in Fig. 4). To analyze the failure, we use the measures that are appropriate for discussion of the static and dynamic properties of the system, starting from the classical measures that are appropriate for discussion of the static and dynamic properties of the system. Reading the classical measures that are appropriate for discussion of the static and dynamic properties of the system, starting from the classical measures that are appropriate for discussion of the static and dynamic properties of the system, starting from the classical measures that are appropriate for discussion of the static and dynamic properties of the system.

3.2.1 Forces, energies, contacts. Fig. 6 shows the normal and tangential average forces, $F_{n,a}$, $F_{t,a}$, respectively, between the particles (and the particles and the intruder), as well as the intruder’s $z$-position. We focus on the time period for which the pulling force is positive (after subtracting scaled intruder’s weight). Fig. 6 shows that the dynamics of the intruder is minimal before the granular system fails: note that the whole range on the vertical $z$ axis is just $1\%$ of the intruder’s diameter (see also ref. 51). While for smaller values of $F_p$, $F_{n,a}$ does not change much, while for larger $F_p$’s, $F_{n,a}$ grows approximately linearly with $F_p$. Since the change of $F_{n,a}$ is considerable, in what follows we will use this time-dependent value of $F_{n,a}$ for normalization of the results discussing properties of the force network.

Tangential force, $F_{t,a}$, also shown in Fig. 6, provides relevant additional information. While $F_{t,a}$ is smaller than $F_{n,a}$ (being limited by the Coulomb threshold), the ratio $F_{t,a}/F_{n,a}$ grows as failure is approached. This result provides an initial insight regarding failure: the particle contacts get increasingly loaded by the tangential force, and approach sliding. A significant amount of sliding contacts appears as a precursor to failure. The sliding effect is also confirmed by the inset which shows the average of $E_k/E_p$ value at each contact (note that this quantity is not necessarily the same as $F_{i,a}/F_{n,a}$). We also comment on the similarities of the insets of Fig. 5 and 6, with both showing similar qualitative behavior: this is not surprising since the tangential inter-particle force clearly plays a role in determining $F_w$. For a larger filling height, $H$, the normal forces between the granular particles will be larger due to gravitational effects and therefore the allowed range for tangential forces would be larger as well, leading to a stronger wall force, consistently with the results shown in the inset of Fig. 5(a).

Continuing the discussion of sliding contacts, Fig. 7 plots three quantities of interest: $N_s$, the ratio of the number of contacts that have reached Coulomb threshold (sliding contacts) and the total number of contacts; $N_b$, the ratio of the number of broken contacts and the total number of contacts, and the ratio of kinetic and potential energies of the granular particles, $E_k/E_p$ (here $E_k$ includes only translation degrees of freedom, and $E_p$ is measured relative to the bottom of the column). All quantities are calculated over the time intervals of duration $\Delta t \approx 0.84$. While the results are rather noisy, we can still reach some relevant conclusions, which could be also verified by inspecting the inset of Fig. 7, which shows an...
expanded view of the energy ratio and $N_b$. First of all, very small values of $E_b/E_p$ suggest minimal rearrangements of the particles during the period before failure, consistently with small $N_b$ (note that the latter quantity is barely visible in Fig. 7, showing that only small fraction of contacts breaks before failure). While detailed inspection of the data does not show any correlation between $N_b$ and $E_b/E_p$, the same conclusion does not apply to $N_c$, for which we find significant (anti)correlation with $E_b/E_p$.

This result shows that while reaching Coulomb threshold may not lead to breaking of a contact, it may lead to sliding, which reflects itself with an increase of kinetic energy. We note that $E_p$ itself is essentially constant before failure.

The results presented so far provide a basic idea about the processes leading to failure: the tangential force increases at particle–particle and particle-intruder contacts faster than the normal force; the number of sliding contacts increases as well, until at failure point the Coulomb threshold is overcome and the intruder starts to move. Until failure occurs, the intruder is essentially static, with the change of position measured as small fractions of the intruder diameter. Additional insight can be obtained by considering spatial and temporal properties of the force network, as discussed next.

### 3.2.2 Force network and failure

The tools of persistent homology, discussed briefly in Section 2.4, provide extensive information about the force networks. We start by discussing rather straightforward measures focusing on the structures (clusters or loops) introduced in Section 2.4. For brevity, we focus in this section on discussing the measures computed using the normal force, $F_n$ only; the findings obtained by considering the tangential forces are found to provide consistent information with the one reported here.

