Abstract
Oral medical wastewater with heavy metal ions (such as plumbum, Pb\textsuperscript{2+}) is regarded as the main pollutant produced in the oral cavity diagnosis, and the treatment process can pose a serious threat to human health. The removal of Pb\textsuperscript{2+} from oral medical wastewater facing major difficulties and challenges. Therefore, it is of great significance to take effective measures to remove Pb\textsuperscript{2+} by using effective methods. A new activated three-dimensional framework carbon (3D AFC), regarded as the main material to remove Pb\textsuperscript{2+} in the oral medical wastewater, has been fabricated successfully. In this experiment, the effects of 3D AFC absorbing Pb\textsuperscript{2+} under different conditions (including solid-to-liquid ratio, pH, ionic strength, contact time, and initial concentration, etc.) were discussed. And the result revealed that the adsorption kinetics process of Pb\textsuperscript{2+} on 3D AFC conformed to the pseudo-second-order model and the adsorption isotherm conformed to the Freundlich model. Under the condition that pH = 5.5 and \( T = 298 \) K, the calculated maximum adsorption capacity of 3D AFC for Pb\textsuperscript{2+} was 270.88 mg/g. In practical application, it has strong adsorption ability for Pb\textsuperscript{2+} in oral medical wastewater. Thus, 3D AFC shows promise for Pb\textsuperscript{2+} remove and recovery applications because of high adsorption capacity for Pb\textsuperscript{2+} in oral medical wastewater due to its high specific surface area, outstanding three-dimensional network structure.

Keywords Oral medical wastewater • Activated carbon • Adsorption • Pb\textsuperscript{2+}

Introduction
Oral medical wastewater containing a large amount of heavy metal ions will be generated in the process of oral diagnosis and treatment (including the removal of old prosthesis, tooth preparation, prosthesis trial wearing and the use of some metal instruments), such as cobalt ion (Co\textsuperscript{2+}), chromium ion (Cr\textsuperscript{2+}), molybdenum ion (Mo\textsuperscript{2+}), silicon ion (Si\textsuperscript{2+}), cadmium ion (Cd\textsuperscript{2+}), and plumbum ion (Pb\textsuperscript{2+}). If the oral medical wastewater containing these heavy metal ions was discharged into the groundwater system through the water system of the dental chair without any special treatment, it will not only increase the difficulty of water purification, but also threat to human health, cause many diseases, such as anemia, kidney dysfunction, brain tissue damage and even death (Shilu et al. 2000). Pb\textsuperscript{2+}, one of the main heavy metal ion pollutants in oral medical wastewater, has the concentration as high as 4–20 mg/g (Bhattacharjee et al. 2003), far higher than the limit of Pb\textsuperscript{2+} concentration in the water released by the World Health Organization (0.01 mg/L) (Rotimi et al. 2011). Therefore, it is of great significance to take effective measures to remove Pb\textsuperscript{2+} in oral medical wastewater.

Currently, various methods can be adopted to remove Pb\textsuperscript{2+} in oral medical wastewater, including ion exchange (Pember et al. 2016), liquid–liquid extraction (Soniya et al. 2015), membrane filtration (Li et al. 2016), biosorption (Oguntimein et al. 2015), electrodialysis (Deghles et al. 2016), electrocoagulation (Ghanbari et al. 2015), and adsorption technology (Zhu et al. 2018; Ghasemi et al.)
2018). However, most of them have some disadvantages, such as high operating cost, low processing efficiency, and the possibility of secondary pollution like toxic products (Zhu et al. 2018), thus limiting their applications in practice. Adsorption technology, however, has become one of the most popular and promising method due to the properties of low cost, high adsorption efficiency, and convenient operation (Zhu et al. 2018). For instance, porous hydroxyapatite-carbon composite material (Zhu et al. 2018) and a new Sawdust/MNP/PEI nanocomposite material (Ghasemi et al. 2018) have been successfully used for the removal of Pb\(^{2+}\) in aqueous solution.

