(Dated: January 6, 2009)

The electron-boson spectral density function $I^2\chi(\Omega)$ responsible for carrier scattering of the high temperature superconductor HgBa$_2$CuO$_{4+\delta}$ ($T_c = 90$ K) is calculated from new data on the optical scattering rate. A maximum entropy technique is used. Published data on HgBa$_2$Ca$_2$Cu$_3$O$_{10+\delta}$ ($T_c = 130$ K) are also inverted and these new results are put in the context of other known cases. All spectra (with two notable exceptions) show a peak at an energy ($\Omega_r$) proportional to the superconducting transition temperature $\Omega_r \approx 6.3k_BTc$. This charge channel relationship follows closely the magnetic resonance seen by polarized neutron scattering, $\Omega_r^{\text{neutron}} \approx 5.4k_BTc$. The amplitudes of both peaks decrease strongly with increasing temperature. In some cases, the peak at $\Omega_r$ is weak and the spectrum can have additional maxima and a background extending up to several hundred meV.

Superconductivity arises when electronic quasiparticles bind together into Cooper pairs which condense into a macroscopic quantum state. The interaction which drives the pairing could be charge or spin polarizations, but in conventional metals, it is the polarization of the lattice of ions which provides the necessary attraction. There is also a smaller Coulomb repulsion. In the phonon case Eliashberg theory accounts for all the experimental data with its central ingredient, the electron-phonon spectral density $\alpha^2F(\Omega)$ specifying the boson exchange pairing interaction [1]. Optical spectroscopy is a powerful tool that can be used to extract bosonic spectral density with high degree of accuracy in a variety of systems where other techniques such as tunneling and angle resolved photoemission (ARPES) are difficult to apply. It has been used in conventional metals [2, 3] and in the high $T_c$ oxides [4, 5, 6, 7, 8, 9, 10] but its interpretation in the cuprates remains controversial. As emphasized recently by Anderson [11], the pairing interaction could involve high energy virtual transitions across the Mott gap with energy set by the Hubbard $U$ which is a large energy and the effective interaction would be instantaneous on the time scale of interest. On the other hand, recent numerical work [12, 13] based on the $t$-$J$ model, has shown that the main contribution to the pairing glue is provided by the spin fluctuations with characteristic energies of at most a few hundred meV. Optical experiments provide a direct probe of this energy region.

The mercury versions of the cuprates, HgBa$_2$CuO$_{4+\delta}$ (Hg1201) and HgBa$_2$Ca$_2$Cu$_3$O$_{10+\delta}$ (Hg1223) provide a unique opportunity to test these ideas. The one-copper layer system Hg1201 shares a conventional transition temperature around 90 K with widely studied systems YBCO and Bi2212, whereas the three-layer compound Hg1223 has a $T_c = 130$ K, nearly 40 % higher. These dramatically different $T_c$’s lead, as we will show, to very different bosonic spectra and place severe constraints on models of superconductivity in the cuprates.

In this letter, we present new data on the optical constants for HgBa$_2$CuO$_{4+\delta}$ (Hg1201). The bosonic spectral density $I^2\chi(\Omega)$, recovered by maximum entropy inversion, is found to have a remarkable resemblance to previous results for optimally doped Bi2212 [8]. For further comparison, using the same methods, we also invert published [14] optical constants in the three-layer Hg1223. The high-quality Hg1201 single crystal was grown by a flux growth technique. Our sample was a millimeter sized platelet with a well oriented $ab$-plane. It is slightly underdoped with a $T_c = 91$ K. The real and imaginary parts of the optical conductivity $\sigma(T,\omega) \equiv \sigma_1(T,\omega) + i\sigma_2(T,\omega)$ follow from the reactivity. In analyzing optical data, we use a memory function or optical self energy $\Sigma^{\text{op}}(T,\omega)$ instead of working with $\sigma(T,\omega)$ [15, 16]. By definition, $\sigma(T,\omega) = (\omega^{2}/4\pi)\left[1 - 2\Sigma^{\text{op}}(T,\omega)/\omega\right]$ where $\omega_p$ is the plasma frequency. The optical self energy defined this way plays a role analogous in optics (which involves a two particle process) to the quasiparticle self energy $\Sigma^{\text{qp}}(T,\omega)$ in ARPES [17, 18]. The optical scattering rate is $1/\tau^{\text{op}}(T,\omega) = -2\Sigma^{\text{op}}(T,\omega)$ and the optical effective mass $m^{\text{op}}(T,\omega)/(m$ with the bare electron mass) is given by $\omega/m^{\text{op}}(T,\omega)/(m - 1) = -2\Sigma^{\text{op}}(T,\omega)$.