Fig. 8 shows the results for the $\beta_0$ (a and c) and $\beta_1$ (b and d), both for the size $S_0$ (a and b) and the (Betti) numbers (c and d) of the structures. These quantities can be easily extracted from the corresponding persistence diagrams: Betti numbers, $\beta_0$, and $\beta_1$ could be found by subtracting the number of components that die from the number of components that are born above specified threshold, and $S_0$ is simply the number of contacts (with force above chosen threshold) divided by $\beta_0$ or $\beta_1$. Consistently with the results discussed in Section 3.2.1, Fig. 8 shows that the force network evolves even while the intruder is almost stationary, and the contact network is essentially unperturbed. This evolution is particularly obvious when considering $\beta_1$ structures for large thresholds values: the (average) size of $\beta_1$ structures increases significantly as $F_p$ increases, see Fig. 8(b), while the corresponding $\beta_1$ decreases, Fig. 8(d), albeit not so fast (note the log scale on the vertical axes). Basically, what happens here is that the loops become smaller and their number grows as the pullout force increases.

The conjecture is that the loops play an important role in stabilizing the system exposed to external forcing, consistently with the findings reached by considering impact experiments, where loops were found to play a significant role in slowing down an intruder entering the domain filled with particles. The changes in the size and number of $\beta_0$ structures are much more gradual, but consistent, showing (again for the large thresholds) a slow increase in the size and slow decrease in the number – essentially, the clusters merge together and encompass more and more contacts as the pullout force increases. Regarding the threshold dependence, we note that the number of $\beta_0$ structures is an increasing function of chosen threshold for the range chosen: here we are considering the range of thresholds at which we still have many contacts (viz. the PD diagrams shown in Fig. 3 and the corresponding animations in ESI†). For even larger thresholds, $\beta_0$ would decrease similarly as observed in a recent study of suspensions. We also note that the sizes, $S_0$, of $\beta_0$ and $\beta_1$ structures are comparable at large thresholds, as expected. We remind the reader that the force thresholds used in this figure are normalized by the current value of the average (normal) contact force plotted in Fig. 6.

The concept of clusters and loops is useful since these quantities provide an initial insight, and also since they can be related to the commonly considered ‘force chains’ and ‘cycles’. However, this concept suffers from a significant deficiency, and that is the threshold dependence. This deficiency is removed by the total persistent, which essentially merges the complete information (for all thresholds) into a single number, as discussed in Section 2.4. Fig. 9 shows the total persistence, $P_T$ for $\beta_0$ (and for $\beta_1$ in the inset) structures. The $P_T$ increases continuously with the pullout force, showing again that restructuring of the force network takes place (even when rescaling by the average time-dependent normal force). We could now ask whether $P_T$ increases across the whole range of the interaction forces, or whether the increase is concentrated in a particular range. Fig. 9 shows that the latter is correct: the values of $P_T$ for the $\beta_0$ structures characterized by the force significantly larger than the average force, $F_{n,av}$ increase strongly, while the $P_T$ values for the structures born at the medium or weak level remain essentially the same. The inset of Fig. 9 shows that the trend for $\beta_1$ structures (loops) is
different, since TP decreases as $F_p$ increases; we discuss this behavior further below.

One could ask what is the nature of the changes in the force networks that leads to such a strong increase of TP for the $b_0$ structures born at a large force level: to use a landscape analogy, one could ask whether the hills become higher, or there are more hills as $F_p$ increases (recall that TP essentially combines the information about lifespans $\tau$, of the generators in PDs, and the number of generators). To answer this question, Fig. 10 shows the number of generators. Most interestingly, we observe that the number of $b_0$ generators is essentially constant, saying that the reason for the increase of TP for strong forces is the increased range of the interaction forces: the strong generators are born at even higher force levels. Regarding the loops, Fig. 10(b), (d) and (f) show an increase of the number of loops in the strong region, at the expense of the medium ones, consistent with the results for TP in Fig. 9 (inset); however the overall number of generators decreases, leading do a decrease of total TP. ESI† provides more detailed insight into the force network evolution prior to failure.