Activated carbon, with large specific surface area (250–3000 m\(^2\)/g), high stability, especially no degradation risk in aqueous solution, has been acknowledged as one of the most popular and widely used adsorbent in the treatment of polluted wastewater in the world. There have been many reports discussing the application of activated carbon adsorbents in the removal of Pb\(^{2+}\), but the adsorption capacity varies. For example, the activated carbon before functionalization has the limited adsorption capacity for Pb\(^{2+}\), being 20.3 mg/g only (Asuquo et al. 2017). The MOS\(_2@\)Kaolin type activated carbon adsorption material (Yuan et al. 2020) greatly improved the adsorption capacity of Pb\(^{2+}\). A new type of protonated graphite carbon nitride and acid activated montmorillonite (g-C\(_3\)N\(_4\)/Mt) composite material was fabricated by Wan et al. (Wan et al. 2019), and the adsorption capacity of Pb\(^{2+}\) was 124.2 mg/g. A dual-ecological pistachio wood-derived activated carbon prepared by a two-stage process (PWAC-2) had an adsorption capacity of 190.2 mg/g for Pb\(^{2+}\) (Sajjadi et al. 2019). In a word, though the activated carbon adsorption materials are fabricated by different methods, they all possess good adsorption capacity for Pb\(^{2+}\). However, the removal of Pb\(^{2+}\) from oral medical wastewater has not been studied. And these activated carbon adsorption materials reported have more or less disadvantages, such as demanding preparation conditions, complicated fabricating processes, and existing difficulty in mass production, hence limiting the applications in practice. In our previous experiments, a new method for the large-scale preparation of three-dimensional framework carbon (3D FC) by directly calcining the sodium citrate without any additional carbon source, template or catalyst was reported in clean energy field, and this method could making the whole process simple and inexpensive (Yang et al. 2018). The fabrication of 3D FC was referred to the methods previously reported by our research group (Yang et al. 2018). The specific experimental steps were as follows: The sodium citrate was calcinated at 1000 °C for 1 h (The heating rate was 5 °C/min) under the protection of nitrogen. And the black product obtained from the above steps was cleaned alternately with deionized water and ethanol at 80 °C until the residual sodium, salt and impurities were removed. Finally, it was dried at 100 °C, hence obtaining the 3D FC. The activation steps of 3D FC were as follows: 2.0 g 3D FC sample was weighed and mixed in sulfuric acid (98%) and nitric acid (70%) with a volume ratio of 1:3, and then it was poured into the reactor. The sample was kept at 100 °C for 2 h. After cooling to room temperature, it was fully cleaned with a large amount of deionized water until pH value reached to 7. When the drying process was completed, the activated 3D FC was obtained, marking as 3D AFC.

### Batch adsorption experiment

The 1 g/L Pb\(^{2+}\) standard solution was fabricated using Pb(NO\(_3\))\(_2\) as the raw material, and all the batch adsorption experiments were completed in polyethylene centrifuge tubes. HCl or NaOH solutions with different concentrations (0.001, 0.01, 0.1, 1.0, and 2.0 mol/L) were selected to adjust the pH value of the solution. 0.0020 g 3D AFC (m/V = 0.4 g/L) was added into the 10 mL polyethylene centrifuge tube and pH value was adjusted to 5.5, ensuring that the total volume of each sample was 5 mL by adding deionized water. Meanwhile, the sample was placed in a thermostatic oscillator for 12 h and filtered. Next, the filtered supernatant was taken and the concentration of Pb\(^{2+}\) ion was determined by flameless atomic absorption spectrophotometry (FAAS). Finally, the effects of solid–liquid ratio, contact time, pH value, ionic strength and initial concentration on

### Materials and methods

#### Material

Sulfuric acid (98%) and nitric acid (70%) were purchased from Sinopharm Chemical Reagent Network. Pb(NO\(_3\))\(_2\) was purchased from Aladdin. And the pH meter model was pHS-3C (Shanghai, China). The Ultraviolet and visible spectrophotometry (UV–VIS) adsorption spectrometer model was UV-1800, MAPADA (Shanghai, China).