Our results for the real part of the optical self energy $-2\Sigma^{\text{op}}(T,\omega)$, which provides an easy comparison with ARPES, often presented in terms of $2\Sigma^{\text{op}}(T,\omega)$, are shown in Fig. 1 as a function of $\omega$ for eight temperatures. The lowest three temperatures are in the superconducting state. The most prominent feature of the curves is the peak around 100 meV seen at $T = 29$ K, which progressively disappears as the temperature is increased. To better see how the bosonic spectrum generates the
self energy we show in the inset of the figure a model calculation based on numerical solutions of the $d$-wave Eliashberg equations. The input electron-boson spectral density $I^2\chi(\Omega)$, shown as the dashed-dotted curve, consists of a large narrow peak (right hand scale) centered at 56 meV followed by a dip and a long background extending beyond 400 meV. The dashed curve, with the same bosonic spectrum, is the normal state result for $-2\Sigma_1^{op}(T,\omega)$ which is to be compared with the solid curve in the superconducting state. The superconducting gap obtained was 22.4 meV giving a gap to $\Delta = 22.4$ meV.

In Fig. 2(b) we show results for the spectral density $I^2\chi(\Omega)$ of maximum entropy inversions augmented with a least squares improvement based on the full $d$-wave Eliashberg equations [6]. Further applications are found in Refs. [8, 9, 10]. The input to the inversion is the optical scattering rate $1/\tau^{op}(T,\omega)$ for Hg1201 v.s. $\omega$ for 8 temperatures (light curves). The wider curves are our maximum entropy reconstructions. Bottom frame, the electron-boson spectral function $I^2\chi(\Omega)$ v.s. $\Omega$. The inset gives the peak position (blue triangles) left scales as a function of temperature and the red squares give the corresponding peak amplitude.

In Fig. 1 we show the real part of the optical self energy $-2\Sigma_1^{op}(T,\omega)$ as a function of photon energy $\omega$ for eight temperatures. Inset, theoretical results based on numerical solutions of the generalized Eliashberg equations. (Solid blue superconducting and dashed black normal state.) The electron-boson exchange spectral density used is shown as the dashed-dotted blue curve. The superconducting gap value is $\Delta = 22.4$ meV.
maximum entropy inversion with the default model set to the previous lower temperature solution instead of being set to the constant of the unbiased inversion.

In the inset to the lower frame of Fig. 3(a) we show the frequency (left scale, triangles) of the prominent peak in $I^2\chi(\Omega)$ as a function of temperature. As also noted by van Heumen et al. [20], $\Omega_r$ is fairly constant at $\sim 56$ meV but in our analysis, this frequency clearly increases for $T$ above 200 K. More importantly, the amplitude of the peak shows strong temperature dependence in the superconducting state and also above 200 K. Further, the width of the peak increases with increasing $T$. As noted for Bi2212 [3], the shift in spectral weight into the peak at 60 meV can be interpreted to proceed through a transfer of spectral weight from high to low frequencies as the temperatures is lowered. We note here that in contrast a bosonic function from the electron phonon interaction would not have these properties: its amplitude, width and center frequency would all be temperature independent and would not vary from one cuprate to another (as shown in Fig. 4 below).

In Fig. 3(b) we display similar results for Hg1223 with $T_c = 130$ K. In Fig. 3(a) we reproduce the optical scattering rate at four temperatures (with $T = 15$ K and 125 K in the superconducting state) from the work of McGuire et al. [14]. Our results for $I^2\chi(\Omega)$ are presented in Fig. 3(b) and the quality of the data reconstruction is demonstrated by the heavy lines in Fig. 3(a) to be compared with the corresponding light line (data). We find significant residual (static impurity $1/\tau_{\text{imp}} \simeq 95$ meV) scattering rate in contrast to Hg1201 which is in the clean limit ($1/\tau_{\text{imp}} = 0$). The superconducting state data (blue, dotted curve) for $1/\tau_{\text{imp}}(\omega)$ at $T = 15$ K shows a peak around 140 meV which is the indication of a gap in the charge carrier density of states (DOS). Currently there is no known kernel which allows maximum entropy inversion of such data and so we do not show results in this instance. On the other hand, in the $T = 125$ K data there is no signature of such a DOS-gap. Results are shown in Fig. 3(b) in LSCO [9], and PCCO [10].

