We present optical photopolarimetric observations of the BL Lac object S4 0954+658 obtained with the 70-cm telescope in Crimea, 40-cm telescope in St.Petersburg, and 1.8-m Perkins telescope at Lowell Observatory (Flagstaff, Az). After a faint state with a brightness level R ~17.6 mag registered in the first half of January 2011, the optical brightness of the source started to rise and reached ~14.8 mag during the middle of March, showing flare-like behavior. The most spectacular case of intranight variability was observed during the night of 2011 March 9, when the blazar brightened by ~0.7 mag within 7 hours. During the rise of the flux the position angle of optical polarization rotated smoothly over more than 200 degrees. S4 0954+658 is a gamma-ray blazar with gamma-ray flux of (5±3)x10^{-10} phot cm^{-2} s^{-1} according to the Fermi 11-month Catalog Extragalactic Sources.

Our analysis of contemporaneous Fermi LAT data does not show any sign of increased gamma-ray activity above the detection threshold except for an elevated flux on 2011 March 5, JD 2455626, coincident with the local optical maximum.

I. INTRODUCTION

S4 0954+658 (z=0.367) is a well studied BL Lac object in the optical bands. Its optical variability has been studied by Wagner et al. (1993) [7], who found large amplitude variations (of the order of ~100%) on time scales as short as 1 day. Raiteri et al. (1999) [6] presented a comprehensive study of the optical and radio variability of the source during 1994-1998. They detected large amplitude intranight variations. Studying the B − R colour variations, they found that the mid and long-term variations in the source are not associated with spectral variations. Gabuzda et al. (2000 and references therein) [13] studied the radio-morphology of S4 0954+658 and showed that both the parsec and kiloparsec jet are bended. They also found substantial intranight polarization variability of the radio core. S4 0954+658 is a gamma-ray blazar with mean gamma-ray flux (5±3)x10^{-10} phot cm^{-2} s^{-1} according to the Fermi 11-month Catalog of Extragalactic Sources, and most of time falls below the detection threshold.

II. OPTICAL OBSERVATIONS

Our photometric monitoring of S4 0954+658 and other gamma-bright blazars is made within the framework of the WEBT/GASP project [5]. We regularly update optical light curves taken by St.Petersburg University team [9]. We intensified our photometric and polarimetric observations of S4 0954+658 following our detection of a new activity stage of this source (Larionov et al., 2011 [3]).

Figure 1 displays the whole set of optical photometric and polarimetric data obtained by our team during 2006-2011, supplemented by additional data from the MAPCAT project and Steward Observatory.

The blazar showed prominent activity during all the period covered with our data, with R band amplitude exceeding 2^m and a record level of polarization more than 40%. Even on that background the outburst started in early 2011 (marked yellow in all panels) is quite impressive. Its enlargement is shown in Fig. 2.

Inspection by eye of Fig. 1 shows that during most of the observational period the position angle of polarization (EVPA) was at a level of 0 degrees, close to the mean direction (−10°) of the inner jet of S4 0954+658, as observed by the VLBA. Unlike all the previous years, starting from the end of February 2011, we observed smooth rotation of the EVPA (Fig. 2 bottom panel), with amplitude of about 300 degrees. The maximum value of rotation was reached when the flux was at its peak. During two of the observational nights, March 9 and April 24, we observed violent intranight variability, 0.7 mag within 7 hours and 1.0 mag within 5 hours, correspondingly, accompanied by synchronous changes in fractional polarization (marked with large symbols in Fig. 2). As far as we know, these are the fastest flux and polarization changes recorded for this source.

Following Hagen-Thorn and Marchenko (1999) [2], we plotted (Q vs I) and (U vs I) Stokes polarization parameters (see Fig. 3) and found that the whole data set can be splitted into a succession of subsets, each with its own behavior in (I, Q, U) space. We mark these subsets with different colors and apply the same colors to the data plotted in Fig. 2.