### The fabrication and activation treatment of 3D FC

Batch adsorption experiment

The 1 g/L Pb\(^{2+}\) standard solution was fabricated using Pb(NO\(_3\))\(_2\) as the raw material, and all the batch adsorption experiments were completed in polyethylene centrifuge tubes. HCl or NaOH solutions with different concentrations (0.001, 0.01, 0.1, 1.0, and 2.0 mol/L) were selected to adjust the pH value of the solution. 0.0020 g 3D AFC (m/V = 0.4 g/L) was added into the 10 mL polyethylene centrifuge tube and pH value was adjusted to 5.5, ensuring that the total volume of each sample was 5 mL by adding deionized water. Meanwhile, the sample was placed in a thermostatic oscillator for 12 h and filtered. Next, the filtered supernatant was taken and the concentration of Pb\(^{2+}\) ion was determined by flameless atomic absorption spectrophotometry (FAAS). Finally, the effects of solid–liquid ratio, contact time, pH value, ionic strength and initial concentration on
the adsorption behavior of Pb\textsuperscript{2+} on 3D AFC surface were evaluated. The adsorption percentage and adsorption capacity of Pb\textsuperscript{2+} were calculated according to formulas (1) and (2).

\[
\text{Adsorption(\%)} = \frac{C_0 - C_e}{C_0} \times 100\% \tag{1}
\]

\[
q_e = \frac{C_0 - C_e}{m} \times V \times 238 \tag{2}
\]

In the equations, \(C_0\) and \(C_e\) represent the initial and equilibrium concentrations (mg/L) of Pb\textsuperscript{2+} in aqueous phase, respectively. \(m\) and \(V\) designate the weight (g) of the 3D AFC and the solution volume (L), respectively.

**Experimental for Pb\textsuperscript{2+} selectivity in oral medical wastewater**

The oral medical wastewater was extracted randomly from the Hospital of Stomatology, Lanzhou University, check and measure the composition and concentration of the main polluted metal ions, that is, Cd\textsuperscript{2+} 0.00235 mg/L, Co\textsuperscript{2+} 2.678 mg/L, Cr\textsuperscript{2+} 0.00268 mg/L, Pb\textsuperscript{2+} 0.00835 mg/L, Sr\textsuperscript{2+} 2.6515 mg/L. And then, a total volume of 5 mL mixed solution was adopted, and the pH value was adjusted to 5.5 at room temperature. 3D AFC material sample of 0.002 g was placed in the sample of the oral medical wastewater, fully oscillated, and fully adsorbed for 48 h. The sample solution was taken to analyze the remained concentrations of each ions.

**Characterization**

The morphology structure and chemical composition of 3D AFC were characterized by scanning electron microscopy (SEM, Hitachi s4800), X-ray diffraction (XRD, panalytical x’pert pro, Cuk \(\alpha\)), and Fourier-transform infrared spectroscopy (FTIR, spectrum 100 Perkin Elmer, USA) before and after Pb\textsuperscript{2+} adsorption. The concentration of Pb\textsuperscript{2+} in solution before and after the adsorption was measured by UV–Vis adsorption spectrometer (uv-1800, mapada, Shanghai, China).

**Results and discussions**

**Characterization of the 3D AFC before and after Pb\textsuperscript{2+} adsorption**

The morphology of 3D AFC was characterized by SEM. As shown in Fig. 1, the SEM results of the fabricated 3D AFC show that the ultra-thin and curved carbon sheets are interconnected to form a porous three-dimensional network structure, and the pore structure size is 50–80 nm. In addition, good three-dimensional pore network structure is conducive to improve the adsorption performance (Cao et al. 2020).