Another question to ask is to which degree TP captures spatial dependence of the particle interactions, illustrated for $F_p = 50$ (so just before failure) in Fig. 2. To answer this question, we compute TP separately for five different parts of the system, according to the distance from $z = 0$ (bottom of the column). Fig. 11(a) shows the results; for simplicity, here we consider $b_0$ TP only, and also normalize TP by the number of particles, $N_p$, in each of the separate regions and the size of the regions was chosen so that $N_p$ does not change much between the regions. We see that the changes of TP are concentrated in the parts of the system that are close to the intruder, with the most pronounced changes in the layer just above the intruder itself, consistently with the snapshot shown in Fig. 2.

So far, we have focused on the analysis of the system properties at a specified time instant, without attempting to discuss the temporal evolution of the force network. However, temporal evolution is very much of interest as well, in

---

**Fig. 9** Total persistence, TP for $b_0$ structures (clusters) (main figure) and for $b_1$ structures (loops) (inset). The total value (solid blue line) of TP is shown, as well as the values of TP for the birth coordinate in the strong range (dashed orange line) ($> 2.5$), medium range (dash-dotted green line) [1.0–2.5] and weak range (dotted red line) [0.0–1.0].

**Fig. 10** Number of generators (points in the PD’s) using the same line and color convention as in Fig. 9: strong (a and b), medium (c and d), and weak (e and f).

**Fig. 11** (a) Total persistence, TP for $b_0$ structures (clusters), computed separately for the five parts of the system, for $0 < z < 1$ (solid blue line), $1 < z < 1.72$ (dashed orange line), $1.72 < z < 2.44$ (dash-dotted green line), $2.44 < z < 3.16$ (dotted red line), and $3.16 < z < 4.18$ (loosely dashed purple line). (b) Distance $d_{W^2}$ for $b_0$ structures for the same five regions as in (a), using the same convention for lines patterns and colors. The inset expands a part of the considered range of the pulling force, $F_p$.

particular, since the animations in ESI†44,51 suggest that time dependency of force networks is far from simple. To gain at least basic insight into this evolution, we use the concept of distance between PDs, discussed in Section 2.4, see eqn (3), normalized by the number of particles in each region, $N_p$. Fig. 11(b) shows the results, again for the five regions mentioned above. For simplicity, we consider only the $d_{W2}$ distance. Fig. 11(b) shows the localized (both in space and time) changes of the distance, which are particularly prominent in the region close to the intruder itself. The inset of Fig. 11(b) shows the expanded view, illustrating sudden changes of the considered distance measure. These results show clearly that the force network starts evolving while the particles (and the contact network) are essentially static, and that the changes of the force network are not continuous, but consist of short bursts of activity, which become more prominent as the system approaches failure.

As mentioned at the beginning of Section 3.2.2, we focus on the normal forces only in this section. While we found that the tangential forces provided relevant information about the mechanism of failure as well, the measures obtained by computing persistence and derived quantities turn out to be qualitatively similar to the ones obtained based on the normal forces only, so for brevity we do not discuss them further.

4 Conclusions

DEM simulations of the pullout of an intruder buried in confined granular media show that the force required to make the material fail varies depending on both the height of the granular material and the column diameter. Frictional effects are found to be important for large material heights only, showing that in the hydrostatic regime (for small filling heights), the frictional effects are not relevant. While for smaller pullout forces the force exerted by the granular particles on the sidewall remains small, for larger pullout forces, these two forces change at the same pace, illustrating the role that the sidewalls and particle-wall interactions play in the failure process.

The analysis of the interparticle forces, using both classical and novel methods based on persistent homology, uncovers the details of the failure process. While the intruder and the granular particles are essentially static before failure, and characterized by a (static) contact network, the (weighted) force network that includes the information about the particle contacts goes through significant changes. The tangential forces between the particles increase as the applied force becomes larger, leading to a larger number of sliding contacts. The normal force between the particles evolves as well, and the force network based on the normal force becomes more structured, involving a larger number of loops and stronger forces between the particles, even when normalized by the mean. The failure itself occurs through a culmination of temporally intermittent changes that take place predominantly in the physical proximity to the intruder. Furthermore, the changes in the force network are focused in particular on the strong forces when considering clusters of contacts, while the loops that form in a network are evolving at all considered levels of the interaction strength. We find that careful analysis of the evolving loops provides particularly useful insight into the failure process.

By combining classical and newly developed approaches for describing both statics and dynamics of a granular system, we have discussed in this work precise and objective measures that can be used to describe a failure process in the considered system. It remains to be seen to which degree the presented findings apply to other systems close to failure. We hope that both the methods and the results presented in the current paper will provide guidance for future research in this direction.