We notice that the regression lines in Fig. 3 tend to converge to the points corresponding to the pre-outburst values of I, Q and U. This means that the source that was probably seen before the outburst still was contributing the same amount of flux and polarization during the outburst. Hence it is possible to
FIG. 1: Optical (R band) brightness, fractional polarization and position angle of polarization of S4 0954+685 for 2006-2011.

subtract its emission to get the radiation parameters of the variable source(s). We estimated the constant sources parameters as \( R = 17.8 \), \( p = 15\% \) and \( \chi = -6^\circ \). The resulting curves are given in Fig. 4.

The position angle of polarization changed systematically. We see a sharp jump of EVPA at MJD 55609 (2011 Feb. 16), followed by steady rotation \( \sim 12.5 \) degrees/day that abruptly stopped at MJD 55632 (2011 Mar. 11), 5 days before the optical maximum. After that only minor changes of EVPA are observed, despite continued strong variability of the flux density and fractional polarization. As for the previously mentioned jump of EVPA at MJD 55609, we believe that this jump may be an artifact caused by the appearance and increased contribution of the new variable polarized source with very different direction of electric vector. Note that this new-born source had very high (40\%) intrinsic polarization.

Most of our photometric observations were made in \( BVRI \) bands. We looked for possible color variations, and found that 10-fold change of flux density was not accompanied by noticeable changes of colors.

FIG. 2: Observed flux density (corrected for galactic extinction), fractional polarization and position angle for January-May 2011. Larger symbols refer to the nights when violent intranight variability was observed.

FIG. 3: The absolute Stokes parameters variation during 2011 January-April. Different colors refer to different stages of evolution of the variable source.

III. RADIO OBSERVATIONS

The BL Lac object 0954+658 is monitored monthly by the BU group with the Very Long Baseline Array (VLBA) at 43 GHz within a sample of bright \( \gamma \)-ray blazars[10]. Figure 5 shows the total and polarized intensity images of the object from 2010 September to 2011 March. The VLBA data were calibrated, imaged, and modeled in the same manner as discussed in Jorstad et al. (2005) [4].
S4 0954+658 was only marginally detected by Fermi LAT during 2008-2010, as shown in Fig. 7. A series of positive detections around 2010.0 may correspond to enhanced optical activity at that epoch (see Fig. 1). We analyzed the LAT data for the period of 2011 January-April with 2-day binning, trying not to miss possible shortlived events, and found only 3 positive detections. All these cases of detection are centered on the highest optical level and are unlikely to be due to chance coincidences, though low signal-to-noise ratio precludes more definite conclusions.

V. CONCLUSIONS

S40954+658 demonstrates very prominent activity starting from mid-February 2011. Our photometric and polarimetric observations densely cover this period. We conclude that:

- The overall behavior of the source can be explained as a superposition of radiation of a previously existing source with unchanged Stokes parameters and a new, strongly variable one, whose polarization vector rotated \( \sim 12 \) degrees/day from the onset of the outburst until the moment of maximum flux and then leveled at \( \sim 590^\circ \). Allowing for \( k \cdot 180^\circ \) ambiguity, this is equivalent to \( 50^\circ \), still quite different
from the preoutburst direction (−6°). This fast and monotonous rotation might be explained as the movement of the variable source in a helical magnetic field (Marscher et al. 2010). [5]

• High-amplitude intranight variations were superposed on both light and polarization curves. This may reflect fine structure of the magnetic field, causing temporary deflections.

• The VLBA radio images show the appearance of a new highly relativistic component K2 with $\beta_{app} \sim 19$ c.

• Fermi LAT data give indication of enhanced $\gamma$-ray activity close to the epoch of optical maximum.

The period of activity of S4 0954+658 still continues, and we hope that further optical and radio monitoring will allow us to construct a self-consistent picture of multi-wavelength behavior of this source.

Acknowledgments

We thank Ivan Agudo and Paul Smith for the possibility to use their polarimetric data. The research at St.Petersburg State U. is funded in part by RFBR grant 09-02-00092 and by the Ministry of Education and Science of the Russian Federation (state contract # P123). The research at BU is funded in part by NASA Fermi Guest Investigator grant NNX08AV65G and by NSF grant AST-0907893. The VLBA is an instrument of the National Radio Astronomy Observatory, a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.