The chemical composition of 3D AFC before and after the adsorption of Pb\textsuperscript{2+} was characterized by XRD and FTIR (Fig. 2), respectively. In the XRD results (Fig. 2a), a large peak appears at \(2\theta = 26.3^\circ\) before the adsorption of Pb\textsuperscript{2+}, corresponding to amorphous carbon (Prabhakar et al. 2020; Zhang et al. 2015). After the adsorption of Pb\textsuperscript{2+}, the peaks at \(2\theta = 23.2^\circ, 36.1^\circ, 39.5^\circ, 43.2^\circ, 47.5^\circ\) and \(48.6^\circ\) correspond to the standard diffraction card (jcpds6-0452) (Tartaja et al. 2001), respectively, indicating that surface precipitation might be one of the mechanisms for 3D AFC to adsorb Pb\textsuperscript{2+} (Farzin et al. 2020; Azouaou et al. 2014). In the FTIR results (Fig. 2b), before the adsorption of Pb\textsuperscript{2+}, a strong broad peak at 3448.53 cm\(^{-1}\) corresponds to the stretching vibration peak of –OH (Azouaou et al. 2014; Ai et al. 2018a, 2018b). Meanwhile, the absorption peaks at the binding energies of 1624 cm\(^{-1}\), 1384 cm\(^{-1}\), 1120 cm\(^{-1}\) and 835 cm\(^{-1}\) correspond to the stretching vibration of C–O, –COOH and C–C functional groups, respectively (Vijay et al. 2019; Ai et al. 2018a, 2018b), proving that the surface oxygen-containing functional groups could be successfully endowed by chemical activation of 3D FC. In addition, after the adsorption of Pb\textsuperscript{2+}, new absorption peaks appeared at the binding energies of 454, 576 and 850 cm\(^{-1}\). It was evident that Pb\textsuperscript{2+} was adsorbed on the surface of 3D AFC. Compared with the
primary simple, the peaks of the oxygen functional groups on 3D AFC did not significantly change after adsorption, with only the intensity changing. This indicated that no chemical redox reactions occurred during Pb²⁺ adsorption (Zhao et al. 2018).

**Batch adsorption experiment**

**The effect of solid–liquid ratio on adsorption**

Variations in the Pb²⁺ adsorption percentage of the solid–liquid ratio were examined to determine the best adsorbent used in the adsorption experiments. Figure 3 shows the effect of solid–liquid ratio on the adsorption percentage of Pb²⁺ on 3D AFC surface. With the mass of 3D AFC increasing, the adsorption percentage of Pb²⁺ gradually increased. At a low solid–liquid ratio value (0–1.0 g/L), the adsorption process with a steep percentage (%) increment, and the inflection point was reached when the solid–liquid ratio is 1.0 g/L (adsorption percentage equal to about 95%). Besides, as the solid–liquid ratio value increases (> 1.0 g/L), the adsorption percentage (%) increased slowly and finally approach 100%. The reason of which was that the adsorption sites of Pb²⁺ increased with the increase of the mass of 3D AFC. According to this result, the solid–liquid ratio was determined to be 0.4 g/L to the follow-up experiments.

**The effect of contact time on adsorption**

Adsorption kinetics are important properties that are used to evaluate the adsorption mechanism of an adsorbate to an adsorbent material. With the experimental condition being m/V = 0.4 g/L, [Pb²⁺]₀ = 4.8 × 10⁻⁴ mol/L, pH = 5.5 ± 0.1, I = 0.001 M NaCl and T = 25 °C, the effect of contact time on the adsorption percentage of Pb²⁺ on 3D AFC surface was explored (Fig. 4a). The adsorption of Pb²⁺ on 3D AFC reached equilibrium within 5 h. The adsorption time required to reach the equilibrium state was relatively short, indicating that the adsorption of Pb²⁺ on 3D AFC was mainly dominated by chemical adsorption or strong surface complexation rather than physical adsorption, which requires more time to achieve equilibrium (Xie et al. 2019; Chen et al. 2008). Combined with FTIR results, we can conclude that the adsorption mechanism is electrostatic adsorption between the Pb²⁺ and oxygen functional groups on the 3D AFC. Meanwhile, 12 h was set as the equilibrium time of the subsequent adsorption experiment to ensure that the adsorption process completely reached the equilibrium state.