In Fig. 4 we place our results for $\Omega_r$, the frequency of the peak in $I^2\chi(\Omega)$, in the context of other such results by plotting $\Omega_r$ as a function of the superconducting $T_c$ for a number of cuprates. In all cases, $I^2\chi(\Omega)$ has been extracted from the optical data but not always using a maximum entropy technique. Some are fits to assumed forms including a broad background introduced in reference [23] to model antiferromagnetic fluctuations, augmented with a resonance peak. Both methods give very much the same results as documented in reference [3]. The heavy long dashed line is a least square fit to all the optical data and gives $\Omega_r \approx 6.3k_B T_c$. This is close to, but not quite, the position of the spin-one neutron res-
onance obtained by He et al. \[24, 25\] where \( \Omega_{\text{neutron}} \approx 5.4k_BT_c \) represented in Fig. 4 as the dotted line.

Several comments should be made about such a comparison between charge excitations and the magnetic susceptibility. First, the neutron resonance plotted in Fig. 4 refers to the sharp peak that appears at \( q = (\pi, \pi) \) whereas the bosonic function that governs the optical response is the \( q \) averaged local susceptibility. This arises because the Fermi-surface to Fermi-surface electron scattering involves momentum transfers to boson excitations that span all momenta in the Brillouin zone, some involving Umklapp processes. Where magnetic neutron scattering data for the \( q \)-averaged susceptibility are available such as in LaSrCuO \[9\] and PrCeCuO \[10\], In YBCO\[6,5\] it is estimated to be \( 3\% \) \[20\] and in some cases there is no resonance \[5, 28\], but it is always the local, Brillouin zone averaged spin susceptibility which controls superconductivity. Finally, the two points at \( \Omega_r = 0 \) (not used in the fit to the data in Fig. 4) are for YBCO\[6,5\] and overdoped Tl2201 \[3\]. In both cases, no optical resonance could be identified. The resonance may enhance but is not essential for superconductivity in the cuprates and the scaling of the position of the peak with \( T_c \) shown in Fig. 4 must be the result and not the cause of the rearrangement of the electronic DOS in the superconducting state as suggested by several theorists \[29, 30\]. We also note here that recent dynamical mean field calculations of the one-band Hubbard model yield bosonic spectral functions very similar to what is shown in Figs. 2 and 3. \[12, 13\]

In summary we find that in Hg1201 and Hg1223 optical resonances are found in maximum entropy inversions of the optical scattering, at 56 and 72 meV, respectively. However, when the temperature is increased towards 300 K, the spectral weight under this resonance moves to higher energy and broadens significantly, in contrast to the findings of van Heumen \[21\]. The optical resonance scales with \( T_c \) over a broad set of materials with \( \Omega_r \approx 6.3k_BT_c \) which is remarkably close to the energy of the spin one resonance seen in polarized neutron scattering, namely \( \Omega_{\text{neutron}} = 5.4k_BT_c \) leaving no doubt that the charge carriers are coupled to spin fluctuations, while there is no evidence for an important phonon contribution.

Note added in proof. We have learned of a neutron scattering study by Yu et al. \[31\], where a magnetic resonance in optimally doped Hg1201 is reported at 56 meV, exactly the same energy as the peak we found here. Recent Raman data \[5\] nd a superconducting gap \( 2\Delta \) very close to the values found in our calculations \[32\].

Note added in proof. We have learned of a neutron scattering study by Yu et al. \[31\], where a magnetic resonance in optimally doped Hg1201 is reported at 56 meV, exactly the same energy as the peak we found here. Recent Raman data finds a superconducting gap \( 2\Delta \) very close to the values found in our calculations. \[32\]