Furthermore, the standard adsorption kinetics models, the pseudo-first-order and pseudo-second-order model were adopted to simulate the adsorption behavior of Pb²⁺ on 3D
AFC (Liu et al. 2019), the equation of pseudo-second-order model according to:

\[
\frac{t}{q_t} = \frac{1}{2k_f q_e^2} + \frac{t}{q_e}
\]

In the equation, \(q_t\) (mmol/g) represents the adsorption capacity of 3D AFC for Pb\(^{2+}\) at \(t\) (h) time node. \(q_e\) represents the adsorption capacity of 3D AFC for Pb\(^{2+}\) at equilibrium state. \(k\) (g/(mmol·h)) is a constant. Figure 4b shows the pseudo-second-order fitting curve. And the calculated correlation coefficient was \(R^2 = 0.9976\) (≈1), indicating that the dynamic adsorption of Pb\(^{2+}\) on 3D AFC surface could be described by the pseudo-second-order equation (Ho et al. 2006). More information about the pseudo-first-order model can be found in Support Information (Table S1 and Fig. S1).

The effects of \(\text{pH}\) and ionic strength on adsorption

It is believed that the Pb\(^{2+}\) adsorption of the 3D AFC depended on the synergistic effects of oxygen functional groups. In particular, abundant oxygen functional groups allowed the 3D AFC to exhibit strong protonation-deprotonation interactions in aqueous solutions (Ayben et al. 2003). From this Fig. 5a, it can be concluded that the \(\text{pH}\) value plays an important role on the adsorption of Pb\(^{2+}\) on 3D AFC. Meanwhile, the adsorption percentage increases with the increase of \(\text{pH}\) value when \(\text{pH} < 7\). This result can be explained by the competition mechanism of different ion pairs for adsorption sites. The effect of ionic strength on Pb\(^{2+}\) adsorption was also tested. When \(\text{pH}\) value is within 3–10, the adsorption of Pb\(^{2+}\) on the 3D AFC surface is not determined by the boundary ionic strength (NaCl) of 0.001–0.05 mol/L, showing that the adsorption of Pb\(^{2+}\) on
the 3D AFC forms an inner ring complex (Wan et al. 2019; Cao et al. 2020).

Visual MINTEQ 3.1 software was adopted to analyze the species distribution of Pb\(^{2+}\) in different pH segments under the experimental conditions. And it can be referred from Fig. 5b that when pH < 7, Pb\(^{2+}\) and PbCl\(^{+}\) are the main ionic forms, dominated by positive charge. Under this condition, the –OH/–COOH functional groups on the surface of 3D AFC would be prolonged, and the formed H\(^{+}\) would compete with Pb\(^{2+}/\)PbCl\(^{+}\) for the adsorption site, which can explain the low adsorption capacity of Pb\(^{2+}\) under the condition of low pH value (Ai et al. 2018a, 2018b; Kilislioglu et al. 2003). However, on the one hand, with the gradual increase of pH value, the oxygen-containing functional groups on the surface of the 3D AFC are deprotonated (negatively charged), increasing the adsorption of positively charged Pb\(^{2+}/\)PbCl\(^{+}\) in the solution, thus leading to the increase of the adsorption capacity. On the other hand, as the pH continues to increase (pH > 7), Pb(OH)\(_3\)^\(–\) is the main existing form with negative charge. At the same time, the 3D AFC is also negatively charged due to the deprotonation, and the two negatively charged substances will electrostatically interact and repel to form the co-precipitation, weakening the adsorption capacity of 3D AFC for Pb\(^{2+}\).

**Adsorption isotherm**

The effect of initial concentration (Pb\(^{2+}\)) on its adsorption performance on 3D AFC surface was detected, and the results are shown in Fig. 6. From Fig. 6, it is obvious that the adsorption capacity of 3D AFC also increases (Fig. 6a) as the initial concentration of Pb\(^{2+}\) increases. Because the amount of Pb\(^{2+}\) in the solution gradually increases with the increase of the initial concentration of Pb\(^{2+}\), thus resulting in that 3D AFC with a certain mass can absorb more Pb\(^{2+}\). Meanwhile, Freundlich model was used to match the adsorption isotherms in order to describe the adsorption behavior of Pb\(^{2+}\) on 3D AFC surface more accurately. Freundlich equation, often used to describe the adsorption reaction on heterogeneous solid surface, is as follows.

\[
\log q_e = \log K_F + \frac{1}{n} \log C_e
\]

In the Freundlich equation, \(K_F\) (mg/g) and \(n\) are the adsorption capacity and adsorption strength, respectively. It is reported that when \(0.1 < 1/n < 0.5\), the adsorption reaction is more likely to occur (Okeola et al. 2010).

Figure 6b shows the adsorption isotherms of Pb\(^{2+}\) on 3D AFC, coinciding with Freundlich model. From the figure, it can be seen that the Freundlich model can fit the adsorption isotherm of Pb\(^{2+}\) on the 3D AFC surface \((R^2 = 0.9444, \approx 1)\). In addition, \(1/n\) is equal to 0.34, which is within the range of 0.1–0.5, indicating that the adsorption process of Pb\(^{2+}\) by 3D AFC is easy to occur (Table 1). At the same time, the adsorption capacity of 3D AFC under different Pb\(^{2+}\) concentrations was calculated by the isotherm results, and it was concluded that with the initial concentration of Pb\(^{2+}\) being 0.35 g/L, the adsorption capacity reached the maximum value 270.88 mg/g. A more detailed description of the Langmuir model can be found in the Support Information (Table S2 and Fig. S2).

| \(K_F\) (mol\(^{1–n}\)L/n g) | \(n\) | \(R^2\) |
|------------------|-------|--------|
| 24.434           | 2.983 | 0.9444 |

**Table 1** The parameters of adsorption isotherm of Pb\(^{2+}\) on the 3D AFC surface
Practical application

Furthermore, actual oral medical wastewater contains not just Pb^{2+}, but various other types of metal ions, the presence of which may out-compete and influence the efficiency of Pb^{2+} adsorption. To identify the practical application of 3D AFC on Pb^{2+} adsorption, the oral medical wastewater was extracted from the Hospital of Stomatology of Lanzhou University, and including Sr^{2+}, Cr^{2+}, Cd^{2+}, Sr^{2+} and Pb^{2+}. The results of selective adsorption experiment of 3D AFC in oral medical wastewater are presented in Fig. 7. As shown in Fig. 7, the adsorption percentage of 3D AFC for Sr^{2+}, Cr^{2+}, Cd^{2+}, Sr^{2+} was 4.1%, 24.1%, 51.1%, and 70.1%, which lower than that of Pb^{2+} (85%). According to the above results, we can conclude that the 3D AFC has a stronger ability to adsorb Pb^{2+} in oral medical wastewater.

Conclusion

The following conclusions can be drawn from the experimental results of 3D AFC adsorbing Pb^{2+} in oral medical wastewater: (1) The adsorption process of Pb^{2+} on 3D AFC surface could quickly reach equilibrium, and the kinetics adsorption process could be described by the pseudo-second-order model. (2) The adsorption of Pb^{2+} on the surface of 3D AFC was largely determined by the pH value. The adsorption capacity gradually increased (pH = 3–7) with the increase of pH value and reached the maximum when pH = 7. Afterward, as the pH increased (pH = 7–10), the adsorption capacity decreased. (3) The adsorption isotherm of 3D AFC for Pb^{2+} conformed to the Freundlich model. And when pH = 5.5 and T = 298 K, the calculated maximum adsorption capacity of 3D AFC for Pb^{2+} was as high as 270.88 mg/g. (4) Combined with the properties of excellent three-dimensional network structure, high specific surface area, simple synthesis method and good adsorption capacity for Pb^{2+}, 3D AFC can be used as the material to remove Pb^{2+} from oral medical wastewater. However, developing low-cost adsorbents with high adsorption ability for Pb^{2+} removal and recycling capability from oral medical wastewater has been a great challenge.
